context of where she will birth, assessment of her progress in labour will require the midwife to be present and 'with' the woman. We have already discussed the importance of viewing each woman's labour as particular to her, rather than trying to 'fit' her labour into a standardised format. The holistic nature of midwifery care means constantly assessing the environment for its impact, as well as watching, talking with and listening to the woman. As labour advances, her contractions will change. From being able to talk through some contractions and having a connection with what is going on around her, a woman in a progressing labour will begin to concentrate with each deeper sensation and may require support to work through each contraction. If her movements are unrestricted she should be encouraged to adopt positions in which she feels most comfortable. Encouraging her to empty her bladder regularly will aid her comfort as well as providing an opportunity for finding alternative positions. Women who have the choice to be upright will have greater contraction intensity and efficiency and are less likely to require pharmacological pain relief (Enkin et al 2000). However, it is important to keep a balance between rest and activity. Some women will need periods of inactivity during the not-uncommon plateaus of labour to recharge and refocus their energy levels (Page 2000).

Clinical point

Facilitating a woman's ongoing labour

- Check how the woman is feeling about the labour and what form of support she wants from you.
- Avoid arbitrary time limits.
- Follow the birth plan in consultation with the woman as appropriate.
- Assess her wellbeing, including her emotional and behavioural responses.
- Check blood pressure, temperature, pulse and urinalysis—look for signs of dehydration and take appropriate action.
- Discuss the need, or not, for a vaginal examination. If VE is done, look for increasing dilatation, anterior position of baby, continual descent and rotation through pelvis.
- Assess contractions, lie, presentation and descent of the baby—look for signs of continual progress and follow up any indication of delay such as lack of descent of baby, slowing of contractions.
- Assess baby's wellbeing, including heart rate—look for continual reassuring signs and follow up any non-reassuring patterns such as decelerations, tachycardia or bradycardia.
- If membranes have ruptured, check colour of liquor—follow up any non-reassuring signs such as meconium.
- Facilitate partner/supporter's involvement as per care plan.
- Encourage the woman to move into whatever positions she feels comfortable in.
- Encourage the woman to drink regularly and to eat if she wishes.

Documentation

It is important that the midwife collates and documents comprehensive assessments of the woman and baby's health and wellbeing (NZCOM 2005). This serves three main purposes:

- to be able to review and assess the progress of labour
- to provide an accurate diary of events for the woman to read, refer to and keep
- to provide a legal document that illustrates the information and care given, and the subsequent events and outcomes.

For the midwifery notes to assist in assessment of progress they should be a time-based diary of events permitting a detailed documentation of all assessments of the woman and her baby. Documentation provides evidence of midwifery decision-making and as such they should contain as much information as possible. In contexts where partograms are used routinely (Australia), additional information must be recorded, as the partogram does not provide enough on its own.

Partograms

Partograms have been shown to be an efficient means of exchanging information about labour progress between teams of caregivers. However, in a continuity of carer setting, the partogram has little value. Partograms provide a visual display of only part of the woman's progress in labour and they assume that there will be vaginal examinations and charting of cervical dilatation (Chapman 2003). They are a structured graphical representation (with alert and action lines) and may rely too much on a strict protocol of action. Partograms can be an agent for regimenting labour rather than supporting the woman's individual process (Chapman 2003; Enkin et al 2000). Observational studies have shown improved outcomes with the use of partograms when the labour is not progressing normally (Enkin et al 2000; Lavender et al 1998). However, there is a need for research into the efficacy of the use of partograms in physiologically normal labour. Albers (1999) suggests that the parameters of normal labour need to be researched and redefined to increase midwifery knowledge by more accurately reflecting women's actual experiences.

Woman-centred midwifery notes

The comprehensive nature of the labour notes means that they need to clearly document and describe midwifery care, advice and consultations. They should be written in a narrative style that is woman-centred and provides the story of events as they unfold. The notes will outline information discussed with the woman and the rationale for the decisions made. The story of the labour and birth is an invaluable aid for later reflection on the birth with the woman. Professional midwifery care requires reflection on practice, and comprehensive notes

support this process. Although some may view constant and concurrent documentation as time consuming and tedious, it need not be.

Tips for documentation

- Involve the supporters in the woman's care to free you for short periods to document events.
- Write something every 15 minutes—e.g. how the woman is feeling, the positions she is using, frequency/strength/length of contractions, vaginal discharge, input from supporters, baby's heart rate.
- If you use abbreviations, explain their meaning when first used and keep the notes in a form that can be understood by the woman and her family.
- If at times you are unable to write full notes, jot down brief reminders and times of significant events—e.g. rupture of membranes, vaginal examinations, fetal heart rate recordings—and update more comprehensively as soon as possible.
- Clearly note references to the woman's care plan and whether there are any changes to this plan. Document details of the discussion with the woman, and the rationale and consent for any decisions or birth plan changes.

Labour: transition phase to birth

Most labouring women and midwives are aware of a transitional period between the first stage of labour and the time when active maternal pushing efforts begin (Downe 2003). Changes in the woman's behaviour, body language and vocal responses towards the end of the active phase of labour may indicate this transition stage. This often tumultuous period can challenge the woman and her supporters, and the midwife needs to guide and support them through the intensity of this time.

A woman's responses to this change in her labour may include increasing restlessness, breathing rhythm changes, shaking, vomiting, a feeling of panic and of being engulfed by the process. The contractions relentlessly roll from one into the next, giving the woman no time to focus as she had earlier. Often at this time, women will vocalise that they 'can't do this any more' and plead to the midwife and supporters to 'help me'. Supportive midwifery care can help the woman by continually reassuring her that she is safe and that these feelings are normal and a sign of labour progress. The midwife's confidence and belief in the woman's ability helps to strengthen the woman and her supporters to meet the challenges of this part of normal labour. She will need to use all of her strength and experience to provide support and encouragement. The midwife needs to acknowledge that this process is taking the woman to the edge of her ability to cope. The constant presence and reassurance of the midwife will reduce the chance of resorting to the use of pharmacological interventions at a time when the woman is at her most vulnerable.

Clinical point

Characteristics of transition to full dilatation of the cervix

- The woman may feel she has lost control and have feelings of panic.
- She may say she cannot carry on, and ask for help.
- She may ask for pain relief.
- She may vomit or feel nauseous and be shaking.
- There may be a heavy 'show' of bloodstained mucus.
- She may have beginning sensations of pressure in her bottom or the urge to push—can be variable.
- For some women, labour slows down and she can rest or may even sleep.

There is no clear timeframe for the transition period. For some women it can be a few hours and for others a matter of just a few contractions. Occasionally women find that the contractions begin to ease off and will benefit from this sudden calm in their labour and may even sleep. It is once again important to reassure the woman that this lull in her labour is very normal and that it is her mind and body preparing her for the next stage and the birth of her baby. If this happens it is often a good time for the supporters to get a break, get some fresh air, go to the toilet, eat and drink before they are needed again. Midwives may often feel a need to 'do something' when the labour slows after a torrent of strong contractions and, as is also the case in misunderstood latent phase, it can be a time when unwarranted interventions are introduced, such as ARM and VE. Patience and trust are the hallmarks of an effective midwife and as long as mother and baby are both well they should not be interfered with. As the woman's cervix becomes fully dilated and the baby descends further, the woman's contractions and her responses give cues to the midwife that the woman is moving closer to the birth of her baby (Walsh 2000b).

Fourth decision point in labour: second stage or birth to skin-to-skin

At this stage there will be a number of signs that the woman is ready to birth her baby. These cues may include the following:

- a pushing urge at the peak of a contraction
- the urge to push accompanied by deep, throaty sounds
- the woman tells you that she is feeling pressure or wants 'to push'
- bloodstained vaginal mucous discharge
- anal dilation
- possible spontaneous rupture of membranes

- perineal distension caused by pressure from the presenting part and/or intact membranes.

If a woman is experiencing urges to push and the other cues do not become apparent, it would be appropriate to consider a vaginal examination to confirm descent and position of the presenting part and dilatation of the cervix.

These sensations are often very intense and can be challenging for the woman. This is a time for the midwife to reassure the woman and explain what is happening for her and her baby. It is important for the midwife to communicate calmly and clearly with the woman. Helping the woman to focus on and trust what her body is telling her enables the woman to work with these powerful sensations and find the positions that help her most effectively.

As the contractions become increasingly expulsive, most women will experience stronger urges to push. Urges to push may vary in frequency and intensity. Supporting spontaneous, involuntary pushing means that the woman pushes only when the contraction has built up and she is unable to resist the pushing urge. Spontaneous pushing is characterised by short periods of breath holding (for no more than six seconds) followed by expiratory grunts (Sleep et al 2000). This is often referred to as non-directed pushing, and has been found to result in shorter second stages, a reduction in maternal fatigue and fetal distress, and less intervention (Walsh 2000b).

Upright positions for pushing are most effective in assisting women to birth their babies. Using upright positions enables women to remain mobile and they often prefer them (Gupta & Hofmeyr 2004). There are a number of physiological advantages in being upright (Rosser 2003).

This part of labour has traditionally been compartmentalised and subjected to strict timeframes in the mistaken belief that this will benefit the mother and baby. Focus on the purely physical aspects of birthing denies recognition of the complexities involved. This has led to a variety of interventions in response to the urgency that has developed around the birthing process. These interventions include directed or coached pushing, vaginal examinations, ARM, episiotomy and assisted or operative delivery. Arbitrary timeframes have not been found to improve outcomes and have subjected women and their babies to procedures that may have been unnecessary and at times caused harm (Walsh 2000b). Previous studies have investigated the outcomes for well women and their babies where the pushing stage has exceeded the traditional timeframes. These traditional limits have restricted primiparous women to two hours and multiparous women to one hour to birth their babies. Research shows that women and babies come to no harm where pushing efforts have exceeded these time limits (O'Connell et al 2003; Sleep et al 2000).

Clinical point

Advantages of being upright for birth

- Reduced risk of aorta-caval compression, which means maximising oxygen availability for the woman and baby.
- Gravity assists the baby into the optimal position and aids descent through the pelvis.
- Stimulates stronger and more efficient uterine contractions.
- Increases the diameter of the pelvic outlet.

(Source: Albers et al 1997; Gould 2000; MacLennan et al 1994).

Clinical point

Effective positions/places for pushing

- Squatting—using support people and/or furniture
- Kneeling—using cushions, mats, beanbags
- Sitting on the toilet or birthing stool
- Standing—leaning against furniture, wall, people, tree
- Use of pool or bath—buoyancy of water supports upright positions

Critical thinking exercise

Consider the labour environments in which you are with women.

1. What can you do to facilitate upright positions for women in labour?
2. What equipment is available to you and how could you adapt it to support the woman to be upright?

Facilitating a supportive birthing environment

The midwife has an important role in facilitating the birth of the baby by ensuring that the environment is appropriate and supportive of this physiological process. It is necessary to consider the following:

- the woman's plan, desires and dreams for the birth of her baby
- privacy—phone off the hook, doors closed, curtains pulled, note on the door saying 'not to be disturbed'
- warmth—room temperature, warm towels for the baby, pool temperature at 37°C
- comfort—positional techniques, hot towels, warm compresses, encouraging words
- a space in which to use a variety of positions and props (e.g. pool, bath, mats, pillows, beanbags, birth stools, mirror)
- involvement of partner and supporters—supplying drinks to the woman, cool cloth for her face, massage or acupressure, applying hot towels, physical support for the woman, encouraging words
- unobtrusive presence of a second midwife who is known to the woman, is supportive of her birth plan and familiar with the safety equipment

- preparation of birthing and safety equipment—oxygen, suction, infant Ambubag, oxytocics, cord ties/clamps, scissors, availability of intravenous cannulation equipment and fluids.

Facilitating effective pushing efforts means that the midwife recognises when it is appropriate to make suggestions for the woman to try a variety of positions. This may be in response to recognition that efforts so far have resulted in little change in the descent of the presenting part of the baby. Identifying a lack of progress usually results from a combination of assessments. These may include:

- the woman stating that 'Nothing has changed'
- no obvious anal dilatation or perineal distension, and no presenting part visible
- abdominal palpation to identify the degree of descent of the presenting part in relation to the pelvic brim
- VE to confirm presentation, assess cervical dilatation, define position, assess station and the development of caput and moulding.

If lack of progress has been identified, sometimes simple changes to the woman's position may be all that is required to enable the labour to advance. The midwife can then guide the woman into more upright, open positions to enhance rotation and descent of the baby. This can be achieved, for example, by the use of supported squatting, sitting on the toilet or birth stool, or standing. Enabling the woman to see the effect of her pushes using a mirror can be very encouraging and energising as the presenting part becomes visible.

As the presenting part descends with contractions, it advances with the assistance of expulsive pushing efforts. It will initially advance, then recede between contractions. This process is necessary to enable the woman's tissues to accommodate the presenting part and also support gentle moulding of the baby's head. The use of hot compresses on the perineum and vulva can provide some soothing comfort at this time and is associated with lower rates of perineal trauma (Jackson 2000). As the presenting part distends the vulva and perineum and then doesn't recede, the woman may experience intense burning and stretching. Hot compresses may provide some relief, and the midwife's calm, clear reassurance will be helpful. At this time the woman and her supporters will benefit from a relaxed, calm and unhurried atmosphere as the birth becomes imminent.

The midwife can encourage the gradual birth of the baby's head by suggesting that the woman breathes gently, pants or gives gentle, small pushes (Chapman 2003). With the intention of reducing perineal trauma, the midwife may have her 'hands on' or 'hands poised' to prevent rapid extension of the baby's head (McCandlish et al 1998). Traditionally, midwives have been taught to apply digital pressure to the occiput to maintain flexion and reduce tissue damage. There is no evidence to support this practice at every birth; however, a midwife must be poised to support the baby's head if it appears to be advancing rapidly or if there is an indication of possible perineal trauma.

Once the baby's head is born there can be a resting period before the next contraction. Midwives have routinely used this time to check whether there is a nuchal cord. There is ongoing debate regarding the usefulness of this procedure and women can find it extremely painful (Wickham 2003). If the cord is present it can be looped over the baby's head or rolled down over the baby's shoulders as the baby is born (Downe 2003). If the cord is wound tightly around the neck it has been common practice to clamp and cut the cord to release it. As this severs the baby's oxygen supply this practice is being increasingly questioned and should be used with caution. Tight nuchal cords have been associated with shoulder dystocia, and depriving the baby of its vital oxygen supply will only aggravate an already serious situation (Iffy et al 2001). Clamping and cutting the cord before the baby is born also alters the physiology of placental separation and commits the woman to active management procedures.

With the next contraction, the baby's shoulders rotate into the anterior/posterior diameter of the outlet of the pelvis and the baby's head will turn to be in alignment with the body (restitution). As the woman pushes, the shoulders are birthed and the rest of the body follows. The degree of hands-on support and guidance the midwife needs to provide will depend on the woman's wishes, her birth plan and the

Clinical point

When is the optimal time to clamp the cord?

The optimal time for clamping the umbilical cord at birth is unclear. Delaying clamping may facilitate transfusion of blood between the placenta and the baby (Rabe et al 2004). In a review of the literature, more than 500 term infants enrolled in randomised controlled trials and controlled trials (Mercer 2001) whose cords were clamped between 3 and 10 minutes or when pulsations ceased, showed no adverse outcome. Benefits are clearly documented for preterm infants (Rabe et al 2004) and suggested for term infants. There is no evidence that early cord clamping is better, and evidence is lacking regarding long-term harm from immediate or delayed cord clamping. Until we have sufficient appropriate evidence showing otherwise, it is better to mimic nature than to interfere with the intricate, complex, and only partially understood design of the physiological neonatal transition.

Level at which the infant is held

Delaying cord clamping and keeping the infant at the level of the introitus for 45 seconds results in an 11% increase in blood volume, but a 24% increase in oxygen-carrying red blood cells (Yao & Lind 1969). Raising the infant significantly (30–60 cm) delays placental transfusion, and lowering the infant 30–60 cm speeds the transfusion of blood from the placenta from 3 minutes to 1 minute (Yao et al 1969).

TABLE 22.3 The Apgar score

	0	1	2
Heart rate	Absent	Slow (< 100)	Fast (> 100)
Respiratory effort	Absent	Slow and irregular	Good and crying
Muscle tone	Limp	Some flexion of extremities	Active
Reflex irritability	No response	Grimace	Cry/cough
Colour	Pale	Body pink, extremities blue	Pink

(Source: Levene & Tudehope 1993)

position she is in. The woman may wish to reach for her baby and lift it to her or have the baby placed gently against her warm skin. It is not unusual for some women to need time before they touch and hold their baby. It is important that the baby is kept warm by skin-to-skin contact and gentle drying with warm towels, to maintain the baby's temperature and stimulate respirations. The towels should be replaced as soon as they are damp. These first few minutes of relief, exhilaration and delight are precious. The midwife, however, needs to be alert to the wellbeing of the mother and baby. An effective, skilful midwife is able to make careful assessments without interfering in these moments.

Assessments should include:

- baby's colour, heart rate, initiation of respiration, muscle tone, reflex irritability (Apgar score at 1, 5 and 10 minutes) (see Table 22.3)
- observing the woman's response to her baby
- observing the woman's general wellbeing and ensuring her comfort
- maintaining observations of blood loss and signs of separation of the placenta.

The Apgar score was devised by Virginia Apgar in 1953 and has since become the most commonly used quantitative measuring tool for assessing the wellbeing of the newborn baby (Levene & Tudehope 1993).

Enabling the new family to savour the moments after the birth involves supporting the woman and her family to take the time they need as they greet their new baby. This time also allows the woman's physiological responses to continue unimpeded. The woman holding her baby close encourages the release of oxytocin to facilitate the separation of the placenta and membranes. As the baby adjusts to the new environment, she or he may begin to look around, nuzzle the breast and display signs of being interested in suckling. It is important not to force this process but to observe for these cues. The baby may bring her hands to her mouth and start mouthing or rooting for the breast. There is no specific timeframe for this to occur but it is important that when the baby is ready, she has the opportunity to latch to the breast. An unhurried, non-interfering approach best achieves this.

Fifth decision point in labour: the third stage

A supportive, warm environment, low lighting, attention to the woman's comfort, and having the baby close to or feeding at the breast have all been found to encourage the spontaneous birth of the placenta (Odent 1999). The birth plan developed by the woman and her midwife will have identified preferences for the birth of the placenta and membranes. Where the labour and birth have proceeded normally with no intervention, it is reasonable to expect that the birth of the placenta and membranes will follow the physiological process uninterrupted. This is referred to variously as expectant, physiological or natural care (Long 2003). It is important for the midwife to be alert to the amount of vaginal blood loss and its effects on the wellbeing of the woman. Usually there is very little blood loss until the placenta begins to separate from the wall of the uterus.

Physiological management of third stage

This process facilitates the birth of the placenta physiologically and without interference. The midwife waits for the following signs of separation:

- uterine contractions
- slowing and cessation of umbilical cord pulsations
- lengthening of the umbilical cord
- gush of fresh blood or clots per vaginam
- placenta visible at the introitus of the vagina.

With the separation of the placenta, the woman will commonly experience low pelvic pain and heaviness as the placenta descends into the lower segment of the uterus. With contractions the woman may feel a pushing urge. She may find it helpful to be in an upright position to assist her to birth the placenta. The use of gravity and pelvic opening positions can facilitate this. It may be helpful to reassure the woman that the sensations when birthing the placenta won't be as intense as birthing the baby. Palpation of the uterus and/or application of traction to the umbilical cord are contraindicated during this process, as they are implicated in the potential for increased

bleeding and retention of the placenta (Sinclair 2004). As the placenta descends into the vagina, the midwife can assist the woman to birth her placenta gently so that trailing membranes can be eased out and not trapped or torn. As part of the midwifery assessment of the woman's wellbeing it is important to monitor vaginal bleeding and uterine contractility immediately after the placenta's birth. Women at this time will often experience a great sense of relief and comfort. When physiological management has been chosen, the therapeutic use of uterotonic drugs, oxytocin and/or ergometrine are only indicated where there is increased or unexpected blood loss before or after the birth of the placenta or where the uterus is atonic.

BOX 22.1 Lotus birth

Some families choose to leave the placenta attached to the baby until the cord separates. This is known as a lotus birth. The cord is not cut, and once the placenta is born it is dried, salted and wrapped in pre-prepared leak-proof material. The wrapping is changed as needed and some also choose to place fresh rosemary or lavender next to the placenta. The cord dries within 24 hours and separates (with the placenta) from the baby within two to five days. Reasons for choosing a lotus birth include the following:

- The family must carry both the baby and the placenta, and so will tend to stay at home and rest.
- The cord falls off in a shorter time than when cut and requires no extra care.
- Some claim the baby is calmer and more in tune with her or his surroundings.
- It is thought to provide the baby with a natural, gentle transition to extra-uterine life from being connected to the mother.

(Source: Rachana 2000)

The timing of cutting the umbilical cord after pulsation ceases can be influenced by:

- the birth plan
- a short cord interfering with the woman's ability to hold the baby close to the breast
- waiting until the placenta is born
- plans for a lotus birth (see Box 22.1)
- the woman's request to change position in order to birth the placenta.

Active management of third stage

Early cord clamping, the administration of uterotonic drugs and the application of controlled cord traction (CCT) are used to shorten the time between the birth of the baby and the birth of the placenta and membranes. This is referred to as active management and the impetus for this is the prevention of postpartum haemorrhage (PPH) (Prenderville & Elbourne 2000).

If uterotonic drugs are used during labour, it is important to continue with the active management procedures of cord clamping and CCT, as the physiological process has been interfered with. Mixing active and physiological care has been associated with adverse effects for the woman and her baby (Rogers et al 1998).

The research concerning management of the birth of the placenta and membranes has been conducted in obstetric settings where physiological management is not necessarily understood. There is a need for studies to be undertaken in a variety of birth settings that investigate third stage practices and outcomes where practitioners are more familiar with physiological management.

Midwives should be aware that blood loss is often minimal in active management. However, it is often the case that when the woman gets up for a shower after the birth, she passes a large clot, and may feel faint and exhibit signs of blood loss. Often this hidden blood loss is not

TABLE 22.4 Management of third stage

Physiological management	Active management
1 Observe for signs of separation.	1 Administer oxytocic after birth of anterior shoulder or after birth of the baby (if midwife is alone).
2 Continuously observe blood loss.	2 Clamp and cut the cord.
3 Assist the woman into a comfortable and upright position for birthing placenta.	3 Feel for uterine contraction.
4 Encourage the woman to push the placenta out.	4 Apply controlled cord traction by winding fingers around cord and applying sustained downward traction; when the placenta is visible, apply upward traction to follow the curve of the birth canal.
5 Ease the placenta and membranes out.	5 While traction is applied, counterpressure can be provided with the other hand placed above the symphysis pubis.
6 Note the time.	6 Note the time of delivery of the placenta.
7 Clamp and cut the cord after it has stopped pulsating.	7 Palpate the uterus to ensure it is contracted.
8 Palpate the uterus to ensure it is contracted.	8 Estimate the blood loss.
9 Estimate the blood loss.	9 Complete the documentation.
10 Complete the documentation.	

Note: Do not mix methods; do not stimulate the uterus by 'fundal fiddling' as this may lead to partial separation of the placenta and blood loss.

recorded and is not recognised in the literature about active management.

Examination of the placenta and membranes

Careful and thorough inspection of the placenta and membranes will need to be undertaken soon after the birth. If there is evidence of retained products, it is important to be aware of this as it may predispose the woman to bleeding or infection. During the examination of the placenta it is ideal to include the woman and her family in this fascinating exploration and to explain your findings with them. The aim is to identify the following:

- condition of the placenta and membranes
- number of vessels in the cord, insertion site and presence of knots
- signs of absence of cotyledons, including vessels through the membranes
- completeness of the membranes.

Assessing injury to the woman's labial, vaginal and perineal area

Episiotomy should be avoided during a normal birth and every effort should be made to minimise perineal injury and discomfort (Karacam & Eroglu 2003). Sometimes, however, a tear to the woman's perineum, vagina or labial area is unavoidable and it is the midwife's role to make a careful assessment of the degree of trauma to this area. The assessment does not need to be done immediately, as every effort should be made to establish bonding between the woman and her baby and to give them time to explore each other and initiate breastfeeding. (Ch 25 provides information about assessment of perineal trauma and repair.)

Ongoing assessment

Following the birth of the placenta and the perineal assessment and repair, the midwife needs to estimate the blood loss sustained and its effect on the woman. This is calculated by measuring actual blood loss and making a visual assessment of bloodstained linen, combined with assessment of the woman's wellbeing, including measurements of pulse and blood pressure. The actual amount of blood loss estimated is subjective. Each woman's individual response will need to be carefully assessed by the midwife. Palpation of the uterus and assessment of the fundal height to confirm that it is contracted and central assures the midwife that the woman's body is responding appropriately. Encouraging the woman to palpate her own uterus and recognise when it is well contracted or otherwise enables her to take responsibility for her wellbeing and know when to ask for assistance.

Examination of the baby

Assessment of the baby occurs from the moment she or he is born. Observing the baby in her mother's arms, her body movements, colour and alertness, allows the midwife to ensure that the baby has made an effective transition from unborn to newborn. The first hour or so of the baby's life will be spent in skin-to-skin contact with her mother and feeding at the breast. At some stage following this it is appropriate for the midwife to examine the baby and to discuss her findings with the parents. It is important that the room is warm and that the baby does not become cold during this assessment. Wrapping the baby in soft warm towels and exposing only the part of the baby you are examining not only keeps the baby warm but also helps to keep the baby calm. It is important to remember that she has just come from the warm, confined space of her mother's uterus. Babies will often cry if unwrapped and left naked, and this can be distressing for the baby and the parents. (Information about full examination of the newborn baby can be found in Ch 27.)

Ongoing care in the first few hours

The woman has expended an enormous amount of effort and will need to eat and drink to help restore her energy. Some families may have a special meal ready to celebrate the birth, others may have cultural preferences about the type of food first consumed after the birth of a baby and yet others know they are hungry but can't think what they would like to eat. Offering light food and fluids is helpful, and organising this can enable the midwife to give the new family some time to themselves.

When the woman is ready, she may like to have a shower or bath. It is important to assist the woman and ensure that she is feeling able to manage; she should not be left alone but given the privacy that she requires. A wash in bed may be more helpful for a woman who is tired and lacking energy. A seat in the shower can provide support if the woman is feeling weak and tired. This is also a useful time for the woman to try to empty her bladder. Encouraging the woman to empty her bladder within an hour or two of the birth is important for a number of reasons:

- It confirms that the woman can empty her bladder and that there are no issues of retention of urine possibly caused by trauma and/or oedema.
- A full bladder can impede effective uterine contractions and therefore increase the potential for bleeding.
- It reduces discomfort.
- Being upright can assist the expulsion of any clots that may have collected in the vagina/cervix.

As the birth process can sometimes result in a loss of bladder sensation initially, encouraging the woman to empty her bladder regularly, every two to three hours, in the first 12 hours or so after the birth, assists the uterus to remain contracted. It also enables the woman to recognise that her bladder is filling. Emptying her bladder regularly, especially just prior to breastfeeding, can help reduce the severity of the 'afterpains' that many women experience in the early postpartum period.

Afterpains (postnatal uterine contractions) are more commonly associated with multiparous women and with breastfeeding, but women can experience afterpains whether or not they have had a baby before and regardless of how they are feeding their baby. There has been a tendency to dismiss these as a mild inconvenience. However, there is a wide variation in women's experiences of afterpains. Some women feel the afterpains to be mildly uncomfortable and others describe them as excruciating or not dissimilar to labour pains. As the uterus contracts there is also usually a concurrent increase in bleeding and this may include some clots. The oxytocin release resulting from breastfeeding can strengthen afterpains and cause women to be fearful when latching their baby. It is helpful to explain to women what the afterpains are and what they achieve. For many women, afterpains settle after a few days but they can last up to a week or so for others. In the initial period after the birth, applying heat to the lower abdomen can be comforting. Ensuring the bladder is empty and not creating pressure on the uterus will also help. Acknowledging that afterpains can be distressing is important for women who may be worried that something is wrong.

Documentation

Documentation of the labour and birth process and the ongoing care provided is intended to give a comprehensive and accurate account of the woman and her baby's experience and wellbeing. Any plans, decision points and actions taken, as well as their outcome, should be recorded. The aim when documenting is to provide a contemporaneously written record of events as they occur. As mentioned previously, this may not be possible at all times but relevant times and events should be noted for further elucidation later. All documentation written retrospectively should be acknowledged as such. In the first few hours after the birth there is often opportunity for the midwife to complete the appropriate documentation. This will include:

- an accurate description of the labour and birth events, actions taken and outcome
- the woman's and baby's responses to the birth and each other
- description of the birth of the placenta and membranes, the examination and any findings—either normal or abnormal, blood samples taken and estimation of the woman's blood loss
- description of the assessment of perineal and vaginal trauma, and the process of any repair undertaken, including suture material and technique used
- assessment of the woman's and baby's wellbeing, including the results of any examinations undertaken, with attention drawn to any concerns and the midwife's actions in response to this
- timing of any drugs given, reason for administration and response
- completing any requirements for notification of birth, newborn records, maternity facility documentation
- midwife's assessment of the woman's and baby's wellbeing prior to the midwife leaving the woman's home, handing care to postnatal ward staff or the woman going home
- any specific plans for the next 12 hours or so regarding rest, breastfeeding, self-care and contacting/accessing caregivers.

Conclusion

The essence of being able to provide midwifery support for women in physiological labour involves a number of beliefs, attitudes and practices. The importance of the midwife–woman relationship and its development over time cannot be overestimated. This relationship enables the woman and the midwife to learn to understand one another, and the midwife to come to know what and who are important for this particular woman. This 'knowing' can enable the midwife to be 'with woman' in the full sense of the term.

Understanding the physiological process of labour and birth enables the midwife to recognise that each woman will respond in her own way. This encompasses the physical, psychological, emotional and spiritual dimensions. What is normal for one woman may be abnormal for another. Being present, and the quality of that presence, enables the midwife to support the woman in the way that is most appropriate for that situation. Not all women wish for a constant presence but when they want the midwife they want her to be 'there'. Being in the room is not enough: it is important to listen and attend to the woman and her supporters. This is most easily achieved through continuity of care provided by a known carer. Words of praise, comfort, encouragement and reassurance are all valuable tools of the midwife who actually means them (Page 2000).

Midwives can support women through labour and its ebbs and flows, by being available to the woman, encouraging and comforting her and helping her support people to do the same. Labour and birth are challenging for most women and they require understanding and belief to work through the challenge. Labours can be affected by a multitude of issues, and the midwife who recognises the potential impact of these issues will be in a position to assist the woman.

There are a variety of assessment tools that midwives can use to identify that labour is progressing. The skilful midwife will use these tools in combination with her observations and knowing of the woman. Understanding the effect of mobility, positions, gravity and environment can enable the midwife to assist the woman through her labour, especially when it is hard work. Knowledge of what supports and what may adversely affect the physiological process are key skills for a midwife.

Review questions

1. What elements is it important to include in a birth plan to enable the midwife to provide effective support during labour?
2. What impact might the birthing environment have on a woman's ability to labour and birth normally?
3. How would a midwife distinguish between latent and active labour?
4. What support does a midwife require to be able to provide a continuous, attentive presence during a woman's childbirth experience?
5. What are the signs that a woman in labour is dehydrated?
6. What key information is gained from a vaginal examination?
7. Describe how to monitor the fetal heart effectively in a normal labour.
8. List the signs of a non-reassuring fetal heart rate.
9. What are the signs of lack of progress in labour?
10. What are the differences between physiological management and active management of the third stage of labour?

CHAPTER 23

Working with pain in labour

Nicky Leap and Stephanie Vague

Key terms

'being with' women, control, empowerment, labour pain, midwife–woman relationship, non-pharmacological pain relief

Chapter overview

This chapter explores the midwifery art of being with women in pain with labour. The advantages of promoting women's confidence in their ability to cope with pain are discussed in relation to evidence that supports this approach. Historical, psychosocial, cultural and feminist perspectives on pain in labour are presented in order to inform and highlight exemplary midwifery practice.

Learning outcome

The learning outcome for this chapter is to encourage midwives to consider how they engage with women around in labour in order to promote women's sense of confidence, ability and self-esteem

Introduction

This chapter is concerned with the midwifery art of being with women in pain in labour. As such, it explores the rationale for engaging with women and their families[1] around the role of pain in normal birth. While acknowledging that midwives must be prepared to support all women in labour, including those who choose to use pain medication (van Hoover 2000), it is not the intent of this chapter to give midwives information about specific methods of 'pain relief' and their administration; there are comprehensive textbooks about pain in childbirth that cover this more fully than is possible here.[2]

There are also handbooks that explore the practicalities of supporting labouring women using 'active birth' techniques (Robertson 1994; Simkin & Anchetta 2000). The authors of this chapter are assuming that midwives will be aware of the benefits of providing supportive strategies such as encouraging women to move around, find positions that feel right and make noise if they wish. It is essential that midwives have these skills if they are to work with women in pain and encourage normal birth. In a culture where epidural anaesthesia is increasingly being promoted, it is also important that midwives are able to articulate why there is value in working with pain in labour, as opposed to taking away pain (Leap & Anderson 2004). This is especially important because, although there has been an increase in numbers of women wanting to use epidurals, there has also been an increase in those wanting to avoid all kinds of analgesia (Henry & Nand 2004; Horrowitz et al 2004).

It has been suggested that anticipation of labour pain causes intense anxiety for many women (Coombes & Schonveld 1992; Lowe 1989; Shearer 1995) and that this can have a negative effect on their experience of birth (Green et al 1988). This chapter offers an overview of the evidence that midwives can draw on in order to engage with women around pain in labour, with a view to addressing these anxieties and enabling situations in which women can feel more powerful and confident as a result of their experiences of pregnancy and birth. In order to achieve this, it is imperative that midwives explore and appreciate the various meanings that may be associated with labour pain for individual women and their families (Mander 2000). An understanding of how perspectives on the physiology of pain and the culture of 'pain relief in labour' have evolved over the past century in industrialised countries will provide a starting point.

Historical perspectives on pain in labour

A comprehensive history of the development of pain theories can be found in Melzack and Wall's *The Challenge of Pain* (1988). The traditional theory of pain is known as 'specificity theory'. Pain is seen as no more than a particularly complex signal, broadcast over nerves leading from the site of injury to the brain, as first suggested by Descartes in 1664 and modified by Muller in 1842 and von Frey in 1894. Various theories on pain were developed in the first half of the twentieth century but a major breakthrough occurred in 1965 when Melzack and Wall proposed the 'gate control theory of pain'; this provided a conceptual framework for understanding how pain messages are filtered and facilitated or inhibited through a 'gate' in the spinal cord that modulates reception and responses (Melzack & Wall 1965). In recent years, Melzack (1999) has proposed the 'neuromatrix' theory of pain, which retains key elements of the 'gate theory', but includes additional inputs from the brain. Memory, emotion, cultural factors, stress regulation, immune systems and past experiences play a role in how the brain processes and synthesises genetic and sensory nerve impulses. The neuromatrix theory of pain can be used to enable understandings about the complexity of responses to pain and may also provide a framework for exploring the beneficial effects of non-pharmacological methods of pain relief in labour (Trout 2004).

The notion of a systematic approach to 'pain control' in labour begins in Edinburgh with the experimental work of James Young Simpson in the 1840s (Caton 1999). Simpson's introduction of inhalation anaesthesia in childbirth spawned a series of campaigns led by middle-class women demanding access to this resource. Such demands played a significant role in the move from home to hospital birth in the twentieth century. Debates and concerns about the advisability of analgesia and anaesthesia in terms of safety and possible physical and psychological consequences have changed little since Simpson's day. The potential harmful side-effects of drugs and the social value of pain versus the preservation of meaning in childbirth when pain is removed continue to be hotly debated issues (Caton 1999) that affect how women approach labour pain.

In the early 1930s, Grantly Dick-Read published *Childbirth without fear: the principles and practice of natural childbirth* (Dick-Read 1933). This book launched the concept of eliminating the cycle of 'fear, tension and pain' through counteractive education and training. Gentle, coached breathing and relaxation, with the emphasis on collaboration with a coach, were to play a vital role in keeping the woman on course in the teachings of the natural childbirth movement and later the 'psychoprophylaxis' movement in Europe and North America. In the latter decades of the twentieth century, the mechanistic focus of psychoprophylaxis increasingly gave way to the psychosexual approach, a model that sees acceptance of labour as purposeful within the highly charged, significant act of giving birth, with its far-reaching sequel for women's lives (Kitzinger 1962, 1987). This approach became incorporated into that of the active birth movement (Balaskas 1983), which drew on activities and philosophies associated with the yoga tradition in teaching women to develop 'all of their bodily resources for giving birth, to follow their own instincts and to take full control of the childbirth experience' (Balaskas 1992, back cover).

In the 1980s, a new dimension to understanding pain in labour, incorporating neuro-hormonal physiology, was provided by Michel Odent (1984), who proposed that intrinsic

opiates, such as the endorphins released by marathon runners, enable labouring women to enter a state of consciousness that enhances the progress of labour as well as providing a way of coping with pain. Odent drew on the work of Newton and colleagues (Newton et al 1966, 1968) in suggesting that privacy, intimacy and non-disturbance are required to enable the delicate balance of hormonal cascades to interact and promote effective physiological processes. Odent (1984, p 14) described the 'virtually ecstatic state' induced by endogenous opiates where women labour undisturbed as something that has always been sensed. This 'sense' of women having some 'inbuilt' coping mechanism has probably always been familiar to midwives in the absence of any physiological explanations, as described here by a retired midwife who practised in the 1930s in Britain:

> I think myself that the system has a certain amount of sedative in itself that it releases at a time like that. I'm sure it has, because I've seen people that looked as if they were half sozzled—and they didn't have anything! Just looked like somebody 'gone'—and they hadn't had any dope (Leap & Hunter 1993, pp 168–9).

The familiarity of women disappearing into their own world in strong labour meant that midwives and childbirth educators embraced the theory of the body's own pain-modifying substances as 'Nature's reward' (Ginesi 1996, p 9). A full scientific description of the role of endogenous opioids in spontaneous labour is needed if 'endorphin' theory is to be given widespread credence. However, it is thought that incoming impulses of pain stimulate the release of encephalins, dynorphins and endorphins in the dorsal horn of the spinal cord and that these opioid-peptides have the ability to inhibit the sensations of pain carried by neurons to the brain.

Overall, in the past few decades, challenges to the concept of managing labour pain with anaesthesia and analgesia in industrialised societies have tended to concentrate on 'non-pharmacological methods of pain relief' (Simkin 1989) and have therefore often upheld the basic concept of controlling and minimising pain. Midwives who have written about the role of the midwife in relation to pain in labour have continued this trend by focusing on the skills needed to facilitate 'pain relief' (Moore 1994). With the development of antenatal education came a belief that midwives should be preparing women for labour by giving them 'informed choice' about all the 'methods of pain relief', the benefits and disadvantages of each.

In recent years, the offering of what Leap (2000b) has referred to as the 'menu' of various methods of 'pain relief' has been associated with the notion of a woman's right to make 'informed choices' about all aspects of her care (Department of Health 1993; NHMRC 1996). This approach requires practitioners to adopt a systematic approach to explaining the advantages and disadvantages of each method 'on the menu' so that the woman may make appropriate choices, usually in advance of labour. Many practitioners and women therefore assume that some form of pain relief in labour is necessary. This assumption also underpins most research in the area. In contrast, midwives are increasingly articulating an approach that contributes to positive birthing experiences through building women's confidence in their ability to find ways to deal with labour pain through drawing on their own resources (McCrea et al 2000). The rationale for this 'working with pain' approach rests in a belief that pain is purposeful in promoting normal birth and that the 'triumph' women experience after a drug-free labour can have far-reaching consequences for how they feel about their capabilities as women and as mothers (Anderson 2000; Leap 2000b; Leap & Anderson 2004). Listening to women's ideas and experiences concerning pain in labour reinforces this theory.

Women's perspectives on pain in labour

Labour pain is complex and it is thought that the experience of pain itself may be mediated by physical, psychological, spiritual and cultural factors such as tradition, anxiety, emotional associations, the position of the baby in utero, and levels of preparation and support (Mander 1998). Importantly, effective forms of pain relief are not necessarily associated with greater satisfaction when women evaluate their experience of birth (Heinz & Sleigh 2003; Hodnett 2002; Morgan et al 1982; Ross 1998). Studies have repeatedly shown that the quality of support and the caregiver relationship are so important to women that they override the influences of age, socioeconomic status, ethnicity, childbirth preparation and the physical birth environment; the influence of pain, pain relief and intrapartum medical interventions on subsequent satisfaction are not as obvious, direct or powerful as the influence of the attitudes of the caregivers (Hodnett 2002).

Women have identified that support for coping with labour pain and access to different ways of reducing or relieving pain is important to them (Chamberlain et al 1993; Lundgren & Dahlberg 1998, 2002). The quality of these supportive interactions is more important to women than the level of pain per se (Callister et al 2003) and the attitudes of midwives have a profound impact on how women feel about their labours (Kitzinger 2000). It has been suggested that a form of reconstruction occurs after birth, when memories of labour pain are based on recall of the remembered emotional and behavioural consequences of the pain (Terry & Gijsberg 2000) and the meanings ascribed to the pain (Mander 2000).

In a number of studies, women have expressed satisfaction with the midwifery care they received when the midwife was 'present' in offering support and information (Hodnett 2002). They also valued feeling respected, and commented on the sense of trust that evolved, even when they had often not met the midwives prior to labour (Berg et al 1996). Culturally diverse groups of women have described childbirth as a difficult but empowering experience leading to a sense of achievement and a feeling of pride in their ability to cope with intense pain (Callister et al 2003; Dickenson et al 2003; Halldorsdottir & Karlsdottir 1996; Lundgren & Dahlberg

1998; Niven & Murphy-Black 2000). In contrast, women who have had obstetric intervention, particularly those who had unknown attendants, describe increased anxiety and pain, and place less emphasis on their active participation in birth (Callister et al 2003).

The rise in epidural and elective caesarean section rates has been apportioned to women making choices that help them deal with uncertainty and the fear of pain in labour (Silverton 2001). However, practice regarding epidurals, narcotics and elective caesarean section varies greatly regionally, between different maternity units and according to practitioner employment status, with particularly high rates in the private obstetrics sector (Roberts et al 2000). Variations appear often to be related to institutional or professional opinion factors rather than population factors or individual women's choices (Hodnett 2002).

Women who express a desire to have a normal birth often cite concerns about the side-effects associated with the use of narcotics and epidurals in labour as a major source of motivation (Henry & Nand 2004; Souter 2004). Such concerns sit within wider debates about the potential public and psychological health impact of rates of intervention that are above those indicated by current evidence (Johanson et al 2002).

Although epidural analgesia is very effective in reducing pain, it is associated with increased risks of prolonged labour, fetal malposition, augmentation and instrumental vaginal birth (Anim-Somuah et al 2005; Howell 2002; Howell et al 2001; Mayberry et al 2002). Controlled observational studies also indicate a possible association with higher caesarean section rates, and although these findings must be viewed with caution due to methodological challenges, there is sufficient evidence to warrant concern. There has also been a suggestion that the rate of crossover in trials is masking the relationship between epidurals and caesarean section (Lieberman 2004). The only uncontaminated randomised controlled trial to demonstrate an association between epidural and caesarean section was published over 12 years ago (Thorpe et al 1993). This small trial showed that women having first babies who were randomised to have an epidural were 11.4 times more likely to have a caesarean due to dystocia than women who were randomised to have narcotic analgesia. The trial was discontinued on the grounds that it was unethical to continue to randomise women to have an epidural. Concerns have been raised that supportive midwifery care may be jeopardised by the monitoring activities associated with epidural analgesia in hospitals where there are high epidural rates; these concerns are particularly acute in terms of women's ability to care for women who choose non-pharmacological pain relief (Mayberry et al 2002).

The use of narcotics, such as pethidine, in labour is associated with harmful effects on the mother's birth experience, longer labours, compromise of the baby and difficulties initiating breastfeeding (Heelbeck 1999; Hunt 2002). Furthermore, while such drugs induce sedation and may therefore give caregivers the impression of having relieved pain, women overwhelmingly report on how ineffective narcotics are in providing pain relief (Bricker & Lavender 2002; Olofsson et al 1996).

Studies comparing different types of pain have identified the severity of labour pain for the majority of women (Melzack & Wall 1965). However, the National Birthday Trust Fund Pain Relief in Labour Study (Chamberlain et al 1993) found major differences between the perceptions of over 1000 women and those of their birth attendants with regards to the experience of pain and the effectiveness of pain relief methods. Professionals' concepts of pain relief tended to be restricted to pharmacological methods—less so with midwives than with doctors—and they were more likely to agree with each other about the efficacy of different methods than with the women. This difference is understandable if one considers that, although today, books for women about childbirth tend to be illustrated throughout with personalised accounts of births, this is not generally the case with textbooks for professionals. Arney and Neill (1982) have suggested that professionals need to listen to the subjectivity of individual women's experience in order to move away from the one-dimensional approach based on anatomy and physiology. Like Bendelow and Williams (1995) and Martin (1987), they stress the importance of learning from narratives in order to make more appropriate responses to those in pain.

The particular quality of labour pain

The Association of Radical Midwives has always paid tribute to the value of learning from women's accounts of their births and, since its inception in 1978, its newsletter has consistently published birth stories written by women. An example is the moving account by Agnes Kotreba (1994), who gave birth after a fast labour, before the midwives arrived. Her account acknowledges aspects of loneliness, potential death, images of water, and the physical and mental challenges of pain that are common themes elsewhere.

> Dear God, how many more hours? I especially don't let myself panic or drown in this tidal wave which breaks my entrails and comes from a distance like the sound of a plane, intensifying until it gets intolerable, and then nothing—nothing, no pain whatsoever. I'm like cleansed, surprised, pulverized—Will I have the strength to endure the next attack? . . . I twist myself in pain . . . I think I emit a sound . . . so far I am unable to show my suffering, it's my business, my biggest intimacy, my most complete and total nudity (Kotreba 1994, pp 16–17).

When listening to such accounts, Kelpin (1992) suggests that it is not useful to compare labour pain to any other pain. She also questions the validity of fragmenting our understanding by analysing the pain of labour within different theories such as physical, psychological, sociological and cultural perspectives. She suggests that such approaches militate against the understanding of the nature of 'painfulness' as lived by women and mothers and that the inwardness of the birth experience is an opportunity to be attentive to:

> the deep significance of the momentous quality of the pain . . . As we are surrounded by the deep sense of inwardness, we are forced to recognize our independence, our loneliness, our selfhood. To

> be conscious of our own existence. This actual self-consciousness exposes to us our wholeness, our strengths and our endurance (Kelpin 1992, p 101).

The pain of labour is constructed by Kelpin as an expression of 'the narrow gateway leading to release in the expanse of life' (p 101). The release she describes with the birth of the baby is given the significance of change from 'self-as-world' to 'baby-as-world' where a new pain comes with the awe of focusing on a new being. She quotes Phyllis Chesler (1979, p 281): 'Being born with motherhood is the sharpest pain I've known' and uses words like 'relief', 'disbelief', 'joy' and exhilaration to describe the excitement and poignancy of the new baby's presence (p 102). This exhilaration usually masks the ability to recall the exact nature of pain.

> But who can remember the pain [of childbirth], once it's over? All that remains of it is a shadow, not in the mind even, in the flesh. Pain marks you but too deep to see. Out of sight, out of mind (Atwood 1987, p 135).

Attempts to describe pain reinforce the elusive nature of pain but also the crossing of borders between the emotional and physical way it is experienced. Pain has a common language, as this passage illustrates:

> Pain . . . is stark and unyielding to decoration, pain fills the world to the hilt, bursting its edges in an unseemly way; pain doesn't admit anything else—it usurps all the space available (Kassabova 1999, p 52).

The pain described above is the pain expressed by a young woman who has had to leave her homeland and flee far across the world to a place of safety. Such is the universal nature of pain that it could equally well be describing the pain of a heart attack or the pain of labour. However, it should be noted that many women say that labour pain is quite different from any pain that is associated with injury or trauma but that this is hard to explain in concrete terms.

In her important study of pain, Elaine Scarry (1985) states that the person in pain may experience pain as 'the most vibrant example of what it is to have certainty': pain is 'effortlessly grasped', while for the onlooker, the other person's pain is so elusive that it could be seen as 'the primary model of what it is to have doubt'; here 'what is effortless is not grasping it' (Scarry 1985, p 4).

> Pain can be seen as capable of bringing about an absolute split between one's own sense of reality and that of another person, even when in close proximity [as during labour] (Scarry 1985, p 4).

This concept is significant for midwives who sit alongside women in pain; they can respond to cues given by the woman in order to offer support and suggestions but primarily the midwife's role is to help the woman identify her own spontaneous coping strategies (Escott et al 2004) and to be alert to aspects of care and the environment that disrupt these (Spiby et al 2004).

Studies have suggested that midwives consistently underestimate the intensity of pain experienced by women in labour (Chamberlain et al 1993; Niven 1994). This may be a coping mechanism on the part of midwives as the onlookers of pain. Scarry's reading of the role of the physician in hearing the fragmentary language of pain, 'coaxing it into clarity' in order to interpret it, could be applied to the role of the midwife, who equally needs not to bypass the person in pain as an 'unreliable narrator' since doubting people in pain amplifies their suffering (Scarry 1985, pp 6–7). However, recognising the severity of pain that a woman is suffering during labour does not necessarily equate to the need to offer pain relief. In fact, women identify that when they are in pain, any offer of pain relief is irresistible and undermines their confidence in their ability to cope without using pharmacological pain relief:

> I didn't really want an epidural. That wasn't what I was saying. What I wanted was something magic that no one's ever thought of before, that you were going to quickly invent right then to make it all better. But I really didn't want an epidural. It was an expression of my pain (Leap 1997, p 49).

Midwives have talked about the significance of the particular nature of pain in labour: its rhythms, the fact that it has a positive, finite goal and that it stops as soon as the baby is born and then cannot be recalled.

> Afterwards, I'm still emotionally and physically wrecked and they've moved on completely. It's like, through a fog they can remember the time they were pleading for an epidural but they've moved on. So that's been significant for me just in terms of women's ability to recover or move on or have a different agenda in a very short space of time. And that's given me enormous confidence to . . . just be there . . . and not see pain as long-term damage (Leap 1997, p 48).

Cultural perspectives on pain in labour

> Pain is never the sole creation of our anatomy and physiology; it emerges only at the intersection of bodies, minds and cultures. (Morris 1991, p 1)

New Zealand and Australia are multicultural societies and, as such, the midwife is likely to be involved in the care of women from a range of backgrounds, including Maori, Polynesian, Asian, Middle Eastern, African and European descent. She needs to be mindful that different cultural practices may be employed to help women cope with pain during labour. For some women, prayers may be read by family members or songs sung to provide support and to welcome a new member of the family. For some Maori women, these would be in the form of *karakia* or *waiata*.

Cultural perceptions and expressions of pain vary widely. Women from some European cultures, such as Greece and Italy, for example, tend to vocalise pain in an uninhibited fashion, while those from other cultures, such as Polynesian women, often appear to value stoicism. Samoan and Tongan women, therefore, may appear very calm during labour, with little outward show of their pain.

Midwives must be aware, however, of the potential pitfalls associated with ethnic stereotyping, and it is important never

to assume that a woman will respond to labour pain in a culturally determined way. A book describing Maori women's experiences of pregnancy and birth, *Ukaipo* (Rimene et al 1998) highlighted communication as an area where possible misunderstandings could arise. One woman pointed to the fact that nodding the head after receiving information from a midwife does not necessarily indicate understanding. Sometimes it is merely an effort to try to please or just to acknowledge that the information has been heard.

Holroyd and colleagues' (1997) study of Hong Kong Chinese women's perception of support during labour from midwives describes how the cultural reluctance of women to express emotions meant that the midwives found it very difficult to interpret non-verbal expressions of pain, even though they were from the same ethnic background. Sometimes clues about the pain women are experiencing and the progress they are making can be as subtle as beads of perspiration on the upper lip, or a slight frown.

Bowler (1993) showed how midwives are in danger of stereotyping women according to their cultural background. In her study, she demonstrated how midwives dismissed Asian women in pain as 'making a fuss about nothing' because they were perceived to have a low pain threshold. This assumption led to women having pain relief withheld and receiving different treatment from that received by other women. The racist notion that all women who share a particular culture are the same can mask the needs of individual women and lead to poorer service provision.

While the pain of other peoples' bodies may be unknowable and indescribable, again, it is through listening to women that professionals may develop an understanding of the complex meanings that women attribute to pain. This may be significant in how midwives engage with women, and facilitate the way they approach pain in labour and how they reflect on it afterwards (Mander 2000). In particular, there is the potential to address issues related to power and control for individual women.

Enabling a sense of control

Enabling women to feel in control during labour is important if they are to feel confident and satisfied with the childbirth experience (Lavender et al 1999; McCrea et al 2000). A sense of control is of great significance to labouring women, although their definition of personal control is complex. For some women, control is associated with feeling in control of their emotions and behaviour in labour (Green et al 1998; Niven 1994). For others, control involves some participation in the decisions that are made about the management of their labour and birth (Berg et al 1996; Bluff & Holloway 1994; Green et al 1988; Halldorsdottir & Karlsdottir 1996; Hundley et al 2001; Niven 1994). However, as Green and colleagues (1988) found, choice can prove threatening for a woman because she is asked to assume responsibility for decisions or because she is overwhelmed by a plethora of options. Bluff and Holloway's important study (1994) coined the phrase 'They know best' where women and their partners believed that the midwife knew what care was best, even when their own specific wishes were disregarded. This study clearly demonstrates a need for midwives to acknowledge the inequality and power dynamics within the relationship. The midwife is seen to hold much 'expert' knowledge and the potential exists for her to abuse the trust placed in her professional judgement. Conversely, the midwife can use the authoritative trust that is placed in her knowledge and experience to encourage women to believe that they can cope with pain in labour, even when the woman has lost confidence in her ability to do so. This often requires courage on the part of both. Resisting women's pleading for pain relief and insistence that they 'can't do it anymore' requires the midwife to be very clear that this is normal labour pain and that as soon as it stops, the woman is going to be very pleased that she 'did it all herself'.

The psychosocial dynamics of pain in labour

> To separate sense from emotion, body from mind is hardly useful when we are trying to understand the whole of female experience, and in particular a function—childbirth—so charged with unconscious and subjective power, and so dramatic in its sensations (Rich 1977, p 157).

Raphael-Leff (1986) has drawn on psychotherapeutic practice in suggesting that conscious and unconscious attitudes or 'orientations' to pregnancy, labour and motherhood will affect whether women see labour as a 'natural event' or a 'depleting, medical event' and that this in turn will affect their experience of labour pain. She encourages midwives to identify the psychological factors that may assist them in recognising and acknowledging individual women's needs in labour. However, it has been shown that stereotyping can occur when midwives attempt to apply an understanding of the psychological factors that may influence an individual's experience of pain in labour (Bowler 1993; Green et al 1990; Niven 1994). Experienced midwives are aware of the pitfalls in deciding who will or will not cope with the pain of normal labour.

> Women constantly shock me and I think I've learnt from those women. You could sit there and think, 'She's a hopeless case, she said her pain threshold's really low'—and all you've got to do is tell her she's doing well, that it's normal and allow her to get on with it in her own way, and I think she will (Leap 1997, p 44).

There has been a questioning of the tendency for midwives to feel that they should work out the deep psychological processes affecting the women they care for and that they should identify and help women get rid of the 'baggage' that might impede the process of childbirth (Leap 2000a; Oakley 1980). Concerns have been expressed about the disempowering effect that such approaches can have on women where there is a shift in the midwife's role from empathetic listener to a more interventionist psychological role (Gosden 1996; Gosden & Saul 1999). Midwives have described the fallacy of predicting how women might cope with pain in labour within a culture where such predictions are a regular feature of informal discussions dominated by 'psychological' value judgements (Leap 2000a).

Feminist perspectives on pain in labour

Adrienne Rich (1976) points out that metaphors of pain in childbirth can be related to wider feminist issues.

> The pains of labour have a peculiar centrality for women and for women's relationship—both as mothers and simply as female beings—to other kinds of painful experience (Rich 1976, p 158).

Rich describes uterine contractions in terms of 'pressing the self out of us' (p 158). She questions whether physical pain can be distinguished from alienation and fear, and poses the notion of 'creative' versus 'destructive' pain. She draws on the work of Simone Weil (1951) in highlighting the difference between the destructive affliction of powerlessness, which can be avoided, and the potentially creative power of pain that can lead to growth and enlightenment:

> where it is unavoidable, pain can be transformed into something usable, something which takes us beyond the limits of the experience itself into a further grasp of the essentials of life and the possibilities within us . . . this insight illuminates much of the female condition, but in particular the experience of giving birth (Rich 1976, p 158)

Rich warns against labelling as 'pain' the complexity of each individual woman's physical experience of labour. Such reductionism can lead to the avoidance of pain through analgesia and anaesthesia, a process that Rich describes as:

> a new kind of prison for women—the prison of unconsciousness, of numbed sensations, of amnesia, and complete passivity . . . a dangerous mechanism which can cause us to lose touch not just with our painful sensations but with ourselves. (Rich 1976, pp 158–9).

However, Rich advises caution when it comes to the metaphor of 'I am a woman giving birth to myself'. For most women there has always been a distinct lack of choice and very little consciousness around childbirth, let alone personal growth. Historically, women have always been told how they should feel about labour pain from the classic victimisation of 'Eve's curse' to the 'ecstatic fulfillment' of the natural birth movement (p 156). Rich makes a plea for us to view childbirth as a challenge rather than pain, 'as one way of knowing and coming to terms with our bodies, of discovering our physical and psychic resources' (p 157) as 'one experience of liberating ourselves from fear, passivity and alienation from our bodies' (p 184). She suggests that there are far-reaching implications in highlighting the need for women to be attended by midwives who respond to a woman's distressing labour as a cry for active care and support, not as a demand to have pain taken away or numbed.

> As long as birth—metaphorically or literally—remains an experience of passively handing over our bodies to male authority and technology, other kinds of social change can only minimally change our relationship to ourselves, to power, and to the world outside our bodies (Rich 1976, p 185).

Pain in labour and the notion of empowerment

> To have experienced birthing pain offers the possibilities of self knowledge, knowledge of our limitations and capabilities, knowledge of new life, as mother and of our place in the mysterious cycle of human life: birth, death and rebirth. As we birth our children, we, in a sense, birth ourselves. We are mothers, like our mothers, and our daughters after us (Kelpin 1992, p 103).

The notion of women 'being born' with their babies is described by one respondent in a study of single women who developed strategies in order to have children. In spite of an extremely traumatic labour and birth, she reported:

> It was about the best thing I ever experienced. I was totally amazed. The labour was like I had died . . . I had just died. The minute she came out, I was born again. It was like we'd just been born together (Lewin 1985, p 135).

This young woman described how the birth led her to make significant changes in her life, in particular in relation to her own parents.

Robertson (1996, p 19) sees the universality of pain in labour as a bond between women, 'a fundamental truth that confirms our special biological role and affirms the importance of our contribution to society'. Feminists may have difficulty with Robertson's biological reductionism, especially when she refers to women's bodies as 'designed to be as efficient as possible' and describes 'the very few failures . . . necessary to ensure reproductive success amongst strong breeding stock' (Robertson 1996, p 19). Robertson makes an impassioned plea for reclaiming pain in labour. She sees its role as vital in stimulating hormonal responses that allow a biological function to take place with optimum efficiency while at the same time promoting the 'innate sexuality' of the experience of labour. The body's 'natural painkillers' can be released and a positive emotional climate is ensured for the meeting of mother and child (Robertson 1996, p 19). Robertson (1994) describes 'transition' (the name given to the end of the first stage of labour, when women are generally expressing most difficulty with pain) as 'the moment of truth' and suggests that 'it may be very important to allow women to have the experience of conquering an overwhelming personal crisis, to promote confidence and self-esteem in the new mother' (Robertson 1994, p 92).

> Submission to the all-consuming and overwhelming nature of birth and the weathering of the inherent pain of labour is an empowering process for a woman, and one that should not be denied unless critical for her own well-being or that of her baby (Robertson 1994, p 88).

Martin (1987, p 202) suggests that the potential joy expressed by one respondent—'the joy will take away from the pain and I'm willing to face the pain'—stood as a lone image among others where women are passively being 'done to', where the concept of the 'involuntary uterine contractions' referred to in childbirth texts and classes creates a culture where women end up feeling a sense of alienation from their bodies:

> We are still a long way from seeing quintessentially female

functions as acts women do with body, mind and emotional states working together or at least affecting one another (Martin 1987, p 204)

Kathryn Allen Rabuzzi (1994) was originally inspired to write about the potential 'ecstasy' of birth after an unanticipated 'natural' birth in the late 1950s which left her with a quest to find out more about the extraordinary and unanticipated feelings of 'dying, being born, and giving birth' and the accompanying sensations of 'outward and inward expansion' (Rabuzzi 1994, p vii). She claims that in order for women to reframe the deeply acculturated belief that childbirth is painful and dangerous, they need to see pain as something to conquer, rather than something posing a threat to conquer us. This way, she suggests, its meaning, though not its intensity, may change, although she recognises that there is a potential problem with reconceptualising around 'control' when many midwives propose a 'letting go' approach to labour (Rabuzzi 1994, pp 98–105).

Pain in labour and the midwife-woman relationship

There is strong evidence that continuity of caregiver throughout pregnancy, labour and birth reduces the amount of pain relief women have during labour, and increases their satisfaction with their maternity care, particularly where women give birth at home (Hodnett 2003). This may be due to the relationship of trust that develops and the ability of midwives to enable situations where both women and midwives feel confident and positive when approaching birth (Reed 2002a,b; Walsh & Newburn 2002). In situations where there is not necessarily a midwifery relationship that has developed through pregnancy, women who have continuous support from a female caregiver who is not a professional during labour are less likely to use pharmacological pain relief and are more likely to have a spontaneous vaginal birth (Hodnett 2003). It may be that midwives who work in situations involving fragmented care are more likely to have to deal with the demands of the institution; they are less likely to be able to concentrate on intensive support of the woman than a lay person, such as a 'doula', who knows the woman and is focused on helping her to find her inner resources in coping with pain without resorting to pharmacological pain relief (Hodnett 2003).

Midwives enjoy a special position where they work with women throughout pregnancy, labour and the postnatal period. They begin to work with pain in labour during the antenatal period during discussions with a woman about the potential challenges of that pain. The midwife's interpretation of pain is a key factor in working with a woman before labour. She strives to convey the message that the pain of labour is a safe and purposeful pain that heralds the birth of the baby.

Midwives have the opportunity to help a woman prepare for her pain by exploring the particular nature of labour pain. It can be argued that this is different from other types of pain because it is of a positive nature. The pain is bringing a baby; it therefore has a different meaning for women (Soutter 2004). In industrialised societies, pain generally has negative connotations—it represents trauma, disease or stress, something fearful, to be avoided or alleviated—and it is therefore a challenge for midwives to help women (re)frame their understanding of pain. Given the high rates of epidural anaesthesia in Australia and New Zealand, the task of enabling situations where women embrace the pain of labour as part of a normal, physiological event is particularly challenging (Fenwick et al 2005).

Where a midwife is able to provide continuity of care through pregnancy, she also has the opportunity to engage with the people the woman has chosen to support her during labour, and explain to them the rationale for not automatically trying to take away pain in labour. This is particularly effective where midwives are able to visit the woman's home towards the end of pregnancy and make plans for the labour and birth, possibly sharing photographs of women in labour (Kemp 2003). This visit to the woman's home provides an ideal opportunity to talk about how being alongside the woman in pain might affect her supporters. The concept of decision-making about the place of birth during labour can be explored, with a clear message that it is safe to stay at home when labour is progressing well and where the midwife is well supported to provide this service by staff in a referral hospital.

Pain and the place of birth

Kitzinger (1991) has argued that the environment and relationships of those present at birth have a profound effect on the way a woman perceives and interprets pain. In a content analysis of letters describing 40 births at home and 40 births in hospital, she concluded that women giving birth at home feel more in control of the process and report less pain. This is in keeping with other studies that have concluded that women perceive home birth as less painful than hospital birth (Chamberlain et al 1997; Chamberlain et al 1993; Morse & Park 1988; Sandall et al 2001).

In making her decision about where to give birth, a woman often confronts her own beliefs and attitudes about the pain of labour. For some women, a hospital will be chosen because she expects that she will need pharmacological pain relief. This perception may reflect the attitudes and experiences of her family and friends who have also given birth in a hospital. Her choice may also be made because she is unaware of any alternatives to hospital birth.

Andrea Robertson (1996, p 20) sees pain as a biological tool to inform women when they are going into labour so that they can 'retire to a safe place while the process unfolds'. She decries the fact that 'of all the animal species on earth, human beings are the only ones who make their nests in one place, then trek elsewhere to give birth' (p 20) and suggests that this

disruption may explain the difficulties experienced during birth by Western women. Helman (1990, p 203) suggests that the rituals associated with hospitalisation cause the patient to enter 'a state of limbo characterized by a sense of vulnerability and danger'. Shizuko and colleagues (1977, p 8) see this state as induced by entering 'a highly politicized area . . . the home terrain of the staff . . . who make and enforce the basic rules which prevail'.

During the antenatal period, decisions about where to give birth allow for discussions about managing pain and the implications of a woman's choice. This midwife describes the importance of thinking ahead about the place of birth in this context:

> If they're opting to have their babies at home . . . they have made it very clear what their perception of managing pain is and that's enormously helpful. They have made a statement about where they're coming from and also indicated that they are resourceful and prepared to rise to the challenge in a way that often women who choose to have their babies in hospital don't (Vague 2003, p 61).

Midwives know that women who choose to birth at home have consciously addressed the issue of how they will manage the pain of labour. They have faith in the ability of their body to birth the baby and trust in their own inner strength to allow this to happen. Where a woman chooses to give birth at a birthing centre or in hospital, she can be encouraged to anticipate spending a significant part of her labour at home. In this familiar environment she is likely to be more relaxed and therefore more able to cope with pain.

The culture of hospital settings creates expectations that women should be offered what Leap (2000b) describes as 'the menu' of pain-relief options. This is particularly acute where women are making noise. There is an unspoken pressure on the midwife sometimes to suggest pain relief to a labouring woman in order to quieten her rather than because she is actually requesting it, as this midwife describes:

> If you're looking after a client in hospital, there's the expectation that you're a good midwife if you keep her quiet and have control. If a woman is making a lot of noise there's a perception that you're not being a good midwife if you are not taking that pain away and helping her to be nice and quiet and appearing to be managing the labour (Vague 2003, p 73).

Labour and birth support

Women have identified that the midwife plays a crucial role in supporting them during labour and birth (Lundgren & Dahlberg 1998). Halldorsdottir and Karlsdottir (1996) studied labour using the metaphor of a journey. Midwives were categorised by women as either 'an indispensable companion' or an 'unfortunate hindrance'. There appeared to be no middle ground in their eyes. Of particular importance was the midwife's ability to make herself emotionally available to address fear and anxiety. This involved being fully 'present' to the woman.

As identified earlier, continuous one-to-one support during labour by midwives and women supporters has been found to reduce the likelihood of analgesia and operative birth and to increase women's satisfaction with their childbirth experience (Hodnett 2003). Common elements of this care include emotional support, information about labour progress and advice regarding coping techniques, and comfort measures. In fact, continuous support has been viewed in itself as a form of pain relief, specifically as an alternative to epidural anaesthesia (Dickenson et al 2003) because of concerns about the deleterious effects of epidural anaesthesia on labour progress.

Support for labour and birth also comes from another important source—the woman's chosen support people. Often a woman's partner will be a vital source of comfort and encouragement and can augment the midwife's supportive role. Increasingly, women are inviting additional family members or friends to provide support at this time too. They can be very helpful, not only to the woman but also in supporting her partner. This midwife sounds a note of caution about expectations that men will always be capable of supporting a woman without back-up:

> Sometimes I think men have their needs and they override what their role is in terms of being there for that woman. Sometimes you are giving the epidural for the partner who's really unhappy and uncomfortable and feels very anxious about their loved one. I'm not talking about all men . . . some are just absolutely fantastic at being brilliant support and as effective as a strong form of pain relief. But I think men often do need to have support and that helps them put things in perspective a bit because the responsibility is not 100% theirs. I think that's where they crumble often and they see what women are doing in labour as a reflection on them as opposed to it just being a normal process (Vague 2004, p 23).

Whoever the woman chooses to be present to support her, she needs to feel comfortable and safe with them. They need to have had their roles clearly explained by the woman. Principally, their job is to focus on the woman and her needs, either physical or emotional. They need to take their cues from her behaviour. Sometimes they will need to just sit quietly because the woman has turned inward on her labour and needs no overt support. Their presence is sufficient, with their unspoken yet unwavering commitment to her and belief in her ability to cope with labour. At other times, they may need to be much more actively involved, with encouraging words, massage, soothing cold flannels for flushed face, cold drinks, assistance in changing position. This is not the time for them to relive their birth experience or to discuss the latest sports results, unless the woman seeks that form of distraction.

Other useful tasks that support people can perform include running baths and making cups of tea or getting light snacks for others, including the midwife. They can keep other family members and friends informed of progress and help care for a woman's other children if necessary.

Working with pain in labour

For any woman, the onset of labour can be a time of conflicting emotions. There is usually excitement that labour is here and that soon she will meet her baby, tinged with apprehension about what it will be like, how long it will last and whether she will be able to cope. Early elation can begin to fade as contractions become increasingly frequent and more demanding. Doubts can begin to crowd in. She may be tired after a lost night's sleep and a little frightened of this force that has taken over her body and gives no indication of stopping for an unknowable period stretching ahead of her.

The midwife can help by reminding her of the physiology of labour's first stage and reinforcing the notion that everything she is feeling is entirely normal and appropriate. Many women benefit from praise and the expression of quiet confidence that all is well. This 'midwifery muttering' (Leap & Anderson 2004) can have a steadying effect on women, particularly when they are doubting their ability to cope. Women can be encouraged to 'tune out' and concentrate on meeting each contraction and then seeing it off rather than interacting too much with their surroundings.

The way in which this midwife sees labour and birth in the context of a normal life event is evident in her words:

> I think [the first part of the labour] is often the most difficult part because they're very intellectually 'there'. They are having to mastermind and intellectualise the process and cope with it on that level. Once they get further up the track in their labour, then they go into 'dozy land' when the endorphins are released and I think it's an easier phase. They capitulate to the process, whereas at the beginning they are often intellectually trying to mastermind it. Once they capitulate and allow the process to go, then I think they usually deal with it a lot better. I often say 'You are not alone. There will be hundreds of women out in the world doing exactly what you are doing right now. This is a really big journey in your life but it is a journey women have made since time began' (Vague 2003, p 74).

A woman who has previously had a straightforward labour is usually more confident because she has an idea of what lies ahead and believes in her body's ability to birth. Generally, successive labours are shorter than the first and that fact, combined with the knowledge that she has already negotiated a birth, adds to a woman's resolve when her next labour starts.

If the previous labour and birth were not a good experience, however, the woman may be harbouring many fears and traumatic memories. These feelings may not have been addressed prior to labour and may cause a woman's perception of pain to be considerably heightened. Clearly this presents a challenge to a midwife. In an ideal situation, the midwife would have already met the woman antenatally and have had a chance to build a relationship of trust. There would have been an opportunity to review her previous labour and possibly obtain her maternity records in order to gain a clear picture of what happened, in order to construct a birth plan that reflected the woman's wishes for a safer and more satisfying outcome in this labour.

Reflective exercise

Consider the following questions in relation to your own practice.

1. How do I discuss labour pain with pregnant women and their families?
2. What messages might I be giving about the advantages of coping with pain in labour and their ability to cope?
3. Am I clear about the evidence regarding the potential unwanted side-effects of pharmacological pain relief?
4. How do I respond when women in complicated labour plead for an epidural?
5. How do I explore women's experiences of pain in labour in order to inform my practice?

The midwife in this story describes such an occasion:

> I had a lady who'd had a very bad experience with her first birth—very, very frightened. I spent a lot of time with her antenatally talking through [her labour experience] . . . When she arrived in labour this time . . . she was still frightened. She started to say that she needed an epidural. I said 'No, you're just saying that because that's where you were last time when you had the epidural. You don't need one. Just trust me. You're fine. Your body is doing it, you're just great. Don't fret, just relax'. And about an hour later, she delivered. She was totally rapt. It's so exciting to see women do that (Vague 2003, p 96).

The force of this midwife's belief that everything was progressing well and that the woman could do it resonates through this story. These feelings were just as strongly felt by the woman because, despite her fears, she was able to place her trust in the midwife and her skilled support.

Conclusion

Midwives have an important role to play in fostering women's belief that they will be able to cope with the pain of normal labour, and this has important consequences for women in terms of empowerment. Where women choose pharmacological pain relief, or if an epidural is necessary due to complications, the way in which the midwife engages with the woman around her experience of labour is equally important. It seems that the experience of being in pain in labour—particularly the kind and unkind things that people say—is never forgotten (Leap & Hunter 1993; Simkin 1999).

Review questions

1. Describe in your own words what you understand as the 'components of labour pain'.
2. Describe ten ways in which you would assist a woman to 'cope' with labour pain.
3. Much has been written about pain in labour. Can you describe some of the different accounts of labour pain?
4. How would you explain the concept that 'pain in labour keeps you safe'?
5. How would you explain the way you observe pain in labour in order to help you understand the progress a woman is making?
6. What are endorphins?
7. What research is there on the effect of the place of birth on pain in labour?
8. Give five examples of the way in which pain in labour has been interpreted historically.
9. Can you describe a way of perceiving pain in labour that is based on a different cultural expectation of pain in labour?
10. What physiological pathways are implicated in pain in labour? How do these differ from those involved in post-surgical pain?

Notes

1 'Families' is used in this chapter in a similar way to the New Zealand concept of 'whanau' to mean the network of significant people to whom the woman turns for support during her experience of pregnancy, birth and new motherhood.

2 See, for example, Mander (1998), Moore (1997) and Yerby (2000).

CHAPTER 24

Using water for labour and birth

Robyn Maude and Shea Caplice

Key terms

anxiety, continuity of caregiver, pain perception, partnership, physiological birth, relaxing effect, water immersion

Chapter overview

This chapter provides an overview of the use of water immersion for labour and birth. It tracks the history and development of the use of water immersion for labour and birth over the past two decades, reviews some of the most recent literature that informs practice, and explores the physiology, potential problems and issues related to practice. We have included women's perspectives on their experiences of using water for labour and birth, and provided recommendations for the safe use of water immersion in labour and water birth.

The key principles of a midwifery model of care that underpin this chapter are that:

- pregnancy and childbirth is a normal life event for most women
- midwifery care is woman-centred
- continuity of care should be provided throughout the entire childbearing experience
- the woman–midwife relationship is a partnership based on:
  - trust, reciprocity and respect for the expertise of both the woman and the midwife
  - the woman's personal knowledge of her health history being considered as important as that of the midwife's
  - both partners having equal status and shared meaning through mutual understanding
  - the sharing of knowledge and power between the partners.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe some of the history of using water for labour and birth
2. To integrate the literature that informs safe evidence-based care for women using water for labour and birth
3. To describe the principles and guidelines for using water for labour and birth
4. To support the use of water for labour and birth as a means of enabling midwives to be 'with women' and supporting physiological birth.

Introduction

Since the early 1980s, when water immersion during labour and birth was used predominantly by women birthing at home, many questions have been asked about efficacy and safety for both the woman and the baby. Globally, women, midwives, doctors and researchers have attempted to answer these questions, and the inquiry continues. The use of water immersion in labour and the phenomenon of water birthing are closely associated with the act of physiological birth, which is widely supported by women and midwives in many countries. However, controversy between professionals has surrounded its use, with much debate over the perceived benefits and potential risks.

The role of water birth in supporting physiological birth

As midwives, we are increasingly searching for the best available evidence to challenge and change many of the practices in obstetrics that are 'routine' and/or based on the risk management processes of institutions and some maternity care providers. Midwives recognise that practice wisdom comes from many sources and use evidence from scientific inquiry and the shared stories that have informed our practice over time. We need to validate the advice we give to women by exploring and sharing the research findings and practice wisdom in order to facilitate the woman and her family making informed decisions about their care, based on this information. Women are entitled to receive thorough, unbiased information about choices for care, place of birth and caregiver, so that they can make informed decisions about their care.

Women know that they should avoid drugs and harmful substances during their pregnancies, yet the protocols for active management of labour subject them to a range of drugs and practices that often start a cascade of intervention, resulting in operative delivery. Wagner (cited in Hall & Holloway 1998, p 31) suggests that 'Many midwives and the women in their care are becoming advocates of more natural forms of childbirth and demand care that is sensitive to the psychological needs of the individual and her family'.

The option to use water is one way of supporting women in labour without drugs, along with continuity of caregiver and the availability of private and peaceful surroundings in which to labour and birth. The demand for water immersion in labour and water birth has grown rapidly throughout the world over the past two and a half decades. Hall and Holloway (1998) suggest that this may be one reaction against medical control of childbirth. This is supported by Kitzinger (1996), who says that the use of warm water also seeks to change the dynamics of the care of labouring and birthing women, to give control back to them. She says warm water immersion and water birth are not just another 'trendy' technique but rather an approach to childbirth that enables the birthing woman to have autonomy, by changing the environment and the quality of interactions between all those involved in the care.

Clinical point

Avoiding pharmacological pain relief

Increasingly, women want to find ways to manage the pain of labour naturally, thereby reducing the likelihood of requiring pharmacological pain relief, but are unsure about their ability to go through a labour without some help, especially women having their first baby. 'I didn't want to use drugs if I could help it but then I'm such a "wuss" when it comes to pain' (Linda, in Maude 2003).

Women and midwives have come to see water immersion as a means of achieving this. These women are encouraged to use other methods to promote comfort and support until labour is established and they are able to get into the pool. Being with the woman, supporting and encouraging her through the sometimes difficult transition phase and honouring her choices has meant that many nulliparous women are able to birth in the pool without interventions.

The history of water birth

The first documented birth in water was reported in a French medical journal in 1805, when a woman, exhausted after a 48-hour labour, climbed into a warm bath to relax, giving birth to her child into the water shortly afterwards (Church 1989, cited in Richmond 2003a). In the following 150 years, the subject of water birth was rarely broached in the medical literature. Igor Tjarkovsky, the Russian water birth enthusiast, generated much interest in this method of birth in the 1960s, both within his own country and around the world, through claims that birth in water improved the psychic abilities of the baby (Zimmerman 1993, cited in Richmond 2003a). There are no data, however, to support this theory.

In 1975, Leboyer's book, *Birth Without Violence*, described the use of water as a healing therapy for babies. His work was based on the idea that birth has a profound effect on the future development of the baby, and stressed the need for peace, quiet and gentleness at the time of birth. Leboyer proposed the use of water immediately after birth as a gentle introduction for the baby, minimising harsh stimuli such as light and sound.

In France in the 1970s, Dr Michel Odent observed that women were attracted to the use of the shower or bath when in labour. As with most practitioners new to water birth, Odent's initial experience was with a woman so completely relaxed in the bath that the baby was born before she was able to get out (Lichy & Herzberg 1993). After that first experience

Odent began to offer water birth to all women who had long labours. In 1983, Odent published in *The Lancet* the summary of the outcomes of 100 water births at his alternative-birthing unit in Pithiviers, France. Odent's article was one of the first major medical publications dealing with birth in water. While Tjarkovsky was concerned with the baby and its development, Dr Odent was more concerned with the labouring woman.

Following on from the work of Tjarkovsky, Leboyer and Odent, the practice of labouring and birthing in water gathered momentum in the 1980s within the home birth community and the practice of domiciliary midwives. With the emergence of a spiritual movement that supported the notion of the dolphin and human connection and rebirthing, there was an increased demand for 'water babies' (Sidenbladh 1983). Inspired by enthusiastic women and midwives, labouring and birthing in water spread into birth centres and hospital maternity units in the 1990s. Its growing popularity is largely attributable to the women and families who have experienced the benefits of birthing this way.

The first water births in New Zealand and Australia

The first of the modern water births in New Zealand, believed to be the first in the southern hemisphere, occurred at Estelle Myer's Rainbow Dolphin Centre in Tutukaka in the north of the North Island on 17 March 1982. The baby's mother had read an article on water birth and the underwater birth experiments of Igor Tjarkovsky. She drove her house bus and three children to Tutukaka, intent on birthing in water. Estelle, friends, a midwife and a nurse attended the woman during her birth. The baby, weighing 3.6 kg, was born in the bath, in a posterior position (her second persistently posterior baby) after two and a half hours of labour. Similarly, a few years later in 1985, Estelle supported a Russian woman who birthed her son into water in Sydney. There were six midwives present to observe this new practice, and hence the water birth movement in Australia was born.

Copyright David Hancock

In New Zealand, to date there are no national data available as to water birth rates and how women use pools and baths during labour and birth. Individual practice or facility audits report a 65–75% rate of pool use in labour (Banks 1998; Cassie 2002) and a 25–38% water birth rate (Banks 1998; Fenton 2004). In New Zealand, Wanganui Hospital's maternity unit led the country by openly using water immersion for birth. The first documented water birth at Wanganui occurred in November 1989. Between July 1991 and December 2000 there were 916 water births in the maternity unit (Young 2001).

Similarly, there is generally a lack of published data in Australia regarding the use of water for labour and birth, which is not indicative of its widespread usage. Labouring in water and births in water have been occurring at planned home births attended by home birth midwives since the early 1980s (Lecky-Thompson 1989) and within hospital-based birth centres in Sydney and Melbourne since the early 1990s (Caplice 1999; Page 1994). Currently the hospital facility audits report a water birth rate of 35–44% of total births at the Royal Hospital for Women in Sydney, which represents a steady increase since the inception of the practice in 1992. In addition, Australian independent midwives report a water birth rate of around 60–80% of total births (Caplice 2004).

Clinical point

The first water births in Indigenous Australia and New Zealand

There is little early documented evidence of the practice of water birthing among the Indigenous women of Australia, although Odent (1990) says that some Aboriginal women on the western coast of Australia first paddled in the sea, then gave birth on the beach. There are stories of traditional birthing practices among the Maori of New Zealand where water was used. It was common for babies to be born on beaches in the Te Kaha area (Binney & Chapman 1986; Irwin & Ramsden 1995) and Makereti records the use of water to facilitate birth of the whenua (placenta) when it was delayed (Makereti 1986).

Using water for labour and birth: the evidence

A review of the literature reveals research documenting the history and development of the use of water for labour and birth, and also a progression of thinking and sophistication, based on the outcomes of the research. When looking at the research into the use of water for labour and birth, it is important to understand the methodology and methods used in the research. This is because research is weighted according to the traditional hierarchy of evidence. The hierarchy of evidence is a standard notation for the relative weight carried by different types of study when decisions are made about the effectiveness of clinical interventions. The randomised controlled trial (RCT) is considered the 'gold standard' and represents the only true means of evaluating the effectiveness of an intervention (in this case, water immersion) in improving outcomes such as operative delivery or exogenous pain relief.

Qualitative studies using techniques such as a grounded theory approach, phenomenology or narrative inquiry are not placed high in the traditional hierarchy of evidence. There are important and valid studies of the use of water for labour and birth that use qualitative methodologies that should be considered alongside the studies employing quantitative methodologies. It should be understood that quantitative designs attempt to answer questions as to 'what works', which is a result that can be measured. Qualitative designs ask 'What is going on?', 'How does it work?', 'How can we understand the factors that affect people?' and 'How do individuals feel and behave the way they do?'.

The Cochrane Database of Systematic Reviews (February 2004) updated reports on eight trials (2939 women) examining the effects of water immersion during labour. The only trial that researched birth in water was too small to determine outcomes for women and babies, and so was not included. Nor were any studies of the third stage of labour in water. The reviewers concluded that there was a statistically significant reduction in women's pain perception, and that the rate of epidural analgesia is reduced, which suggests that water immersion during the first stage of labour is beneficial to some women (Cluett et al 2004a).

There was no evidence that the benefits were associated with adverse outcomes for babies or longer labours. To date there is insufficient evidence about the use of water immersion during second stage to enable the formation of firm conclusions about the safety and effectiveness of giving birth in water. Water immersion during the first stage of labour can be supported for low-risk women (Cluett et al 2004a).

To date there are no significant or multicentred RCTs comparing birth in water with land birth, even though numerous authors have called for such rigorous testing. A commonly held belief has been that the ethical considerations of an RCT for water birth make the prospect of such a study unlikely (Woodward & Kelly 2004). However, a recent pilot study conducted by Woodward and Kelly (2004) to assess the feasibility of an RCT and the willingness of women to participate in such a trial has produced some positive results. The study proves that women are willing to enrol in an RCT comparing water birth with land birth and that randomisation does not necessarily affect women's satisfaction with their birth experience. This research paves the way for the organisation of a multicentred RCT to evaluate the differences between land and water births with large enough numbers to produce statistical significance.

In the meantime, however, there is some good-quality descriptive research that gives us information to consider. This review will attempt to provide an overview of the current debates about birthing in water. Most of the studies reviewed refer to the use of water immersion in labour rather than water immersion during birth, unless otherwise specified.

Physiological effects

The calming and relaxing effect that water immersion has during labour and birth is well recognised. How this helps women to birth without exogenous pain relief and other forms of interventions was first described by Odent (1983). Church (1989) also proposed that water immersion decreases anxiety in the woman and that this works to reduce adrenaline levels, thereby encouraging the uninhibited flow of natural oxytocins and endorphins. A natural balance of pain and relaxation is achieved, and labour progresses normally.

Much of the research to date has attempted to quantify the absolute effect of pain relief afforded to the woman by water immersion during labour and birth. Women in trials have been asked to rank their level of pain using a visual analogue scale. The prospective RCT by Cammu and colleagues (1994) found no statistical difference between the absolute values of labour pain between the two groups of women in their trial. They reported that bathing provided no objective pain relief, but did have a temporal pain stabilising effect, possibly mediated through the improved ability to relax in between contractions. This was supported in the historical cohort study by Aird and colleagues (1997), who found that labouring in water allowed greater relaxation of the mother during the first stage of labour, thereby allowing her to reach the second stage better prepared to give birth without assistance. The pain relief effect of warm water immersion is probably associated with a reduced level of endorphins and catecholamines, as 'there is a tendency to fall asleep in a comfortable tub' (Odent 1997, p 415). The explanation for this effect is related to the 'soothing warmth', 'support of the body' and 'pleasurable sensation' of water, the effect of which stimulates the closing of the gate for pain at the level of the dorsal horn, and supports the notion that water provides women with a temporal stabilising effect (Cammu et al 1994).

The hydrothermic effect relates to the conduction of heat from the warm water through the skin, leading to peripheral vasodilation. The resultant release of muscle spasm contributes to the reduction in pain (Brown, cited in Richmond 2003a). The hydrokinetic effect refers to the feeling of weightlessness often described by women (Deschennes 1990). The combined

Clinical point

Women's perceptions of pain

Women's stories of their experiences of using water for labour and birth indicate that they do not necessarily use water to take the pain of labour away. Instead they see water immersion as helping them to cope with pain, and to reduce their fear of pain and of childbirth itself (Maude 2003). A woman in water may remain fearful and scared, but is presented with the opportunity to relax in between contractions to the extent that her labour may progress more rapidly. Relaxation enables women who use water to focus internally on what is happening to them, their body and their baby.

Clinical point

Relaxation and the effects of water immersion

Labouring in water may allow greater relaxation of the mother during the first stage of labour, allowing her to reach the second stage better prepared to deliver the fetus by her own. 'I almost fell asleep in between [contractions]. I just let my head loll on the side. I would just lie it against the side of the bath and I'd just about . . . go to sleep. I was so relaxed in between, it was really nice and it was nice to keep warm' (Marion, in Maude 2003). Odent (1983) claims to have observed that water seems to help labouring women reach a certain state of consciousness where they become indifferent to what is going on around them. Odent continues to explore the biochemical and physiological effects of warm water immersion and concludes that, 'when a parturient enters a bath at body temperature, there is immediate pain relief. This pain relief is probably associated with a reduced level of endorphins and catecholamines' (Odent 1997).

effect of warmth and weightlessness contributes to women feeling more relaxed and less anxious (Ginesi & Neiscierowicz 1998). The vasodilation of the peripheral blood vessels and the redistribution of blood flow when women are immersed in warm water during labour have been observed to contribute to a reduction in blood pressure (Church 1989; Nightingale 1994). A common concern has been that vasodilation and relaxation of uterine muscles might lead to an increased possibility of postpartum haemorrhage. However, numerous audits in units that use immersion in water for labour and birth do not support this (Caplice 2004; Garland 1994; Rosenthal 1991). It would seem that the natural processes already in place in the body are sufficient to counteract this theoretical problem (Richmond 2003a).

What women say about water immersion

Reviewing the qualitative research on birthing in water revealed strong themes, including the following:

- Women feel more in control. Water reduces their anxiety about pain and about the process of childbirth itself.
- Women use water to cope with pain, not necessarily to remove or diminish it.
- Women feel more relaxed and the water promotes their comfort.
- Women feel sheltered and protected in the water, which promotes privacy.
- Women are able to move around more easily and feel supported by the water (Hall & Holloway 1998; Maude 2003; Richmond 2003b).

Stories of women's experiences of using water for labour and birth have broadened our understanding of the meaning they make of the experience, and have demonstrated that the efficacy of water immersion goes beyond measurable outcomes. Being in water during labour and birth is not the end product; it is not the water itself that makes a difference. It is a shared philosophy and a shared belief in birth as a normal life event that supports women to use water. It is also the planning, preparation, education and anticipation of using water for labour and birth, supported by safe and judicious use, that creates an environment that promotes relaxation, privacy and a release that enables and empowers women to maintain control. It appears that it is not necessary for women to actually give birth in the water to achieve these benefits (Maude 2003).

Safety and efficacy of using water

Water immersion during labour and water birth is widely practised globally by practitioners who employ a holistic approach to birth and support women to birth physiologically. While most health professionals involved in the care of women during pregnancy and birth now agree that there is adequate evidence to support labouring in water, there continues to be tension between health professionals concerning its safety, particularly birth under water. This section examines the literature relating to some of these issues.

Water temperature

The temperature of water used in labour and for birth has caused concern in relation to fetal outcomes. In the late 1980s, this concern focused on the potential dangers of temperatures below 37°C, with a suggestion that low temperatures may stimulate the baby to breathe (Gradert et al 1987; Lecky-Thompson 1989; Lenstrup et al 1987). Subsequently, attendants erred on the side of caution, maintaining pool temperatures at levels around 37–38°C. However, in 1994, maternal hyperthermia became an issue when two babies were born with perinatal asphyxia after the mothers were immersed in water for some hours during labour, as it was thought that

the temperature of the water had been a contributing factor (Rosser 1994). This assumption was never proved.

Johnson (1996) explains that, as the baseline fetal temperature is normally 0.5–1°C above maternal temperature, the fetus is placed at risk when the mother experiences hyperthermia. The fetal oxygen demands increase, making the baby susceptible to fetal distress. In response to this information, guidelines have been set to reduce the risk of birth asphyxia in water: the recommended temperature of the water is no higher than 37.5°C, which is normal body temperature (Deans & Steer 1995; Duley 2001; Richmond 2003a). In contrast, in a paper on fetal hyperthermia, Charles (1998) explains that a maternal temperature rise of up to 1°C may be beneficial to the baby as there is an increase in oxygen transfer across the placenta; however, this research does not define temperature thresholds that might be considered too hot.

Geissbuehler and colleagues (2002) measured maternal and neonatal temperatures of women who birthed in water and compared them with those of women and babies who birthed on land. The authors concluded that birth in water did not pose a thermal risk to either mother or baby. Furthermore, they assumed that women self-regulate their body temperature according to changes in the water temperature and that this mechanism of self-regulation of core body temperature would be far superior to any water temperature guideline. There is no reason for practitioners to adhere to protocols that recommend keeping the water at a set temperature, other than the mother's physical comfort. More recently, in support of Geissbuehler's proposition, Tricia Anderson (2004) suggests that practitioners give up their obsession with the temperature of the water and instead focus on ensuring that the woman has control over her environment and on facilitating her comfort. It would seem therefore more appropriate to check the woman's temperature before she enters the pool and during the time that she is in the pool, while regularly checking with her about the temperature of the water. It is useful to also have supplies of cool water or ice chips and access to a fan.

Immersion and duration of labour

Studies investigating a reduction in the duration of labour in relation to water immersion have been inconclusive. In 1994, Garland and Jones analysed data from 209 primiparous women and 220 multiparous women and demonstrated a median and mean reduction in labour length, but since then other studies have been unable to replicate these findings. Schorn and colleagues' (1993) prospective RCT of the use of warm water immersion by 93 women could not demonstrate a shortening of labour; however, the immersion was only for an average of 30–45 minutes. Other retrospective comparative studies show small decreases in length of labour. More recently, Cluett and colleagues (2004b), in their RCT comparing water immersion with standard management for labour dystocia, reported water immersion as being of benefit, but the mean duration of labour was similar in both groups.

Use of analgesia in labour

Being immersed in water does not necessarily take the pain away. What it does appear to do, and this is supported in the literature, is provide a release from the pain in the form of warming, soothing, comforting and relaxing. For women who want to avoid pharmacological pain relief and for midwives who support these women, judicious use of water immersion may offer the means to achieve this. One historical cohort study of the effects of immersion in warm water during labour found that the requirement for both pethidine and epidural analgesia was significantly reduced among women having their first baby (Aird et al 1997). The Cochrane Review (Cluett et al 2004a) reports that there is evidence that water immersion during the first stage of labour reduces the use of analgesia and reported maternal pain, without adverse outcomes on labour duration, operative delivery or neonatal outcomes.

Most maternity care providers and facilities accept that the use of water immersion during labour significantly reduces pain. However, recent research suggests that the role of the birthing pool may be even more important than care providers realise. Cluett and colleagues (2004b), from Southampton Hospital in England, have discovered that women with labour dystocia who use water immersion during the first stage of labour are less likely to need analgesia or an operative delivery. The research compared women who used water immersion during labour with those who had standard augmentation for dystocia and demonstrated that the women who used the birthing pool had significantly fewer epidurals, needed less assistance with giving birth and had fewer obstetric interventions.

The women in a study by Taha (2000) also reported less pain when using water immersion in labour. Two qualitative

Copyright David Hancock

studies on women's experiences of water immersion report that in addition to the pain-relieving effects of water, the therapeutic qualities of water helped the women to cope better with the pain of labour and birth (Maude 2003; Richmond 2003b).

Perineal trauma

The findings regarding perineal trauma associated with birth in water consistently show a higher intact rate in the water birth group and a higher rate of sustained perineal trauma in the land birth group (Aird 1997; Burke & Kilfoyle 1995; Geissbuehler & Eberhard 2000). The most startling evidence is the reduction in episiotomy rates, demonstrating the protective aspect of water birth against intervention. In Geissbuehler and Eberhard's (2000) study, the episiotomy rate in the water birth group was 12.8% compared with 35.4% in the land birth group. One could argue, however, that there is no place for episiotomy in the practice of water birth, because if you are performing an episiotomy out of concern for the condition of the baby then you should not be continuing with a birth in water!

Risk of infection

The theoretical risk of infection to either the woman or her baby has often been put forward as an argument against the use of water for labour and birth, particularly for women with ruptured membranes. Waldenstrom and Nilsson (1992) conducted a non-randomised controlled study at the Stockholm Birth Centre comparing women who used the bath after ruptured membranes with women who had ruptured membranes but did not use the bath. The authors concluded there was no statistically significant difference between the groups with regard to infection, infant respiratory problems or symptoms of amnionitis in the mother. More recently, Robertson and colleagues (1998) conducted a medical review that examined the association between the use of water immersion in labour and the development of chorioamnionitis and endometritis, and found no significant association. Similarly, Geissbuhler and Eberhard (2000) analysed 7508 births and reported no statistically significant difference in infection rates between infants born in water and those born on land.

Michel Odent (2001) discussed bacteriological colonisation of babies at birth. He explained the concept of the 'race to the surface' used by bacteriologists, meaning that the first bacteria to reach a bacteria-free surface will be the likely rulers of the territory. Babies are born sharing the immunoglobulin G (IgG) antibodies of their mothers and therefore it is beneficial for a baby to be colonised by the mother's bacteria. From a microbiological perspective, it would seem that birth in water is a positive action, in line with skin-to-skin contact. It is when babies come in contact with unfamiliar bacteria from caregivers and hospitals that the bacteria they are colonised by become potentially dangerous. This theory supports the idea that caregivers should stay out of the water unless absolutely necessary, but partners and siblings should not be discouraged, as they are likely to have similar bacterial colonisations to those of the mother.

The literature indicates that if pools/baths are adequately cleaned, there is no increase in neonatal or maternal infection (Global Maternal/Child Health 2000, cited in Harper 2000). Infection risks to babies appear to be caused primarily by gram-negative organisms that colonise pump systems of spa baths and filling and draining hoses, and by inadequate bath-cleaning procedures (Vochem et al 2001).

The issue of blood-borne viruses such as HIV and hepatitis B and C was discussed at the First International Waterbirth Conference in London in 1995. It was concluded that the water diluted such viruses to the point where they became impotent and posed much less of a threat than the blood splashes that may occur in a land birth (Beech 1996). In researching the risk of work-related HIV exposure or infection to midwives attending water births, Colombo and colleagues (2000) took pool water samples from 14 different water births and measured the haemoglobin content to estimate the viral load the liquid would be carrying. The authors concluded that because of the diluting effect of the water, the potential risk for HIV-exposure to intact skin was minimal and unlikely to have consequences. However, in their opinion, the risk of nosocomial hepatitis B infection is significantly higher, and they recommend wearing gauntlet gloves and ensuring that all healthcare workers are vaccinated.

Third stage and blood loss

There have been no documented cases of complications in relation to the third stage being conducted in the bath. In 1983, Odent proposed a theory that water embolism could be a risk factor. This has now been largely dismissed, and Odent himself has withdrawn the hypothesis, admitting that it was unfounded and a mythical concept.

Richmond (2003a) hypothesises that there is an increased potential for postpartum haemorrhage associated with water birth. Her rationale for this is based on the hyperaemia induced by warm water and the relaxing effect it has on uterine muscles. However, in the many audits in units practising water birth this has not proved to be a problem (Caplice 2004; Garland 2002; Garland & Jones 1997).

Effects on the baby

Johnson (1996) describes in depth the physiology of fetal breathing in utero and the main factors that inhibit breathing in the newborn until she or he is lifted into air. Fetal breaths in utero are intermittent isometric movements with very little inspiration of amniotic fluid. Approximately 24–48 hours prior to birth, in response to the increase in prostaglandin E_2 levels from the placenta, the fetal breathing movements slow down or cease. This decrease in fetal breathing movements allows more blood flow to the vital organs, including the brain. At birth, when the prostaglandin level is still high, the baby's breathing response is still slow—this is the first inhibitory response.

A second inhibitory response is related to acute hypoxia in the newborn. Babies are born experiencing a lack of oxygen

in response to the birth process. This normal inhibition of breathing may be overridden if the baby becomes compromised in utero. Acute hypoxia causes apnoea and swallowing, but if severe and prolonged, it will cause breathing and gasping (Fewell & Johnson 1983).

Another important inhibitory component is the 'dive reflex'. Central to the physiology of the dive reflex is the larynx, which is covered with chemoreceptors (like taste buds). With application of foreign stimuli such as water to the larynx, these chemoreceptors initiate the closure of the glottis so that the water is swallowed and not inhaled (Harding et al 1978). Johnson (1996) reports that while substances such as water, non-species milks, isotonic alkalis and ammonia initiate the full diving response, physiological saline, amniotic fluid, lung and gastric fluids, urine, blood, meconium and milk from the same species at body temperature illicit little response when instilled to the larynx.

The last main factor thought to inhibit the newborn from initiating a breathing response while in water is environmental temperature. Johnson (1996) reports that the fetus is co-dependent on maternal temperature control and with the fetal core temperature 0.5–1°C above the mother's, there are important implications for practice. Maternal hyperthermia and the resultant hyperthermia in the fetus may override the inhibition to breathe. Therefore it is advisable that strategies be put in place to avoid maternal hyperthermia or overheating. However, the issue of keeping the water at maternal body temperature and no less in order to maintain the inhibitory effect needs to be reconsidered in light of births taking place in oceans, where the babies are reported to be born with no adverse effects (Harper 2002).

Perinatal mortality and morbidity/adverse outcomes

In England and Wales, an extensive survey was conducted of the extent to which women were labouring or giving birth in water. In addition, the survey assessed the problems reported following births in water (Alderdice et al 1995). Of the 4834 births in water from 1992 to 1993 it was reported that there were six stillbirths/neonatal deaths, none of which could be attributed to the use of water. The estimated mortality rate was 1.24 per 1000 live births. Women giving birth in water are generally perceived as low risk, and therefore this figure needs to be viewed accordingly.

In 1999, Gilbert and Tookey compared the perinatal morbidity and mortality rates for babies born in water with those for babies born on land in the British Isles, England and Wales. The key message from this study was that perinatal mortality and risk of admission to special-care baby units is similar for babies delivered in water and for low-risk deliveries that do not take place in water (Gilbert & Tookey 1999).

Polycythaemia

In 1997, an isolated case of neonatal polycythaemia following a birth in water was reported in *The Lancet*. The labour and birth were uneventful and the mother remained in the water for 30 minutes following the birth. There was a delay in clamping and cutting of the cord for a further 10 minutes. At two days of age, the baby was diagnosed as severely polycythaemic and an exchange transfusion was performed. The baby developed normally and the interpretation was that the warm water prevented the normal vasoconstriction of the cord when exposed to air (Austin et al 1997). As an isolated case, the implications for practice are minimal.

Cord snapping

Gilbert and Tookey's (1999) surveillance study and postal survey of perinatal mortality and morbidity among babies born in water identified that delivery in water may have contributed to snapped umbilical cords in five babies (out of a total of 4032 births in water). One of the five babies required a blood transfusion. The snapped cords were probably the result of cord traction when bringing the baby to the surface rapidly.

Cro and Preston (2002) report on an audit conducted following an instance of cord snapping at a water birth. They identified four cases of snapped umbilical cord out of 100 water births between September 1996 and March 2001. In three instances the cord was noted to have snapped while bringing the baby to the surface, and the ends were immediately clamped with no adverse effects for the babies. In the fourth case, the snapped cord was discovered when it was noted that the baby was becoming paler and making reduced respiratory effort. A lot of blood was noted in the water. The baby required a blood transfusion and was discharged from hospital after three days. Follow-up at eight weeks found the baby to be developing normally.

There is no way of knowing how many umbilical cords snap during birth under water, nor indeed is there any research on cord snapping during birth in air. Some authors have suggested lowering the level of the water just prior to second stage; however, this is not thought to be wise as it decreases the advantages of water immersion (comfort, buoyancy, hydrostatic pressure and freedom of movement). The baby's being born completely under water can only be assured when the water is high enough to ensure the woman's comfort (at the level of the breasts while sitting). Midwives supporting women who birth in water should be aware of and prepared for this rare event. It is recommended that the baby be brought to the surface slowly, to avoid undue traction on the cord. The midwife is advised to check the cord as soon as possible after birth.

Neonatal resuscitation

An RCT in Australia comparing outcomes of women who used water immersion during the first stage with those who did not concluded primarily that there was no reduction in the use of pharmacological pain relief for the water immersion group. The secondary finding was that the babies in the water immersion group required more resuscitation than those in the control group, which is an unexpected finding, particularly when the trial did not include any actual births in water

(Eckert et al 2001). This publication caused some clinicians and services to rethink the practice of water immersion in labour. The flaws in the research, however, limit its reliability and clinical applicability. The short time that some women spent in the bath (times varied from 5 to 360 minutes) causes the reader to question the commitment of the midwives to the practice of immersion in water. It is unrealistic to believe that five minutes in the bath would have any analgesic effect or significant effects on the baby.

The large number of women who 'crossed over' from their allocated group is a concern. This high crossover level may have directed the groups to have similar outcomes because the intervention essentially became the same. Furthermore, it is difficult to see how some of the outcomes could be convincingly linked to the intervention—being allocated to a room with a bath.

Another concern with this study identified by Homer (2004) is the choice of analysis and the conclusions reported. In spite of stating at the outset that the neonatal outcomes studied would be clinical and laboratory signs of infection, antibiotic use, and nursery care, the authors use resuscitation at birth as a significant outcome. Resuscitation at birth is considered a 'soft' outcome that is directly related to the experience of the attending clinicians and their individual assessment of the baby's condition. In addition, the type of resuscitation used in the study was described as waving oxygen around the baby's face, a practice that one could argue might be directly related to practitioner anxiety with regard to the use of water immersion.

Potential near-drowning

More recently, Nguyen and colleagues (2002) reported, in *Pediatrics*, four cases of babies admitted to the neonatal unit following birth in water at other hospitals and at home. These babies presented to hospital with moderate to severe respiratory distress and were reported to have water aspiration and subsequent pulmonary oedema. With clinical support, all the babies improved over a 24-hour period. This article highlights a concern about potential near-drowning associated with birth in water, and the authors call for all water births to be prospectively audited.

Similarly, Bowden and colleagues (2002) report, in *Pediatrics*, on four admissions to a neonatal intensive care unit after birth in water. The first case was suspected to have water inhalation; however, his discharge diagnosis was respiratory distress syndrome. The second baby developed seizures at eight hours of age and his discharge diagnosis was probable water intoxication after birth in water. The third baby had a congenital abnormality diagnosed on day two. The fourth baby was admitted at four days of age with Group B streptococcal meningitis not directly attributable to birth in water.

In response to the concerns raised by their paediatric colleagues regarding the effects of birth in water on the neonate, Pinette and colleagues (2004) conducted a retrospective review of the literature regarding possible complications associated with birth in water. They identified 16 citations that reported on complications with neonates that could be attributed to birth in water. The possible complications included freshwater drowning, neonatal hyponatraemia, hypoxic ischaemic encephalopathy, and death. The authors, however, state that the rates of these complications are likely to be low.

Clinical point

Key messages from research

- Women are highly satisfied with using water for labour and birth.
- Women feel more in control of the process of birth, which ultimately leads to a more positive experience.
- Outcomes and risks are similar for low-risk women who labour and birth in water, and those who labour and birth in air.
- There is a need to continue to audit the practice in combination with comments on experiences from women and midwives. Research into the effects on the baby of birth underwater is recommended.
- Research evidence should continue to inform practice.

Conclusions about adverse outcomes need to be considered in relation to the small sample sizes of all the trials reviewed. Women contemplating birth in water need to know the possibility of adverse effects on the baby, in order to make an informed decision. However, because of insufficient data, the evidence for attributable risk associated with water birth is unclear. The literature informs us that there are occasional poor outcomes that may be associated with birth in water.

There is a continuing call to research birth in water and to monitor the outcomes for both mother and baby. All maternity facilities, birthing units and independent practitioners offering water immersion and birth should be collecting prospective outcome data. In light of Woodward and Kelly's (2004) pilot study, it seems that a multi-centred RCT comparing birth in water with birth on land is now more feasible.

Using water for labour and birth: the practice

Women and midwives have used water for labour and birth, at home births, for decades. At home, women use their domestic bath, portable birth pools and sometimes inflatable paddling pools bought especially for the purpose. Women birthing at home actively seek to avoid any intervention into their birth process and are largely very well informed and knowledgeable about the benefits of using water for labour and birth. Home birth midwives have explored, with women, the means of birthing physiologically. The use of water is one method used to achieve this. To this end, home birth midwives generally have become knowledgeable and experienced in water immersion and water birth.

Globally, and not just at home births, there has been an increase in the number of women seeking to use water for labour and birth. In response to the increasing demand from women and midwives it has become more common to find water-immersion facilities in maternity units at all levels. This is an attempt by institutions to provide a home-like environment that supports a more holistic approach to birth. Hodnett 2000 has found that women who were allocated to care in home-like settings were less likely to use pharmacological pain relief measures during labour, less likely to have labour augmented with oxytocin, less likely to be immobile during labour, less likely to have fetal heart abnormalities, and were happier with their care, than women who received standard care. Hospitals and birth units have spa baths/birth pools that vary widely in size, shape, depth, place and position in the birth room.

Ideally, women will have antenatal preparation and education regarding, amongst other things, the use of water for labour and birth. This education is best provided by the midwife who provides care throughout pregnancy, labour and birth and postnatally. Continuity of caregiver supports informed decision-making. However, not all midwives are able to practise as the lead maternity carer, enabling continuity of care and the formulation of a midwifery partnership. This places greater challenges on the midwife, especially in the maternity facility where the midwife may not have met the woman until she is in labour, to ensure that the women she recommends water to are fully informed of all the possibilities.

In the studies reviewed, women had made an informed decision to use water immersion for labour and birth. They were therefore strongly motivated to labour without pain relief and medical intervention. Furthermore, the presence of a midwife throughout the labour and birth potentially affects the research, given that constant support of a female companion has been shown by a large number of studies to decrease both the length of labour and the need for pain relief (Hodnett 1999).

Subsequently, one needs to ask whether the women in the studies had such straightforward labours because of this constant companionship and the environment, rather than any benefits associated with water, or whether it was a combination of all these components. In addition, most of the studies do not give any clear indication of the attitudes of the midwifery staff towards the use of water immersion during labour and birth. This will surely affect the outcome for women. Midwives who are unfamiliar or opposed to water immersion for labour and birth may become more sensitive about potential problems and are therefore more likely to use resuscitation and initiate unnecessary interventions such as directing the woman to leave the water. Midwives need to be educated in how to support women during labour and birth in water, as well as having the opportunity to witness water labour and birth before they attend one, and to have ongoing professional development.

Clinical point

Continuous support in labour

Research supports the need for a continuous supportive presence with women during labour. This by itself has been shown to reduce the likelihood of medication for pain relief, a caesarean section or a forceps delivery. For the women in this study, to be able to labour and birth in water meant that they were required to form a relationship with a midwife who was philosophically in tune with them and would support their choices. There is a need for partnership and teamwork between women and midwives.

Guidelines and principles for the use of water for labour and birth

The principles that underpin midwifery practice are the belief that pregnancy and childbirth are normal life events for most women, that midwifery care is woman-centred and continuity of care is desirable throughout the entire childbearing experience. These philosophies provide midwives with the opportunity to support physiological birth. One of the strategies used by midwives in support of physiological birth is the use of water during labour and birth. Midwives recognise that warm water immersion changes the dynamics of labour and birth and empowers women, in most instances, to birth without intervention.

While guidelines will vary in each location, there are general principles that can be drawn from the literature regarding the benefits and considerations of using water for labour and birth.

Benefits of labour and birth in water

For the woman:

- Warm water cradles, supports, relaxes, comforts and soothes, thereby reducing anxiety.
- It enables instinctive behaviour and increases the feeling of being in control, which in turn leads to a high degree of postnatal wellbeing.

- There is less operative delivery and perineal trauma.
- It provides buoyancy and increased mobility, reduces pressure on muscles and vena cava (reduces BP).
- It reduces the need for pharmacological pain relief.
- It provides a protected, secure birthing space.

For the baby:

- The reduced maternal need for pharmacological pain relief reduces the side-effects on the baby.
- Theoretically, the baby's first breath is gentle, as the air above the water is warm and humidified.
- Theoretically, it provides a smooth, trauma-free transitory passage for the baby.

For the midwife:

- It provides the increasingly rare opportunity to witness and facilitate physiological birth.
- It develops and enhances the fundamental skill of working in partnership with women.
- It enables her to extend her knowledge base and participate in research into the use of water for labour and birth.

Important considerations for attending labour and birth in water

Two important considerations are:

- the birthing family's attitude and expectations. Education regarding the use of water for labour and birth is important antenatally to prepare women and their families. A woman's fear/anxiety about birthing in water is a contraindication.
- the midwife's attitude, experience and confidence in supporting women to use water for labour and birth. Women who labour and birth in water should expect practitioners who have appropriate skills.

Who can use water for labour and birth?

Because each woman is an individual and her pregnancy unique, her care should be individually negotiated by a known midwife. The midwife uses her clinical judgement as to the suitability of using water for each woman. Many maternity facilities have developed water immersion and water birth criteria that are too prescriptive, inhibit autonomous midwifery practice and are more to do with facility risk management than what women want.

Criteria:

- low-risk pregnancy > 36 weeks (no adverse factors noted in maternal or fetal wellbeing during pregnancy or labour)
- the woman's choice to use water for labour and birth
- established labour
- no specific requirement for continuous fetal heart rate monitoring.

Some reasons why it may *not* be advisable for a woman to use the birth pool include the following:

- maternal temperature > 37.5°C
- thick meconium staining of liquor
- recent use of a systemic opioid for analgesia.

Most practitioners consider breech presentations and multiple pregnancies unsuitable for underwater birth; however, there is anecdotal evidence that these do occasionally occur both in hospitals and at home.

Equipment

- purpose-built birthing pool, portable birth pool, spa bath or inflatable paddling pool with firm sides
- a continuous supply of hot and cold water (temperature can be maintained by immersion heater or continuous supply of temperature-regulated water)
- adequate supply of dry linen, especially towels
- sieve—for keeping water as free of faecal contamination as possible
- light source (e.g. waterproof torch or headlamp)
- mirror
- protective clothing (personal choice or according to hospital guidelines)
- plastic waterproof support pillow or a rolled-up towel for head or arm support
- portable delivery pack, oxygen and suction, oxytocics
- waterproof Doppler and a Pinnard
- portable nitrous oxide/entonox as appropriate, though generally not at a home birth
- foot stool
- fan
- bed or mattress nearby.

Occupational health and safety considerations

- back care—midwife awareness
- protective clothing:
  - long latex gauntlet gloves
  - knee pads or low stool
  - plastic aprons
- infection control:
  - Hoses and jets in the pool are not recommended. However, when hoses are required for filling pools, especially at home births, two different-coloured hoses, one for filling and one for emptying pools must be used.
  - an agreed policy for cleaning the birth pool (and hoses)—chlorine agents are most effective against HIV, hepatitis B and C
- non-slip flooring/mats in pool
- electrical equipment kept away from 'wet' areas
- adequate room ventilation
- promotion of the safety and wellbeing of all, particularly children.

Care of woman and baby

During labour:

- Advise and assist the woman to wait until she is in active labour before entering the pool.
- The water in the pool should be filled to the level of the woman's chest while she is sitting in the pool.
- Maintain the water temperature according to the woman's comfort.
- Do routine labour observations and FHR recording.

- Encourage the woman to drink as desired while in the water.
- As much as possible keep faecal contamination of the water to a minimum.
- Encourage the woman to explore different positions in the pool.

During a birth in water:

- The woman should not be left alone when in water, and during the second stage the midwife should remain in the room.
- Attend to routine second-stage observations.
- Encourage physiological pushing. Physiological or non-directed pushing is less likely to tire the woman and her baby (Paine & Tinker 1992).
- A 'hands-off' technique by the midwife is advised when appropriate, supported by verbal guidance.
- A hands-off technique keeps tactile stimulation to a minimum (Johnson 1996).
- The practice of checking for nuchal cord is to be avoided.
- In most cases the nuchal cord can be loosened and disentangled as the baby is born (Burns & Kitzinger 2000).
- The baby should be born completely under the water and brought gently to the surface, being careful to minimise unnecessary cord traction. In the surveillance study reported by Gilbert and Tookey (1999), the incidence of five snapped cords highlights the importance of minimising traction on the cord during birth. If the cord is short, then the woman is instructed and assisted to stand out of or above the water to receive her baby.
- Following the birth, do *not* allow the baby's head to re-submerge. It is important to communicate to the woman the need for the baby's head to remain above the water once born, and for the midwife to ensure that while in the woman's arms the baby does not inadvertently slip back into the water.
- Carry out routine observations and Apgar score on baby. Experienced water birth practitioners observe that babies born in water appear more relaxed and quiet at birth, which may affect the one-minute Apgar score.
- Maintain the baby's temperature by using a woollen bonnet and keeping the baby's body under the warm water. There is a need to maintain a neutral thermal zone for the baby and minimise oxygen consumption by reducing heat loss. Babies lose a lot of heat from their heads. Replace wet blankets with warm, dry ones as needed.
- Conduct a physiological third stage, where the cord is left unclamped until the placenta and membranes are born. This is encouraged wherever possible. Active management may be used if indicated. When a midwife is judicious in conducting a physiological third stage, there is no increase in postpartum haemorrhage. There is no evidence to suggest that third stage must be conducted out of the water (Burns & Kitzinger 2000; Levy 1990).
- The woman is assisted from the pool to a nearby couch or bed, as required, when she is ready.
- Ensure the baby's warmth by drying thoroughly and maintaining skin-to-skin contact with the woman, as appropriate.

Complications

The midwife's use of wise clinical judgement is of paramount importance.

As with all aspects of care during pregnancy, labour and birth, there is an expectation that the midwife will have discussed the full range of possibilities and actions with the woman in her care. A woman who is fully informed will trust the midwife's judgement and immediately heed her advice to leave the water if there are any concerns for her safety or that of the baby. It is important for midwives to acknowledge that 'uneasy' feeling they may have even though it may not appear clinically justified. Experienced midwives often describe acting on intuition that, on reflection, was very predictive of outcome. Be honest with the woman regarding your feelings—she may be feeling the same!

- *fetal distress—FHR irregularity/abnormality.* Where there is any non-reassuring fetal heart rate, the midwife should advise the woman to birth out of the water (Johnson 1996).
- *grade II meconium staining.* Grade I meconium is considered normal. The woman is requested to leave the water if time permits and she is able when > Grade I meconium is present. If she is unable to exit the water in time, continue with the birth and suction the baby's airways when the baby's head is above the water. Thick meconium is the most ominous sign and requires the woman to exit the water immediately (Enkin et al 2000).
- *slow progress in labour (any stage).* Sometimes the water slows the labour down. Often simply assisting the woman from the water will remedy this situation (Eriksson et al 1997). Ask the woman to have some time out of the water (advising her to go to the toilet to pass urine is useful), thereby allowing gravity to help contractions to re-establish. Going back into the water is still an option.
- *use of narcotic analgesia.* Women who have used a systemic opioid for pain relief in labour need to be carefully assessed due to the sedating effect of the medication on her and her baby.
- *tight nuchal cord.* In the rare event that the cord needs to be cut, the mother is asked to stand out of the water. The cord must not be cut and clamped under water (Burns & Kitzinger 2000).
- *maternal hyperthermia.* This may lead to the overriding of the baby's normal inhibition to breathe (Johnson 1996).
- *episiotomy.* The most common indication for episiotomy is fetal distress, and therefore one could argue that there is no place for it in the practice of water birth because if the midwife is worried about the wellbeing of the baby, the mother should be assisted out of the water to birth on land (Cluett et al 2004a).
- *shoulder dystocia.* This is considered an obstetric or

Critical thinking exercise

Sally has just given birth to the head of her baby under water in the bath, when you notice signs of a shoulder dystocia. Describe some of the signs of shoulder dystocia and your management of the situation when a woman is in the bath/pool.

midwifery emergency. When shoulder dystocia is diagnosed, the woman is assisted to stand up and place her leg on the side of the pool (this encourages hyperflexion of the leg, as in the McRoberts manoeuvre). The over-stimulation from the manipulation of the baby may initiate respirations or fetal distress in the baby and subsequent gasping under water. Often the act of changing position alone dislodges the shoulders.

- *postpartum haemorrhage*. Blood loss is assessed as > 500 mL or < 500 mL due to the difficulty of accurate estimates in water. A useful guide is how dark the water is getting and whether you can still assess the skin colour of the woman's thighs. It is wise to assist the woman out of the water sooner rather than later, when her condition may be compromised (Harper 2000).

Conclusion

History and over two decades of research and literature have informed midwives' practice around the use of water for labour and birth. From the most recent Cochrane Database Systematic Review of immersion in water in pregnancy, labour and birth, the reviewers have concluded that there is evidence that water immersion during the first stage of labour reduces the use of analgesia and reported maternal pain, without adverse outcomes on labour duration, operative delivery or neonatal outcomes. Water immersion during the first stage of labour can be supported for low-risk women (Cluett et al 2004a).

Critical thinking exercise

Kiri is expecting her first baby. She is very healthy and carefully monitors her nutrition, exercise and rest. She is very keen to avoid any interventions in the normal process of labour and birth, and especially wants to avoid pharmacological pain relief. What information can you give her about the use of water for labour and birth to help her to make an informed decision?

Generally, there is a lack of published data in Australia and New Zealand on the use of water for labour and birth, and this is not indicative of its widespread usage. To date there is insufficient evidence regarding the use of water immersion during second stage to enable firm conclusions to be drawn about the safety and effectiveness of giving birth in water, and researchers and practitioners have called for further research and prospective auditing.

In response to the increasing demand from women and midwives, it has become more common to find water-immersion facilities in maternity units. This is an attempt by institutions to provide a home-like environment that supports a more holistic approach to birth.

Women report that the use of warm water changes the dynamics of labouring and birthing and gives control back to them. Women also report that being immersed in water does not necessarily take the pain away. What it does appear to do, and this is supported in the literature, is to provide a release from the pain in the form of warming, soothing, comforting and relaxing. For women who want to avoid pharmacological pain relief and for midwives who support these women, judicious use of water immersion may offer the means to achieve this.

For midwives, the option to use water is one way of supporting women to birth physiologically and to experience the skill of being 'with woman'.

Review questions

1. What are the key principles of a midwifery model of care that supports women in using water for labour and birth?
2. What do women like about using water for labour and birth?
3. The Cochrane Database of Systematic Reviews, updated February 2004, reports on eight trials (2939 women) examining the effects of water immersion during labour. What conclusions did the reviewers reach?
4. What are the main mechanisms that inhibit breathing in utero to prevent the inhalation of water during a water birth?
5. What is the current thinking on the recommended temperature of the water during labour and birth?
6. Who can use water for labour and birth? When is it *not* advisable?
7. Discuss the research evidence associated with perineal trauma and the use of water immersion for labour and birth.

Review questions—cont'd

8 Describe the occupational health and safety considerations for the woman and the baby during a water birth.

9 Discuss a midwife's care of a woman and a baby during a water birth.

10 Describe how a midwife would assess a woman's blood loss during a water birth.

CHAPTER 25

Maintaining the integrity of the pelvic floor

Sue Hendy

Key terms

episiotomy (midline, mediolateral), first-degree tear, fourth-degree tear, pelvic floor exercises, perineal suturing, perineal trauma, postnatal pain, second-degree tear, third-degree tear, urinary incontinence

Chapter overview

The *pelvic floor* is the term given to the structures that fill the outlet of the bony pelvis. These muscles have extensive functions, and disruption to their integrity can have serious consequences for a woman's physical, social and sexual health. Their main function is to support the internal pelvic and abdominal organs and maintain the integrity of bladder, uterus, vaginal and rectal function. They are also important for sexual function. During pregnancy and birth, the structure of these muscles is altered, and it is crucial for the midwife to have an understanding of the anatomy of the pelvic floor in order to minimise trauma and prevent long-term morbidity. The midwife's role in the education of women in the antenatal and postnatal periods can ensure that they avoid long-term incontinence and sexual dysfunction. This chapter outlines the anatomy and physiology of the pelvic floor, methods for prevention of damage based on the latest evidence, surgical repair, and care and advice.

Learning outcomes

Learning outcomes for this chapter are:

1. To identify the structures of the pelvic floor and its importance in midwifery practice
2. To discuss best available evidence in the prevention of damage to and repair of the pelvic floor
3. To discuss health promotion advice that can be given to women in the antenatal and postnatal periods that will reduce damage and provide optimal health outcomes for women post birth.

Anatomy and physiology of the pelvic floor

This section describes the main structures of the pelvic floor, and its functions.

Structures of the pelvic floor

Pelvic peritoneum

The pelvic peritoneum lies over the uterus and ovaries. The front aspect forms the uterovesical pouch and this covers the upper surface of the bladder. At the back, it dips behind the posterior vaginal fornix and forms the Pouch of Douglas prior to passing over the rectum.

Pelvic fascia

The pelvic fascia consists of connective tissue that fills the spaces between the pelvic organs and forms strong ligaments to support the uterus (see Fig 25.1).

Broad ligaments

The peritoneal covering of the uterine tubes are called the broad ligaments but they do not have a supportive function.

- Transverse cervical ligaments (Cardinal or Mackenrodt's ligaments) (2) are attached to the sides of the cervix and extend laterally in a fan-like structure and adhere to the walls of the pelvis.
- Uterosacral ligaments are attached to the upper portion of the posterior wall of the cervix and extend upwards and back, encircling the rectum before attaching to the anterior part of the sacrum.
- Pubocervical ligaments (3) originate in the cervix, pass under the bladder and attach to the pubic bone. They suspend the uterus at the level of the supra-vaginal cervix. Their function is to aid mobility of the uterus but they also act as a hammock to assist in the prevention of prolapse.
- Round ligaments are two bands of fibrous tissue enclosed in the peritoneum that originate near the fundus of the uterus. They pass between the folds of the broad ligament to the sides of the pelvis, through the inguinal canal and fuse with the labia majora. Their function is to maintain the uterus in the anteflexed (bent on itself) and anteverted (tilted forward) position.

Deep muscle layer

The deep muscle layer is composed of two levator ani muscles. These originate from the back of the pubic bone, follow the obturator fascia and the ischial spine. They pass backwards and downwards to meet in the perineum around the anal canal. They insert into the coccyx and lower sacrum. This anatomical structure provides the hammock of strong muscle that supports the vaginal walls and uterus. The levator ani muscles also provide some support to the bladder and anal canal, and are critical to maintenance of the integrity and strength of the pelvic floor. They are divided into three muscles (see Fig 25.2):

- The pubococcygeus muscles form the anterior section of the levator ani. Originating from the posterior aspect of the pubic bone, they pass backwards on either side of the urethra and the lowest part of the vagina and anal canal, terminating into the coccyx and anococcygeal body.
- The iliococcygeus muscles arise from the white line of pelvic fascia, pass downwards and inwards to the coccyx and anococcygeal body. This is the broader muscle section of the levator ani.
- The ischiococcygeus muscles originate at the ischial spines and pass downwards and inwards to be inserted into the coccyx and lower sacrum.

Superficial muscle layer

Although these muscles are small and contained in the superficial layer of the pelvic floor, they are critical to the

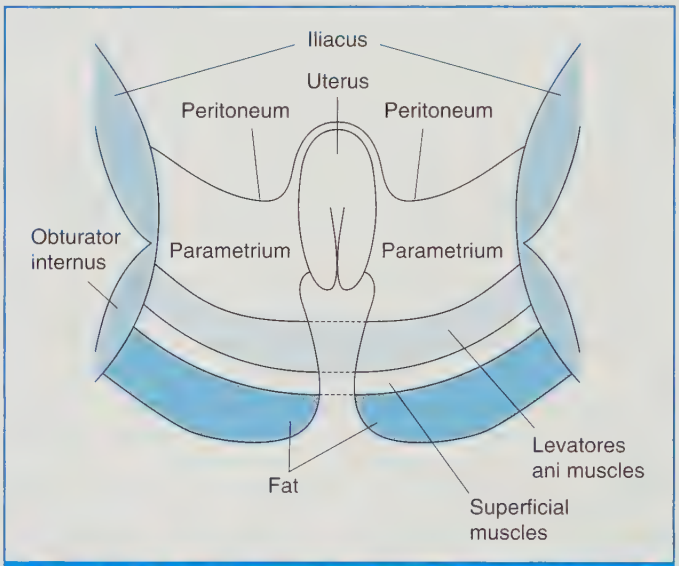

Figure 25.1 Tissue layers of the pelvic floor (based on Davis and Geck)

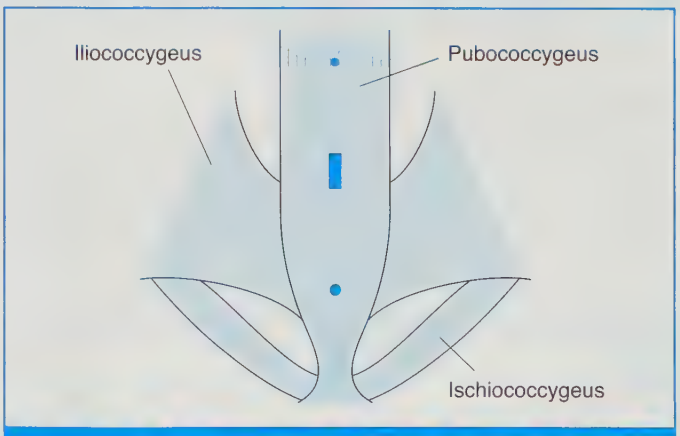

Figure 25.2 Deep muscles of the pelvic floor (levator ani muscles) (based on Davis and Geck)

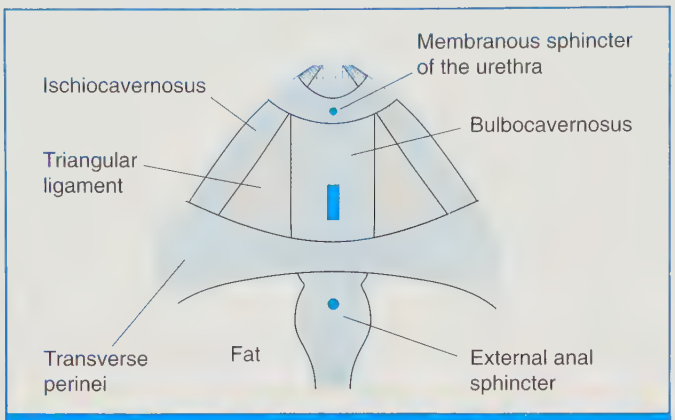

Figure 25.3 Superficial muscles of the pelvic floor (based on Davis and Geck)

overall function and strength of the pelvic floor. These muscles extend from the perineal body around the vagina to the clitoris (see Fig 25.3). They strengthen the sphincter action of the vagina and urethra, and play a part in sexual function.

- The ischiocavernosus muscles (2) originate in the ischial tuberosities and terminate in the clitoris. They are part of the triangular ligament across the pubic arch that supports the neck of the bladder and prevents urinary incontinence.
- The transverse perineal muscles pass from the ischial tuberosities to the perineal body and their function is to provide additional support across the perineal region.
- The external anal sphincter muscle encompasses the anal opening and passes in front of the perineal body before attaching posteriorly to the coccyx. It controls the passage of faeces and flatus.
- The membranous sphincter of the urethra are two bands of muscle that originate at one of the pubic bones, pass above and below the urethra before inserting into the other pubic bone.
- The bulbocavernosus muscles (2) arise in the centre of the perineum and pass on either side of the urethra and vagina, encircling the orifices before inserting into the pubic bones.

Nerve, lymph and blood supply

The third and fourth sacral nerves and the pudendal nerve supply the pelvic floor. Lymph drainage is via the internal iliac glands, and the blood supply is from the internal iliac arteries and veins. The final layer of the pelvic floor is composed of superficial fascia, fat and skin.

Functions of the pelvic floor and perineal body

Pelvic floor

As noted earlier, pelvic floor is the term given to the structures that fill the outlet of the bony pelvis. Their main function is to provide support for the internal pelvic and abdominal organs, which include the bladder, uterus, vagina and rectum. When intra-abdominal pressure is increased (during sneezing, coughing etc), the pelvic floor works to balance the pressure. These muscles have extensive functions, and disruption to their integrity can have serious consequences for a woman's physical, social and sexual health. Pregnancy and birth pose an enormous challenge to these structures, weakening them and causing stress incontinence (involuntary leakage of urine). This is a common complication of childbirth—some studies cite 20% of women experiencing stress incontinence many months after birth and one in four adult women being affected (Herbert 1998).

Under the influence of pregnancy-initiated hormones, the pelvic floor relaxes during pregnancy. This is to enable the structures to expand considerably during birth to allow passage of the fetus through the birth canal. Paradoxically, this process also assists practitioners in performing vaginal examinations, as the musculature is less rigid and the woman less uncomfortable. Due to the elasticity and complex structure of the pelvic floor, it is possible for a woman to gain full control and function of her muscles within a short time after the birth. The midwife has a crucial health promotion role here. During the late antenatal period, women should be advised not to undertake any high impact exercises, as these increase stress on the pelvic musculature, which has already been adversely affected by pregnancy hormones and the gravid uterus (Dunkley 2000). However, the midwife should include education for women about pelvic floor strengthening to prevent urinary incontinence.

Perineal body

The perineal body is a triangular structure located between the lowest part of the vaginal introitus and the anal canal (see Fig 25.4). This is the point at which the levator ani muscles and superficial muscles unite and is the structure that stretches to a large extent during crowning of the baby's head. The core strength of the pelvic floor is contained within this structure. It is made up of skin, and the superficial and deep muscles of the pelvic floor:

- bulbocavernosus
- transverse perinei
- pubococcygeus.

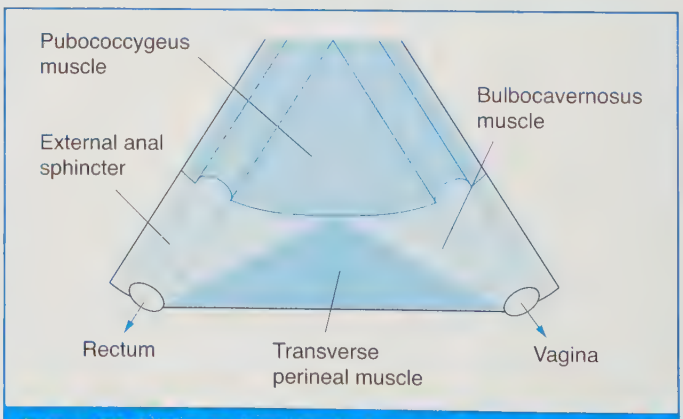

Figure 25.4 The perineal body (based on Davis and Geck)

The nerve supply is from the perineal branch of the pudendal nerve, lymphatic drainage is via the inguinal and external iliac glands, and blood supply is from the pudendal arteries and veins. Its chief function is control of defecation and childbirth. The perineal body varies in size and can be absent in some women. There is an association between a small perineal body and severe perineal trauma.

It is important for the midwife to understand the underlying anatomy and physiology of the pelvic floor, to assist in maintaining its integrity during childbirth. A clear anatomical understanding is vital for repair of the pelvic floor, to achieve optimal outcomes for women. The following sections outline the types of perineal trauma, and management during and after birth.

Perineal trauma

Perineal trauma can be caused by perineal laceration or episiotomy. Cervical lacerations can cause significant brisk bleeding after birth and these are also briefly discussed.

Perineal trauma can be classified as first-, second-, third- or fourth-degree (see Table 25.1).

Further definition of third- and fourth-degree tears are provided by a recent clinical guideline:

- Third: injury to perineum involving the anal sphincter complex:
  - 3a less than 50% of external anal sphincter (EAS) thickness torn
  - 3b more than 50% of EAS thickness torn
  - 3c internal anal sphincter (IAS) torn.
- Fourth: injury to perineum involving the EAS and IAS and anal epithelium (RCOG 2004).

Labial lacerations

Labial lacerations are very superficial tears that generally do not require sutures unless haemostasis cannot be achieved. Like skin grazes they can be very painful in the first few days after birth, particularly on micturition (passing urine). Women should be advised to keep the area clean and dry, and to use a douche when urinating. Analgesia can be given and if pain persists, the midwife must exclude infection and deeper trauma. The use of an alkaliniser such as Ural® for the first couple of days can make the urine sting less when urinating.

Vaginal and cervical lacerations

Vaginal and cervical lacerations can cause serious postpartum haemorrhage. Both structures are very vascular and careful inspection should be carried out after birth to exclude trauma, which can precipitate excessive blood loss. Once detected, suturing should occur without delay. Caution is required, and the midwife may need to seek advice to avoid the formation of a vaginal haematoma. An experienced obstetrician should carry out cervical suturing to avoid excessive bleeding and cervical complications in subsequent pregnancies.

TABLE 25.1 Classification of perineal trauma

First degree	Involves only skin of the fourchette and/or vaginal mucosa
Second degree (episiotomy)	As above, with involvement of skin of perineal body and muscles: • superficial—bulbocavernosus, transverse perinei • deep—pubococcygeus. The rectal mucosa is not involved.
Third degree	As for second degree, with involvement of the anal sphincter
Fourth degree	Third-degree tear that extends into the rectal mucosa

Prolapse

When the perineal muscles are overdistended, the musculature is unable to provide appropriate support for the organs, resulting in a prolapse of the pelvic organs. Those most at risk are grand multiparous women or women who have had a long, difficult labour with vaginal birth of a large baby. Types of prolapse are:

- uterovaginal prolapse—the vaginal wall is weak and the uterus protrudes down into the vagina
- cystocele—the bladder bulges into the vagina due to a weakened upper anterior vaginal wall
- rectocele—the rectum bulges into the vagina due to a weakened posterior vaginal wall
- cervical prolapse—the cervix protrudes into the lower half of the vagina.

Depending on the severity, most prolapses require surgical intervention. The mode of delivery for subsequent pregnancies would need to be carefully considered, to prevent further damage.

Episiotomy

An episiotomy is an incision through the perineum and perineal body that is performed immediately prior to birth. It enlarges the vaginal outlet to expedite the birth of the baby. The presenting part should be distending the perineum and analgesia should be given. This is usually in the form of local anaesthetic (see below). A midwife is trained to infiltrate the perineum and perform an episiotomy. The use of episiotomy is restricted to the following indication:

- to expedite birth when the presenting part is distending the perineum and there is evidence of non-reassuring fetal heart rate pattern.

Further consideration can be given to the following situations:

- maternal exhaustion
- to reduce maternal effort if cardiac disease, epilepsy or hypertension is present
- rigid perineum—in some cases, increased rigidity of the

perineal musculature causes a prolonged delay in the second stage.
- 'button holing' of the perineum.
- to prevent perineal trauma associated with a history of surgical repair of the pelvic floor, bladder repair or fistula.

Women should be fully informed about the need for an episiotomy and give consent to the procedure. This issue should be discussed in the antenatal period so that women can understand the criteria that would require a midwife to seek permission to perform an episiotomy. This is then noted on the birth plan. Unexpected changes to a woman's birth plan in labour need to be fully discussed so that the woman understands the need to perform an episiotomy and can fully consent. This is then documented in the notes.

Performing an episiotomy

There are two types of episiotomy (see Fig 25.5):
- Mediolateral—the incision starts in the midline of the fourchette and runs backwards to a point between the ischial tuberosity and the anus. This type of incision appears to be less likely to extend to involve the anal region and helps prevent damage to the Bartholin's gland.
- Midline—the incision is from the fourchette directly down towards the anus. It is easier to repair and has been associated with less pain and bleeding, although there is an increased risk that it will extend to a third- or fourth-degree tear.

The structures involved when performing an episiotomy include the skin of the fourchette, posterior vaginal wall and perineal muscles (superficial and deep).

Infiltration of the perineum

Prior to performing an episiotomy, analgesia should be considered. This is usually achieved by infiltration of the area with local anaesthetic such as lignocaine 0.5% or 1% (10 mL). The baby's head should be distending the perineum so that the muscles are thinning. The area should be cleaned with an antiseptic solution. The midwife inserts two gloved fingers into the vagina to protect the baby's head. The needle is inserted into the muscle layer in the area of the incision. The plunger of the syringe is withdrawn to ensure that the needle is not in a blood vessel. If blood is seen in the syringe then the needle should be withdrawn slightly and another area tested. The anaesthetic should never be put into a blood vessel. Once clear of blood vessels, the anaesthetic is inserted into the muscle as the needle is withdrawn from the tissue (approximately 3–4 mL). Just prior to the needle being completely withdrawn, the needle is reinserted to the side of the incision site, where 2–3 mL of local anaesthetic is discharged and this is repeated on the other side. Each time, the midwife must check to avoid blood vessels. This provides a fan-like cover of the area. The infiltration should be performed three to five minutes prior to the incision, to ensure adequate analgesia. However, lignocaine transfer to the fetus is quite rapid and so caution should be exercised with local anaesthetic (ALSO 2000).

Women with epidurals need to be assessed carefully, especially if the anaesthetic effect has worn off and may require extra cover with infiltration. An obstetrician sometimes performs a pudendal block for episiotomy prior to instrumental birth. Very little research has been carried out in the area of pain experienced by women undergoing episiotomy, but many women are not given adequate analgesia for this procedure, some being offered nothing or the use of nitrous oxide (Maunders 1998).

Once anaesthesia is achieved, the midwife inserts the same two fingers into the vagina to protect the baby's head. An episiotomy is performed using blunt-ended Mayo scissors. These are now opened and one blade is placed between the fingers and the other blade along the area where the lignocaine was introduced. A single, confident cut, approximately 4 cm long, is made, preferably during a contraction, to minimise pain. A thin, well-stretched perineum is also less likely to bleed. Remove the scissors quickly and prepare for the imminent birth of the baby's head. It is critical to control the birth of the

BOX 25.1 Episiotomy

History and clinical practice

Perineal lacerations have been documented throughout history, with reference to them even in ancient times. It is estimated that, even with a restricted episiotomy policy, approximately 51–77% of women sustain sufficient trauma to the perineum during birth to require suturing (Beckmann & Garratt 2005). During the early part of the twentieth century, a new surgical procedure was introduced, called *episiotomy* (cutting of the perineum to enlarge the vaginal opening). This procedure, which was used to speed up birth of the baby, quickly gained popularity, particularly during the medicalisation of childbirth in the 1950s and 1960s. Midwives and doctors readily accepted the procedure as good practice, without any scientific evaluation, until it became the most commonly used surgical procedure after cutting of the umbilical cord.

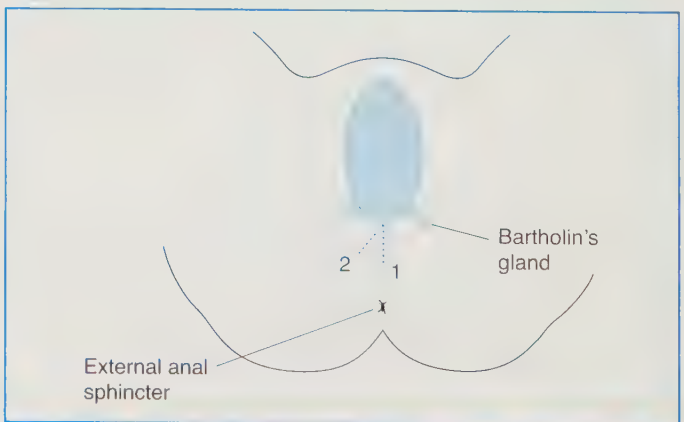

Figure 25.5 Types of episiotomy: 1 midline, 2 mediolateral (based on Davis and Geck)

head, as rapid expulsion could extend the episiotomy. If the baby is not born, the midwife will need to apply pressure to any bleeding points in the incision to minimise blood loss.

Episiotomy for vaginal birth

The claimed benefits of universal use of episiotomy were that it prevented severe tearing of the perineum, aided suturing by avoiding ragged edges, prevented long-term damage and protected the baby by expediting birth. In the early 1980s, midwifery students were taught at least nine indications, which included abnormal presentation, preterm birth, instrumental delivery, rigid perineum and fetal and maternal distress. The lack of research to evaluate the policy continued until Sleep's seminal work (1984), which revolutionised practice in the United Kingdom. Previously, the only controversy was concerning the type of incision rather than the benefits. In a review of all available trials, Sleep concluded that:

> Liberal use of episiotomy is associated with higher overall rates of perineal trauma. There is no evidence that this policy [liberal use of episiotomy] reduces the risk of serious perineal or vaginal trauma (Sleep et al 1987).

After publication of this research, a restrictive use of episiotomy was advocated. This meant that only fetal or maternal distress were used as indications for episiotomy. More recently, a Cochrane Review has supported this practice while noting an increased risk of anterior perineal trauma (Carroli & Belizan 2005). However, as the presence of an anterior tear did not significantly contribute to overall suturing, there are suggestions that anterior tears are less severe than posterior tears (Hartmann et al 2005). This review also states that women who have had an episiotomy have reduced pelvic floor muscle strength at three months post partum compared to women with tears. Certain risk factors have been identified, with rates particularly high in nulliparous women (see below). Episiotomy is known to be the greatest risk factor for a third- or fourth-degree tear (ALSO 2000). These tears require suturing in theatre under general anaesthetic by an experienced obstetrician. The stress of undergoing this procedure, as well as pain and fear, can prevent women enjoying the birth of their baby. Previous experience of severe perineal trauma and long-term morbidity can create enormous anxiety in a woman embarking on a subsequent birth. The woman should be offered counselling prior to or during pregnancy and supported to make an informed choice about mode of birth and the likelihood of recurring damage. Caesarean section may be an option for some of these women.

Even with a restrictive policy, rates of perineal trauma requiring suturing remain high at 51–77% (Kettle & Johanson 1998). Wide variations in practice exist between midwives and obstetricians, with place of birth, training and public or private status affecting episiotomy rates. These persistent wide variations in clinical practice suggest that episiotomy use is 'heavily driven by local professional norms, experiences in training and individual practitioner's preference rather than variations in the needs of individual women at the time of vaginal birth' (Hartmann et al 2005). This systematic review identified 26 articles outlining the best available evidence in relation to the use of restrictive versus routine use of episiotomy. Synthesis of these studies reported more pain and delayed healing, increased rates of third- and fourth-degree tears, no difference in rates and duration of urinary incontinence, and an increase in dyspareunia (painful sexual intercourse) at three months post partum with the use of routine episiotomy. There was also no reported benefit in respect of preserving pelvic floor integrity and decreasing the incidence of stress incontinence when using episiotomy. It is suggested that an episiotomy rate of 15% or less with spontaneous births is achievable and should be implemented immediately, and that this would clear the way for study of other techniques aimed at decreasing perineal trauma. The authors conclude that:

> Our systematic review finds no benefit from episiotomy . . . Indeed, routine use is harmful to the degree that some proportion of women who would have had a lesser injury instead had a surgical incision . . . In the absence of benefits and with a potential for harm, a procedure should be abandoned . . . The time has come to take on the professional responsibility of setting and achieving goals for reducing episiotomy use (Hartmann et al 1995).

In the current era of midwifery, many students do not get the opportunity to perform an episiotomy. It is important that students and midwives do acquire and maintain this skill, as judicious use of episiotomy is still an important aspect of contemporary midwifery care.

Risk factors for severe perineal trauma

- routine episiotomy (midline more likely than mediolateral)
- birth in lithotomy position
- operative birth, particularly forceps delivery
- experience of accoucheur
- prolonged second stage and use of oxytocin
- nulliparous women
- malposition (e.g. occipito transverse or posterior position)
- anaesthesia (local and epidural)
- increasing fetal head circumference and weight > 4 kg
- ethnicity (some ethnic groups are at higher risk).

Prevention of damage

There is a potential for perineal trauma with significant morbidity after vaginal birth, and some of these women may seek a caesarean section in subsequent pregnancies to alleviate their anxiety and pain. This is of concern in an era of increasing operative delivery rates. What role can the midwife play in reversing this trend, and what advice can be given to women to decrease their likelihood of sustaining significant perineal trauma? Perineal massage has been shown to increase the likelihood of an intact perineum when commenced at 34 weeks in nulliparous women but has no effect in subsequent pregnancies (Labrecque et al 1999). As nulliparous women are at an increased risk of severe perineal trauma, this may be an effective intervention to promote during antenatal

care. Further reviews of evidence are currently under way (Beckmann & Garratt 2005). Perineal massage can be carried out during pregnancy using a pure vegetable oil such as almond. The woman or her partner should insert a thumb into the lower vagina and massage the skin gently externally to improve elasticity.

It has been suggested that ethnicity, age tissue type and nutritional state in pre-pregnancy years influence extent of trauma to the perineum (Renfrew et al 1998). Nutritional advice, including prevention of anaemia, will aid healing of any trauma in the postnatal period.

A meta-analysis of randomised controlled trials showed evidence that spontaneous vaginal birth or vacuum extraction reduced the incidence of perineal trauma (Eason et al 2000). There is no clear evidence or consensus about guarding the perineum in the second stage of labour, maternal position in labour (apart from the avoidance of lithotomy) or perineal massage in the second stage of labour (Beckmann & Garratt 2005; Enkin & Keirse 1999; Stamp et al 2001). It has been suggested that adopting a squatting position during labour evenly distributes vaginal and perineal pressure, maximising perineal stretching (McKay 1984). Use of a birthing chair has been associated with increased rates of postpartum haemorrhage, although this may be due to improved accuracy of estimation of blood loss. However, it has been suggested that use of the birth chair may increase blood loss from perineal trauma due to obstructed venous return as a result of pressure on the buttocks and perineum. Excessive perineal oedema and haemorrhoids have been reported in women who are upright in birth for long periods. Hands and knees or all-fours position is associated with less perineal trauma, although it may increase the risk of anterior tears and vulval trauma (Enkin & Keirse 1999). Warm pads applied during the second stage have also been used, but to date this technique has not been fully evaluated. The warm pack trial is now complete and awaiting publication (Stamp et al 2001)

It is important for the midwife to allow time for perineal thinning during crowning of the head and to seek assistance from the woman at this time to facilitate a slow, controlled birth of the head. An uncontrolled expulsion of the baby's head will not only risk perineal trauma but can also cause trauma to the baby's brain.

Birth can be an overwhelming and frightening experience for women, particularly during the second stage. A midwife's role is to support the woman and provide her with information to assist in ensuring that the birth has the best possible outcome. Working with women in this way can greatly assist in reducing perineal trauma and subsequent postnatal pain for the mother.

Perineal suturing technique and materials

Continuity of care includes completion of the birth process by suturing the perineum if required. This may also mean that the suturing is attended to promptly rather than having to wait for a medical colleague. Immediately after birth, the sensation in the perineal area is often diminished and so it is preferable to complete any suturing then. A midwife who has undergone training and is competent to do so may suture perineal trauma. However, a midwife must always be aware of her own level of expertise and seek advice and medical support as required. In Australia each health service will have a policy concerning authority to suture perineal trauma. Severe perineal trauma, excessive bleeding or problems with haematoma formation should always be referred to a senior medical colleague. Verbal consent should be sought from the woman, with a full explanation of what the procedure entails.

Controversy exists over non-suturing of perineal lacerations in terms of pain, infection rates and healing (Maunders 1998). Minor lacerations and labial tears are often a matter of personal choice for the woman. Trauma that involves more than superficial perineal muscles requires suturing. The practice of leaving first- and second-degree tears unsutured is associated with poorer wound healing but no significant difference in short-term pain outcomes (RCOG 2004). A woman's health status, hygiene and understanding may necessitate suturing of minor tears as well. The type of suture material, technique of repair and skill of the operator are the main three factors that influence perineal repair outcome (RCOG 2004).

The use of absorbable synthetic sutures such as polyglycolic acid and polyglactin 910 (Dexon or Vicryl) is associated with less perineal pain, analgesia use, dehiscence and resuturing, but increased suture removal, compared with catgut (ALSO 2000; RCOG 2004). Polyglactin 910 is associated with a significant decrease in pain and suture removal and is rapidly absorbed. It is the most appropriate material for perineal repair at present (RCOG 2004). Subcuticular sutures also disperse oedema through the whole stitch rather than being concentrated at each suture site.

Perineal repair

After delivery of the placenta, the midwife must make a through inspection of the vagina and perineum to ascertain the extent of the trauma. If an episiotomy has been performed, it is essential to identify the apex of the incision on the post vaginal wall. Failure to do so can result in haematoma formation and postpartum haemorrhage. Similarly, bleeding points should be identified and haemostasis achieved. Placing a pack or pad in the vaginal vault and leaving for a while can sometimes resolve superficial bleeding. It is essential that this be removed prior to transfer to postnatal. This procedure must be documented, including removal of the pack. If control of haemorrhage is not generally achieved within half an hour, suturing will be required.

Once a thorough inspection is complete and the midwife is satisfied that the suturing is within her capabilities, the repair is carried out under aseptic conditions. A good light is essential and the woman should be positioned appropriately to maximise the visual field. A lithotomy position is not generally required for suturing as long as inspection is easily managed and the woman is comfortable. The area is swabbed with an antiseptic solution or warm water. Sterile drapes are used as required before insertion of a local anaesthetic such as lignocaine (0.5–1%, 10–30 mL) or bupivicaine 0.25% with

adrenaline 1:400,000. This is injected under the skin into the perineal muscles in a similar fashion to that used before an episiotomy. It is very important to wait for this to work, which normally take four to five minutes. Women should be advised that inserting the local can sometimes be uncomfortable. The addition of sodium bicarbonate to anaesthetic will reduce pain on infiltration (1:20 solution, e.g. 1 mL sodium bicarbonate to 20 mL lignocaine). Also, local anaesthetic with adrenaline added will help with vasoconstriction of a bleeding wound. It also prolongs the action of the anaesthetic. If the woman has an epidural it should be topped up prior to suturing, otherwise local anaesthetic is required. A woman who is pain-free will be able to relax, which makes suturing much easier. Prior to commencing, test with a needle to ensure the local is effective.

A taped tampon is sometimes inserted into the vagina to prevent vaginal loss obscuring the wound. Bleeding points are identified and sutured to prevent haematoma formation. It is important to repair the muscle layer competently, to prevent dead spaces that can also fill with blood. The repair is planned, and at each stage progress is evaluated by ensuring that edges are coming together and that the finished product realigns the anatomical structures. Perineal trauma is traditionally repaired in three layers:

1 The suture at the apex of the wound is very important, as it provides the anchor for the procedure. The vaginal epithelium is closed with a continuous running suture, which starts at the apex of the wound and finishes at the fourchette, which is then taken through into the deeper muscle layer.
2 The deep and superficial muscle layers are closed with three or four interrupted sutures aimed at approximating the muscles—continuous running sutures may also be used. Care is taken not to bite too deep into the muscle, as this may cause the rectal mucosa to be involved.
3 Finally, the skin is closed with interrupted or continuous subcuticular sutures. The continuous subcuticular technique of perineal repair has been associated with less perineal pain in the immediate postpartum period than interrupted sutures (RCOG 2004). The sutures are placed in the subcutaneous tissue instead of in the nerve-rich superficial skin.

It is important to ensure that the tension of the sutures is just right. Too tight will cause unnecessary pain and too loose will not align the structures appropriately, impairing healing and decreasing integrity of the pelvic floor. An overly tightened introitus may lead to dyspareunia.

On completion of the suturing, the vaginal tampon is removed and the vaginal vault inspected. A finger is then inserted into the rectum to ensure that no sutures have been placed in this area. This can be uncomfortable, so an explanation should be given.

Accurate documentation of the procedure should be completed, including anaesthetic used, insertion and removal of the vaginal tampon, extent of the wound and layers repaired, suture material used and advice given to the woman. All sponges and needles *must* be counted before the procedure and after the procedure before leaving the room.

Severe perineal trauma

An experienced obstetrician should suture third- and fourth-degree tears under general anaesthetic or epidural. Faecal incontinence and vesicovaginal fistula formation (where a hole is present between the bladder or urethra and vagina) are serious complications of severe perineal trauma and can have long-term physical and psychological effects. A full explanation is given and a broad-spectrum antibiotic prescribed to reduce the incidence of infection. Continuous drainage of the bladder is necessary for two to three weeks to enable the fistula to close spontaneously. If this does not happen, operative closure will be required. Hydration, diet and aperients are used to prevent constipation. Postnatal follow-up with a medical practitioner is important to detect and prevent long-term sequelae. Assessment of urinary and anal integrity via ultrasound and urodynamic tests should be performed. Counselling should be provided prior to another pregnancy.

Pelvic floor exercises

Urinary incontinence and childbirth are inextricably linked, and antenatal, postnatal and lifelong pelvic floor exercises have been shown to have a protective effect (Dunkley 2000). Midwives have an important role in providing education and advice for women in this area. Kegel (1948) was the first to advocate the promotion of pelvic floor exercises after birth to prevent stress incontinence (the involuntary loss of urine on sneezing, coughing etc). It is estimated that as many as one in four women suffer from incontinence after birth, and many women think this is a normal consequence of pregnancy and vaginal birth. Caesarean section has been shown to reduce the incidence of incontinence. However, coupled with the risks of

Scenario

Massive PPH from perineal trauma

A primigravida had given birth after a prolonged labour due to a persistent occipitoposterior position (POP). The midwife performed an episiotomy due to a non-reassuring fetal heart rate pattern and maternal distress. After the birth the woman had a 2500 mL PPH despite appropriate management, which included prompt suturing of the episiotomy. She was taken to theatre for an examination under anaesthetic (EUA), where it was discovered that the apex of the episiotomy had been missed during repair. The woman required blood replacement and intensive care as a result.

How would you document this and what information would you give to the woman about the outcome?

injury to the bladder during surgery and the other significant morbidity associated with operative birth, caesarean section is a radical step when pelvic floor exercise can cure incontinence (NICE 2004). Recent studies have continued to find significant benefits to women who are taught pelvic floor exercises, particularly in the antenatal period. Midwives should use the antenatal period to educate women about urinary and faecal incontinence and to raise awareness of this previously taboo subject (Dunkley 2000). It is important that women do not see incontinence as a normal event after pregnancy, regardless of their culture or societal background. The midwife will need to direct questions that enable women to be frank and open about any problems. Asking women if their bladder and bowel functions are 'normal' or 'okay' is ineffective communication (Scowen 1996).

Perineal trauma (prolonged second-stage, third-degree and episiotomy) and parity greater than four have been linked with the problem of stress incontinence, although women with an intact perineum and post caesarean section can also have stress incontinence. Therefore the mechanism is not fully understood, but it is believed that overstretching of the pelvic floor muscles and damage to the pudendal nerve may be risk factors. Another study compared caesarean section, parity and obesity and urinary incontinence at three months post birth. Operative birth was excluded, but parity and obesity were significant risk factors (Wilson et al 1996).

Teaching pelvic floor exercises

It is important for the midwife to explain to women the anatomy and physiology of the pelvic floor, as many women do not understand the location and structures of this important area of their body. The use of diagrams is advisable. Their use during childbirth should be outlined, as well as their long-term function.

Two types of muscles control continence: slow-twitch and fast-twitch. Both sets must be exercised to ensure effective control. Slow-twitch muscles make up 70% of the pelvic floor and are designed to be more durable in strength as their main function is to support the pelvic organs. The levator ani muscles are fast-twitch, as they react quickly to acute changes in intra-abdominal pressure such as during coughing or sneezing. This muscle group fatigues quickly. For total control, both sets of muscles must be exercised. Despite education, some women may still not contract the correct muscles. There are two ways to ensure that the right method is employed. A woman can place two fingers into the lower vagina, and should feel the muscles pull away from her fingers as she contracts the muscles.

Alternatively, she can stop and start the flow of urine mid-stream. This method enables a woman to locate the pelvic floor but must *not* be used to exercise the muscles, as it can lead to damage of the sensitive nerve fibres in the bladder. Once a woman understands the location and feel of the muscles, the midwife can teach effective exercises (see Box 25.2).

This ensures that both sets of muscles are exercised. Ideally this should be done five times a day and increased as strength is gained. Women often get discouraged from continuing these exercises after birth because they may not be able to hold on and the muscles release involuntarily. There *will* be progress and this can be demonstrated by recording the length of discernible contraction and time until fatigue sets in. All women should be taught these exercises and encouraged to do them regardless of mode of birth.

BOX 25.2 Pelvic floor exercises

1. Squeeze your back passage (anus) together as if you are stopping yourself from passing wind.
2. Squeeze your front passage (urethra) together as if you need to stop the flow of urine.
3. Lift both together and count to 10.
4. Repeat 10 times.
5. Repeat 1 and 2 and release quickly, 10 times.

Care of the perineum and postnatal pain

A major issue for many women in the postnatal period is vulval and perineal pain, particularly after suturing. Perineal pain can cause considerable distress for women and can dominate the postnatal period. It can negatively affect breastfeeding, and cause maternal exhaustion and depression. This pain is often underestimated, and women may suffer in silence. As mentioned earlier, since Sleep's Berkshire Trial in 1984, there has been very little comprehensive research to guide practice. Sleep's comprehensive study found that 20% of women still had perineal pain at 10 days and that 7.5% of women still had problems at three months post birth.

It is important to educate the woman about the extent of the perineal trauma. Even with an intact perineum, labial lacerations can be very uncomfortable, particularly when passing urine in the first few days. Women can be advised to douche the area with warm water the first couple of times they pass urine, and then pat dry. This can prevent stinging. Care should be taken to ensure that dysuria is caused by lacerations rather than a urine infection. General care consists of mild analgesia (e.g. paracetamol), bathing and inspection of the perineal area to exclude infection, haematoma and so on (WHO 1998). Hygiene is very important during the healing period. Although the Berkshire trial found no benefit from adding salt or antiseptics to baths in relation to improved healing or effective pain relief, 93% of women still felt that bathing reduced perineal pain. Women often worry about

BOX 25.3 HIPS

(source: Dahlen 2001)

opening their bowels after birth, and sensation and control are often altered. Constipation should be avoided. Women should be advised that absorbable suture material might break off during the healing process, which can take several weeks to complete.

Other methods of pain relief include the use of an ice pack enclosed in a soft cloth (to prevent ice burns), which has been commonly used. There has been some concern in the literature that ice packs can delay healing (Grundy 1997). However, Low and Reed (2000) have identified that initial vasoconstriction followed by vasodilatation will increase vascularity and promote healing. Application of witchhazel to the perineum to promote healing, and the use of homoeopathic drugs such as arnica to reduce bruising, have not been fully evaluated.

Ultrasound and pulsed electromagnetic energy have also been used but again are unproven. Application of lignocaine gel or aqueous 5% lignocaine spray are recommended in the literature, as long as they do not contain steroids, which can cause wound breakdown (Grant & Sleep 1989). Intense pelvic floor exercise has also been associated with a decrease in perineal pain (Henderson & McDonald 1998, p 481).

Conclusion

Childbirth and perineal trauma are linked, and the midwife has an important role in providing advice and education to women in the antenatal, intrapartum and postnatal periods to decrease trauma and prevent long-term morbidity. Midwives who are skilled in perineal repair can provide holistic care to women. It is important for midwives to understand the anatomy of the pelvic floor and its role in childbirth. Although the use of episiotomy is restricted, midwives should be proficient in performing an episiotomy when required. Urinary incontinence must not be viewed as a consequence of childbirth, and the midwife must be proactive in educating women about pelvic floor exercises and prevention of long-term morbidity.

Review questions

1. Succinctly describe the structure of the pelvic floor.
2. List the structures of the pelvic floor.
3. Describe the function of the pelvic floor.
4. Explain the importance of the perineal body and its relationship to the pelvic floor.
5. Explain the effects of perineal trauma caused by perineal laceration or episiotomy.
6. Provide a definition for each of the following: first-, second-, third- and fourth-degree perineal trauma.
7. List the main types of prolapse of pelvic organs.
8. Illustrate the different types of episiotomy.
9. Describe the role of the midwife in teaching women pelvic floor exercises after the birth of their baby.
10. Discuss methods of pain relief that midwives can provide for women who experience perineal pain after their baby is birthed.

CHAPTER 26

Supporting women becoming mothers

Lesley Dixon

Key terms

afterpains, anti-D gammaglobulin, baby blues, backache, constipation, debriefing, deep vein thrombosis, direct Coombs', dyspareunia, endometritis, episiotomy, fatigue, fourth trimester, haemorrhoids, headaches, involution, Kleihauer test, lochia alba, lochia rubra, lochia serosa, lochia, micturition, perineum, postnatal period, puerperium, pulmonary embolism, pyrexia, secondary postpartum haemorrhage, tachycardia, thromboembolism, tiredness

Chapter overview

This chapter discusses the midwife's role in assessing maternal health and wellbeing in the postnatal period. In a partnership model of midwifery care there will be continuity of care and a holistic approach to assessing a woman's health, with equal emphasis on the physical, emotional and social aspects of a woman's wellbeing. Midwifery support and care that recognises a woman's cultural heritage, existing knowledge, practices and values will enable the woman to have a positive experience in becoming a mother.

Learning outcomes

Learning outcomes for this chapter are:

1. To identify normal responses to changes in the postnatal period, and assess maternal wellbeing
2. To recognise the integration of physical, emotional and social aspects as women adapt to motherhood
3. To discuss the importance of support for each woman in the postnatal period
4. To explore the role of the midwife during the postnatal period.

Introduction

> The glow of having our baby remained with me during those first few days when I rested on the couch. My husband did everything for us and the baby lay snuggled with me. We didn't have to drive anywhere and didn't have to report to anyone. Everything in my home was there for me, the food I liked, the view out my window to the mountains as I dozed on the couch in front of the fire, a short walk in the garden when I was strong enough, a shower and to sleep in my own bed. That first morning after our baby was born, I woke early with excitement and leant over just to see him, to be near him ... I feel like it carries forward so far, the feelings about the birth and even now I go back through it in my mind when I look at my little baby and it gives me a glowing feeling. I recall the rushes of love, the reverence of the moment there in front of the fire. I didn't expect to find the confidence in myself and my own body that I now know. Perhaps in my heart and my body, I always knew how to have a baby, I just didn't know I knew. So our midwife didn't direct me how, she just showed me that I knew how. What a wonderful, inspiring gift. I am grateful. And confident.
>
> (Extract from *Bea's Story,* In *Having a Great Birth in Australia,* Vernon 2005, p 63)

Giving birth is a major life change for each woman, affecting her personal identity and social role, and there is need for emotional, physical and social support during this time (Percival & McCourt 2000). Support can make a difference to the emotional wellbeing and coping ability of each individual, and family, friends, professional helpers and social institutions can all provide it in various ways (Ball 1994). In most societies throughout the world, women have traditionally helped each other by providing care and support following a birth. This help could be with domestic chores, care of existing children, or personal care (Goldsmith 1990; Marchant 2004; Podkolinski 1998).

Following the birth of a baby there is a period of adjustment and recovery for the mother from both the pregnancy and the birth. This adjustment period involves physical, emotional and social changes, and may take weeks or months. The six-week period following the birth has been referred to as the puerperium or the postnatal period. However, Coad and Dunstall (2001) suggest that the puerperium should be seen as a transitional phase, which begins at the birth of a child and ends with a return to fertility, although a woman does not return to the same physiological and anatomical state as before pregnancy. Davis (1997) discusses the postnatal period as the fourth trimester, suggesting that the first three months following birth are transformative and culminate in the reintegration of women as mothers into society.

The parenting role requires adjustments to behaviour, lifestyle and relationships in the weeks and months following the birth (Percival & McCourt 2000). How women will react to motherhood does not become apparent until after the birth, so the continuity and support of the midwife in the first few weeks can have a significant contribution and influence on a woman's coping process (Ball 1994).

The midwife and postnatal care

In the nineteenth century, because of high levels of maternal mortality due to postpartum infection, formalised postnatal care was instituted in order to identify poor health and pathological conditions in women (Donnison 1988; Marchant 2004). In the United Kingdom, legislation (in 1902) set 10 days as the time for 'lying in' after a birth when the woman was expected to rest, and a midwife would visit daily to ensure her physical recovery (Ball 1994, p 15). The midwife was expected to perform a complete examination of the woman's physical health during the postnatal visit (Sweet 1989).

Since the nineteenth century, maternal mortality has dropped significantly, due to the development of antibiotics and other new treatments for pathological conditions; however, there continue to be significant physical and psychological health problems following birth, many of which are not reported or identified (Brown & Lumley 1998; Glazener et al 1995).

Women's health following childbirth has not been a focus of research until recently. This may be a reflection of the low status attributed to postpartum care by both society and health professionals (Wray 2003). Many obstetric and midwifery textbooks emphasise only physical aspects of postnatal care, particularly abnormal or ill health, and ignore the emotional and psychological aspects of the transition to motherhood (Beischer & Mackay 1991; Bennett & Brown 1999; Sweet 1989). Ball (1994) suggests that the aim of maternity care should be to help women become successful mothers, and that to achieve this there needs to be as much emphasis placed on the psychological and emotional processes as on the physiological processes. Ball (1994, p 117) has defined three objectives of postnatal care:

- to promote the physical recovery from the effects of pregnancy, labour and birth
- to establish good infant-feeding practices and foster good maternal–child relationships
- to strengthen the mother's confidence in herself and her ability to care for her baby in her own social, cultural and family situation.

In New Zealand, a consensus workshop on postnatal care in 1993 suggested that the following were desired outcomes of care:

- The mother is comfortable, free of pain and physiologically stable, in an environment that provides safety, rest and nourishment.
- The mother feels in control of the pace and framework of events.
- The mother is given information specific to her culture and knows when and how to get help for herself or her baby.
- Information is shared between the mother, family and care providers.
- The transition to motherhood is individual but each mother goes through naturally occurring phases at her own pace. Good-quality care recognises this and

provides guidance and intervention as appropriate (National Advisory Committee on Core Health and Disability Support Services (NACCHDS) 1993).

Infant feeding and transition to parenthood are discussed in Chapters 9 and 28, so this chapter focuses on supporting women during the postnatal period. It includes discussion of a woman's response to the physiological changes of the postnatal period, and practical aspects of assessment and support. Caring for women during the postnatal period involves being aware of the physical, emotional and social adaptations that women make and how these are interrelated. The postnatal period can be seen as the time of maximum change and growth for women and families as they complete the transition to parenthood.

Assessment of women's health

The midwifery partnership model, which encompasses continuity of care, enables the building of a supportive relationship between a midwife and a woman and her family throughout pregnancy and childbirth (Guilliland & Pairman 1995). This relationship continues to be important during the postnatal period, when there is a time of physical recovery and emotional adaptation to parenthood. Assessment of a woman's health includes assessment not only of her physical recovery but also of her emotional responses to the demands of parenthood and the social supports that she has to help with these changes. Ussher (2004) argues that depression following childbirth is an understandable response to the difficulties of motherhood. She suggests that having good social support, realistic expectations of the difficulties of the mothering role, and practical help with child care can reduce the likelihood of becoming depressed following birth (Ussher 2004).

A midwife is able to assess a woman's health holistically, sharing her own knowledge and experience and encouraging the woman to monitor her own health. The impact of the woman's culture, beliefs, values and previous experiences with parenting must be recognised and respected.

In New Zealand, the minimum specifications for postnatal care have been defined (Box 26.1) and each woman is entitled to at least this level of care (Ministry of Health 2002a). There are no similar specifications for minimum levels of care in Australia; care varies across all states and territories depending on the models of maternity and midwifery care available to women.

Phases of the postnatal period

Regional workshops were held throughout New Zealand in 1993 to achieve consensus agreement on the level of care of a

BOX 26.1 Postnatal care in New Zealand

As described in Chapter 1, all pregnant women within New Zealand are expected to choose a practitioner as their lead maternity carer (LMC). The LMC is responsible for ensuring the following services after the birth:

- Visits to assess and care for the mother and baby in a maternity facility and at home until four to six weeks after the birth. These visits include the following:
  - a detailed clinical examination of the baby within the first 24 hours of birth
  - a daily visit while the woman is receiving inpatient postnatal care, unless agreed otherwise with the woman and the maternity facility
  - a total of five to ten home visits by a midwife (and more if clinically needed)
  - a minimum of seven postnatal visits as an aggregate of home and postnatal facility visits
  - one home visit within 24 hours of discharge
  - a detailed clinical examination of the baby within seven days of birth
  - a detailed clinical examination of the baby prior to transfer to the well child provider
  - a postnatal examination of the mother at a clinically appropriate time and prior to discharge from LMC services.
- Assistance with and advice about breastfeeding and the nutritional needs of the woman and baby
- Assessment for risk of postnatal depression and/or family violence, with appropriate advice and referral
- Provision of Ministry of Health information on immunisation
- Provision of or access to services, as outlined in the Well Child Tamariki Ora National Schedule
- Advice regarding contraception
- Parenting advice and education.

A plan of care should be documented, reviewed and updated with progress, care given and outcomes in the maternal notes. If the woman is receiving inpatient postnatal care, then the maternity facility should have a copy of this care plan.

The Maternity Facility Service Specifications are the national documents that describe the services that maternity facilities are required to provide to women and their families (NZCOM 2004). There is an expectation that women will be ready to go home within 48 hours of the birth. The LMC, in discussion with the woman and the facility, may identify clinical reasons for a longer length of stay. The reasons may include:

- breastfeeding problems
- postoperative recovery
- ongoing medical problems
- psychological problems
- babies with special needs
- geographical isolation.

mother and baby following a normal birth. These workshops included lay experts as well as health professionals and identified the following phases of the postnatal period:

- phase 1—the first few hours
- phase 2—the early days
- phase 3—the early weeks
- phase 4—completing the transition to parenthood (NACCHDS 1993).

Each phase has different characteristics and each woman will go through these phases at her own pace (NACCHDS 1993).

In phases 1 and 2, physical recovery is a main focus of concern for most women, along with caring for and being able to breastfeed the baby. Women need to be reassured regarding their physiological wellbeing, supported in a comfortable environment, and be pain-free. High levels of physical discomfort can cause emotional distress and lessen the ability to cope with the physical and emotional changes. At this time the midwife needs to be aware of normal physiology and be able to give practical help and advice.

Women should be encouraged to spend time holding, touching and breastfeeding the baby, as this will increase levels of oxytocin and prolactin. Oxytocin acts to keep the mother relaxed and calm, and there are indications that it is involved in tolerance and adaptation, and feminine responses such as 'tending' and 'befriending' (Buckley 2004, p 205). Prolactin is produced during lactation and stimulates breast milk production (Riordan & Auerbach 1993). Buckley (2004) suggests that it also reduces the stress response, alters sleep patterns and stimulates natural hormonal analgesia.

During phase 3, as a woman's physical recovery and breastfeeding abilities progress, she will gain confidence in her ability to care for herself and her baby. At some point the emotional aspects of the changes to her social world will start to have an impact. A woman will begin to realise and understand the significant changes that have occurred to the family dynamics, since becoming a mother. Being able to talk about how she feels is an important part of the coping process; listening, understanding and reassuring may be of more value to the woman than physical assessment. A supportive partner, family and friends can make a lot of difference to how a woman feels about herself and her baby. A midwife will need to discuss support and, if necessary, help the woman to identify where support can be obtained, perhaps from groups that are culturally appropriate. Each interaction that a midwife has with a woman and her family should be seen as an opportunity to enhance the woman's self-knowledge and learning, as well as promoting health, confidence and independence.

Phase 4, the completion of the transition to parenthood, involves a woman and her family accepting the change in family dynamics and shared responsibility for the baby. In most cases this will occur during the six-week postnatal period and signals a time when a midwife is no longer needed because the woman and her family are independent. Completing the midwifery relationship is discussed fully in Chapter 30 and will not be discussed here.

Frequency of midwifery visits

In New Zealand the minimum number of visits that a midwife should make for postnatal care is specified (see Box 26.1), but this is not the case in Australia, where opportunities for postnatal visiting in the woman's home after discharge from hospital are limited according to models of care and funding. Ideally a midwife would decide, on an individual basis with each woman, the frequency and length of visits that are required and when these visits should cease (Ministry of Health 2002a). There are many aspects of a mother's or baby's health that may indicate the need for more frequent visits.

The New Zealand College of Midwives *Midwives Handbook for Practice* (2005) outlines decision points that can be used to help identify times when there should be full midwifery assessments during the postnatal period. Each decision point summarises the assessments that should be made, investigations that should be performed, possible treatments, legal requirements and health information and education that should be shared. The timing of decision points should be based on individual need but the first decision point should occur within the first 24 hours of the birth (NZCOM 2005). Subsequent decision points should be every 24–48 hours until the woman is confident in her home environment (NZCOM 2005) (see Box 26.2).

Munday (2003) suggests that postnatal care should include time for physical assessment as well as a discussion of the socio-emotional issues important to women. She contends that midwives should facilitate continued contact with the woman for as long as the woman feels that the contact is of benefit (Munday 2003). Different countries have individual legislation and expectations regarding the timeframe for formal postnatal care, as well as differences in frequency of home visits, so it is difficult to make comparisons about what constitutes the correct amount of postnatal care. However, it seems unlikely that a woman would complain about too many visits, and much more likely for concerns to be raised about insufficient visits. A survey of 2909 women who gave birth in New Zealand during February and March 2002 found that women were generally positive and satisfied with their postnatal care, although some 23% received conflicting breastfeeding advice while in hospital and 36% stated that they received fewer than the required minimum of five postnatal home visits (Ministry of Health 2002b).

Emotional responses to change

The transition from pregnancy through the birth to becoming parents is a challenging time for a mother and the wider family (Percival & McCourt 2000). A range of emotions are felt in the postpartum period, and many women describe relief, euphoria, joy, pleasure, and also despair, fear and concern. These emotions will vary depending on the woman, the

BOX 26.2 Decision point

Decision point up to and including the first 24 hours post partum

Reflect on the birth experience with the woman and assess the health and wellbeing of the woman and her newborn baby.

Information shared:

- identify and discuss ongoing support
- discuss general wellbeing
- identify assistance required with breastfeeding.

Examination

Full physical assessment of woman, including:

- involution of the uterus and blood loss
- perineum
- breasts.

Full physical assessment of baby, including:

- heart sounds
- hip check
- weight and measurements when appropriate.

Possible tests:

- blood group for Rh factor and direct Coombs'/Kleihauer

Possible treatment

Respect the birth plan, developed antenatally with the woman, in relation to:

- vitamin K for baby
- anti-D gammaglobulin
- hepatitis B vaccine and gammaglobulin for baby
- facilitate BCG vaccination for baby.

Health information and education:

- Facilitate mother–baby relationship. Give opportunity for peace, quiet and breastfeeding if that is the woman's choice.
- Facilitate rest and ongoing support if at home.
- Education for self-care related to:
  - uterus
  - blood loss
  - perineum
  - breasts
  - bladder
  - bowels
  - emotional wellbeing
  - social support.
- Identify when and how to call for assistance.
- Guide and assist with breastfeeding as required.
- Information given for baby care related to:
  - feeding
  - breathing
  - passing urine and meconium
  - umbilical cord
  - crying, warmth
  - safety.
- National Immunisation Register
- Information concerning development of parenting skills, including feeding.

Legal requirements

- birth notification—BDM 9

Subsequent decision points in postnatal period every 24–48 hours until woman feels confident in her home environment

The timing provides the opportunity to promote the woman's independence while ensuring the wellbeing of the woman and baby.

Information shared:

- Discuss woman's health status, both physical and psychological.
- Discuss lactation and ongoing feeding.
- Discuss parental and baby's wellbeing.

Examination:

- full physical assessment to ascertain recovery from birth process, including breast examination and perineal examination if required
- full physical assessment of baby

Tests:

- Guthrie test
- consider SBR

Possible treatment:

- rubella vaccination
- red eye reflex

Health information and education:

- opportunity for rest and ongoing support
- parenting including feeding
- self-care for self and family
- other support agencies.

(Source: NZCOM 2005)

birth, her own life experiences, family roles and history, all of which will influence her adjustment to the new or expanded responsibilities of becoming a mother. In the first days and weeks following the birth there are disruptions to previous routines as the needs of the baby become dominant. Disrupted sleep, lack of freedom, lack of social life, and changes to relationships with partners and other family members add to the emotional rollercoaster of the first few weeks and months following the birth of a baby (Ussher 2004). Ussher (2004) discusses the paradox of motherhood: the need to be with your child but also the wish to have time alone; the wish to be selfish and independent but also to enjoy the needs and dependency of the baby. She discusses the overwhelming love between mother and child but also the exhaustion, frustration and relentless hard work, and says, 'It involves endless sacrifice, patience and self-control and when that is impossible (for no one can be patient and calm at all times), the ability to forgive oneself, for not being perfect' (Ussher 2004, p 107).

Birth stories

In the first few days following birth, most women will tell their family and visitors about their labour and birth. Often

Reflective exercise

1. Think about a time in your life where there were major changes. How did you feel? What helped you to cope? Who provided the most support?
2. Think about women you have worked with during the postnatal period. What range of emotions did you observe? What coping mechanisms did these women use?

the story is told repetitively and with incredible detail as the woman sorts out what happened and when. These birth stories are retained for many years and will be told at different times around pregnancy and births of friends and relatives. It is important that a midwife is aware of women's need to assimilate the events of their births and takes time to discuss with each woman her perceptions of the birth, what was said and done, who was present, and the order of events by which each woman builds a picture of her birth. Ideally the midwife who attended the birth will talk through the birth with the woman, but if this is not possible, another midwife can assist a woman with this by reference to notes and giving the woman time to talk. In building her picture of the birth, a woman draws on her own experiences, comments and discussions with the people who were present during her labour and birth, and the documentation and timelines provided for her by her midwife through the midwifery notes. Lyons (1998) suggests that in writing notes and in talking through birth stories, a midwife should focus on the positive qualities shown by the mother, especially in situations where the mother may have a sense of failure or disappointment. Lyons (1998) takes talking through birth stories one step further, to a more formal process of debriefing, and suggests that the primary aim of psychological debriefing is to 'provide the person with as much information as possible to enable the person to assimilate and emotionally adjust' (Lyons 1998, p 137). She contends that in the postnatal context it provides a mother with the opportunity to tell her own story and access information about the birth from health professionals, as well as allowing mental processing, in which the mother sorts out the sequences of the events (Lyons 1998). Debriefing may be used as a screening process when there are

MIDWIFE'S STORY

The importance of talk

Cindy was a late referral for booking, and when I went to see her she was bubbling with happiness. She was 35 years old and had been married for many years but had remained childless. Following investigations for infertility, which found no cause for her inability to conceive, she had given up hope of having a family (her husband was not keen on adopting) and had planned to change her career by going back to college. She went to see her GP to discuss her issues about weight gain, digestive and bowel problems, which were thought to be due to irritable bowel syndrome. The doctor palpated her abdomen and said, 'I think you're about six months pregnant'. He organised a scan, which found that she was 28–30 weeks pregnant *with twins*! Cindy and her partner were astounded but very pleased and started to re-plan their lives. During what would have been early pregnancy, Cindy had had a laparoscopy and had also been taking various medications. She was now concerned about harmful effects on the pregnancy. A detailed scan reassured her that both babies appeared well and normal.

About two months later (38 weeks), Cindy went into labour and had an emergency caesarean section. She gave birth to two lovely little girls, who were both well. At the time, as a community midwife, I didn't visit women at the hospital, only when they were discharged home. Two days after Cindy's birth I received a phone call from the ward staff, who were concerned about Cindy's behaviour, which was unusual, in that she couldn't seem to stop talking. She seemed unhappy, and would talk non-stop when a midwife or anybody entered the room. They asked if I would visit her to see if this would help. This was an unusual request from the hospital midwives. When I went to see Cindy she was very happy to see me and explained that nobody really understood how difficult it was for her. Three months ago she had had no expectation of having a family and now here she was having just given birth to twins. She said other women had nine months to get used to becoming a mother, whereas she had had two months! She needed to tell everybody about this so that they would understand why she wasn't able to look after her babies like other mums were able to. That first visit I was there for two hours as she talked and talked. I went every day until she was discharged home and we just talked. I helped her with breastfeeding her twins if needed but my main task was just to be there for her to talk to and support her in this environment, so that she was able to come to terms with becoming a mother. When Cindy went home I continued to visit her at home, but by this time my visits were a lot shorter and she was coping really well and had good support from her partner and family.

On reflection I realised that Cindy had needed to talk in order to be able to come to terms with the enormous life change that she was going through. Talking to anybody and everybody about it was her way of vocalising her need to have others understand this as well as helping her to organise her thoughts and feelings about becoming a mother.

I saw Cindy when the twins were 18 months old, and she was the happy, bubbly person that I'd first met. She told me proudly that things were going well and that she was still breastfeeding her twin girls.

concerns for post-traumatic stress disorder. (This is discussed more fully in Ch 37.)

Hormonal influences or 'baby blues'

Following the birth, many women feel high or elated; often they get very little sleep and are very happy to socialise with their visitors, friends and relatives. This high mood often turns to a low mood on about the third to fifth day post partum, and the characteristic tearfulness, anxiety and irritability are often called the '*baby blues*'. Despite a great deal of research, the cause is still unknown, although one theory is that it occurs because of the decrease in oestrogen and progesterone, and changes in the blood electrolyte balance and in the balance of serotonin and dopamine (neurotransmitters) (Stables 2000). It is estimated that 50–80% of women experience this mood swing, which is generally transient and lasts only a few days (Dennis & Kavanagh 2004). Paradice (2002) cites studies in which there were similar mood changes in groups of men and women following surgery, and argues that the blues could be a normal response to a stressful event rather than a response that is unique to postpartum women. Postoperatively it occurs immediately after surgery and is recognised as an understandable response to stress and part of normal recovery (Paradice 2002).

For women who do experience the blues there is a tendency to cry for no reason, feel overwhelmed, tired, and for everything to ache or feel sore. It often coincides with the onset of full lactation and unsettled behaviour in the baby. Women need help to achieve physical comfort as well as emotional support and reassurance at this time (Sweet 1999).

Physical assessment of maternal health

In the early postpartum period, a midwife needs to ask specific questions related to physical recovery, in order to establish whether there are any problems or concerns that may otherwise not be voiced. Following the birth, the baby is often the focus of attention and a woman's health can become secondary. Childbirth is a time when intimate areas of a woman's body become a focus of attention and some women may feel uncomfortable with this and reluctant to volunteer information about their private body functions. Taking time to talk about a woman's health and feelings is an important way of reinforcing the need for the woman to look after herself and of the normality of the physiological changes she is experiencing. While there is little evidence to support the routine taking of temperature, pulse and blood pressure on a daily basis, there should always be individual decision-making regarding the necessity of these physical observations. Women who have previously had raised blood pressure in pregnancy should have regular postpartum assessment of blood pressure. Temperature and pulse should be taken if there are concerns regarding postpartum infection.

Breasts and feeding

As part of the postnatal assessment there should be a discussion about the breasts, breastfeeding and any breast discomfort. (For more information see Ch 28.)

Involution of the uterus

A midwife will normally palpate the uterus shortly after the expulsion of the placenta, to ensure that there is a reduction in size of the uterus and an overall contraction of the uterus. The uterus can be felt as a hard round or ovoid structure at about the level of the woman's umbilicus or sometimes just below. The fundus of the uterus should be central and feel firm to the touch.

It is common practice for the midwife to palpate a woman's uterus to check for involution on a regular basis after birth and until the fundus is no longer palpable outside the pelvis. A tender uterus can be a sign of infection or retained products of conception, as can slow involution, which is known as subinvolution (Coad & Dunstall 2001). The uterus can also be tender to the touch and slower to involute following a caesarean section (Coad & Dunstall 2001).

Previously, midwifery textbooks have discussed the rate of involution and suggested that the height of the uterus should decrease at a rate of 1 cm a day with an expectation that the uterus will be within the pelvis and no longer palpable at 10 days post partum (Coad & Dunstall 2001; Howie 1995; Stables 2000). However, Cluett and colleagues (1997), in a small study of 28 women, found considerable variability in the pattern of involution within the normal puerperium. Measurements of the height of the fundus of the uterus were undertaken daily and showed that most women had an episode of slow decline (less than 1 cm over three or more days) and that for most women the uterus ceased to be palpable between 11 and 16 days, while a small group (three women) took 19 days. All the women had normal postnatal recovery. As this research was undertaken in the United Kingdom, there were several midwives providing postnatal care. Having a midwife who knows the woman and is able to discuss the woman's understanding and perceptions of her health would probably give more insight into problems than physical observations alone (Cluett et al 1997).

Marchant and colleagues (2003) looked at midwives' records in the United Kingdom to determine how involution was described and recorded within the midwifery notes. They found marked differences in how midwives in two different health districts recorded the involution of the uterus. These records varied from measurements, with or without a description, to some form of abbreviation or symbols used. The researchers identified the need for improved and consistent record keeping, arguing that there is little point 'in undertaking and recording an observation if the record cannot be unambiguously understood by others and used to construct an accurate chronological picture of events' (Marchant et al 2003, p 139).

Marchant and colleagues (2003) suggest that women could self-assess the condition and involution of their uteri in the

postpartum period. They argue that women often touch their enlarging abdomen during pregnancy, but after the birth there appears to be little interest in the reducing uterus. They asked women as part of the larger Blood Loss in the Post Partum (BliPP) study (1999) whether they had felt for their own uterus since the birth of the baby. The majority of women had not done so (67%) but 31% had tried to feel their own uterus; some had been unable to find the uterus (15%), whereas others had tried but were unsure what they were feeling (49%) and 36% were able to describe the position, size and texture.

A continuity-of-care model ensures that in most circumstances one midwife will provide care within the postpartum period, thus increasing consistency of physical assessments and the identification of potential morbidity. Palpation of a woman's uterus provides an opportunity to show her what is being done and discuss the signs that involution is normal. Advising women on how to palpate their own uterus early in the postpartum period promotes an understanding by women of their own bodies and returns the ability to monitor their own health to each woman. The midwife will need to judge on an individual basis whether assessing her own uterine involution is a viable option for each woman. Descriptions or measurements, when done, need to be consistently and accurately recorded, whether recorded by the midwife or the woman during the postpartum period.

Vaginal blood loss

Many textbooks refer to the blood loss following birth as the 'lochia' and suggest that there are three types of lochia (Howie 1995; Stables 2000; Sweet 1999). These are known as lochia rubra, lochia serosa and lochia alba. However, research by Marchant et al (1999) found that these colour changes were not supported by the majority of women's experiences and that women reported vaginal loss to be more predominantly red/brown in colour. Marchant (2003) argues for the term 'lochia' to be abandoned and replaced with 'postpartum vaginal blood or fluid loss' as this is language that is familiar to women and therefore of more value to both the woman and the midwife. She contends that as women are used to blood loss during menstruation, they are able to identify the colour and consistency of vaginal loss quite clearly after the birth (Marchant 2003).

It is important for a midwife to discuss with the woman the blood loss following birth. Excessive bleeding or infection (endometritis) is detrimental to maternal health but precise definitions and the incidence of either problem are not consistent (Bick et al 2002). Excessive bleeding is regarded as a secondary postpartum haemorrhage if it occurs after 24 hours and before six weeks post partum (Bick et al 2002). If there were concerns regarding excessive blood loss at any time, the midwife should check the blood pressure and pulse; a rapid pulse and low blood pressure would confirm that the blood loss is affecting the maternal physiology.

Assessing normal vaginal blood loss is subjective and the volume of blood loss is difficult to measure when it occurs over several days and weeks. Immediately after the birth, women should expect the vaginal blood loss to be heavy and this may continue for the first few days (Bick et al 2002). It is also normal for blood loss to be heavier following breastfeeding. The amount of blood loss should start to diminish over the first few days but the duration of blood loss is variable (Bick et al 2002). It is not unusual for women to pass blood clots as part of vaginal fluid loss; the size and frequency of these clots need to be described as these may be related to excessive or prolonged bleeding. Marchant (2003) suggests that using familiar items to identify and record the size of clots can be a useful guide in assessing the extent and size of blood clots and the extent of postpartum bleeding. Another method of determining the extent of postpartum blood loss is by how frequently a woman changes her sanitary pad, although this has to be interpreted with some caution, as some pads are more absorbent than others and some women will change pads more frequently depending on their hygiene requirements. Changing sanitary pads frequently due to full pads (several times in an hour) would be an indication of heavy, possibly excessive, vaginal bleeding.

As each woman is individual and will have different expectations of vaginal blood loss following the birth, the midwife needs to use and integrate all these methods to obtain an overall picture of the woman's blood loss and to assess whether it is a problem for that woman.

The BliPP study undertaken by Marchant and colleagues (1999) was a prospective survey of women's experiences and the duration, amount and colour of vaginal loss after childbirth. The objective of the research was to describe the range of normal vaginal loss as reported by women from 24 hours after birth until three months post partum. There were 524 women recruited to the survey, and these were asked to keep a record of the amount and colour of their vaginal loss daily until the tenth postnatal day, and then at 14, 21 and 28 days post natal. Findings showed that women report a more varied duration, type and quantity of vaginal loss than has been described in textbooks, although the overall trend was for the amount of vaginal loss to decrease from the time of birth. Two women reported no loss after two days and a few had no loss after one week, but for the rest there was considerable variation in patterns over the first month. Of these, 17% recorded no loss or a small loss on day five but subsequently experienced moderate or heavy loss again. By the 28th day postpartum, 48% of the sample reported no loss, 47% reported a small or variable loss and 5% reported a moderate or heavy loss. Women were also asked to record the frequency and size of blood clots, and again there was wide variation reported, although the presence of blood clots rarely led to any further problems (Marchant et al 1999). In this study 2% (7) of the women were unaware that there would be a blood loss following the birth.

As many women may be reluctant to discuss vaginal loss it is important for midwives to discuss the subject during postnatal visits and to reassure women if they are concerned about the amount or continuation of blood loss. Asking women to

describe their vaginal loss and listening to concerns related to the amount of blood loss is useful in determining whether the amount of vaginal blood loss is extensive and life-threatening or within normal expectations. Documentation of the nature of the blood loss needs to be reflective of the woman's words and experiences. Recording the blood loss in the woman's words will also increase the participation of the woman in monitoring her health, as well as aiding in the detection of ill health (Marchant 2003).

An increase in blood loss along with uterine tenderness and/or raised temperature could indicate endometritis or retained products of conception, and would require referral to a medical practitioner. If a woman is feeling unwell and an infection is suspected, the midwife should always remember to take the temperature and pulse to check for pyrexia and tachycardia.

Afterpains

Many women have afterpains following birth; these are common in multiparous women but can also be experienced by primiparous women. Afterpains are contractions, of varying intensity, of the uterine myometrium following birth. Theories on the cause are that the pain is due to the ischaemia of the uterus following the birth (Sine & Cameron 1968), or that because the tone of the uterine muscle becomes more relaxed and for longer with each pregnancy, more forceful contractions are required to keep the uterus contracted (Waite 2002). Afterpains can cause a significant level of pain that can be debilitating and distressing for many women (Phipps 2003). Descriptions range from 'like going into labour all over again' to 'like a dull backache that starts in my hips and around my back, then becomes like a strong period pain' (Phipps 2003, p 121). Uterine pain is normally more intense in the first 12 hours but will often continue for two to three days following the birth. Acknowledging this pain and discussing ways of alleviating the pain is an important aspect of providing care and support.

The relief of afterpains has not been a focus of recent research. Sine and Cameron (1968) suggested practical methods of easing afterpains that arose from observation and experience. These included keeping the bladder empty, massaging the uterus to aid expression of clots and applying pressure to the abdomen (Sine & Cameron 1968).

Critical thinking exercise

The information provided in the list above (at top right) has been accumulated through practice experience and has not been evaluated. Midwives and women have found these measures helpful as a means of alleviating afterpains. Further research is required to ascertain the most effective methods of alleviating afterpains. How would you undertake research to investigate this area further? What research designs could be used?

An audit undertaken at Rangiora Hospital (New Zealand) highlighted midwives' concerns about how to provide adequate practical help and pain relief for women experiencing afterpains. A pamphlet was developed which advises the following (Waite 2002):

- frequent emptying of the bladder
- regular oral analgesia
- gentle massage of the fundus by the mother
- a heat pack applied to the abdomen
- applying pressure to the abdomen by the mother lying on her stomach with a pillow against the lower abdomen
- homeopathic remedies such as arnica—following discussion with a suitably qualified practitioner.

Perineal healing

Following birth, many women will experience some pain, swelling or tenderness in the perineum. The intensity of the pain will be subjective but women who have had some degree of perineal trauma such as a tear or episiotomy are more likely to have higher levels of pain in the perineum (Bick et al 2002). A painful perineum can have a negative impact on a woman, as she is unable to move freely, sitting can be uncomfortable and caring for her baby becomes more difficult, marring her enjoyment of the early motherhood experience. Longer-term problems may arise when sexual intercourse is resumed, as dyspareunia (pain or discomfort during sexual intercourse) can also occur. Avoiding damage to the perineum and appropriate repair is the best way of avoiding and alleviating high levels of pain (Hedayati et al 2004).

When there has been trauma, perineal pain is generally more severe in the first few days but discomfort can continue for up to two weeks for some women and for up to three months for a small number (Hedayati et al 2004). Recognition and acknowledgement that perineal pain is distressing is important, along with discussion about different methods of alleviating the pain and support of the choice that is culturally valid for the woman. Many women who have had perineal trauma are concerned about urinary, bowel or future sexual function; discussion and reassurance will help to relieve these concerns (Marchant 2003). Most perineal trauma will heal within seven to ten days of birth (Marchant 2003). (For a fuller discussion of perineal pain and healing see Ch 25.)

Where trauma has occurred, midwives should check the perineum and assess the healing regularly until they are sure that full healing has occurred. Marchant (2003) suggests that the level of perineal discomfort experienced or degree of anxiety exhibited by women may mirror the progress of healing. If perineal pain is unchanged or diminishing, there is unlikely to be infection or haematoma development (Marchant 2003). Increased pain may indicate the development of inflammation or infection. In a continuity-of-care model the midwife will know the woman and the type of birth, which will assist in assessing the need for and frequency of perineal examination. A physical assessment of healing and exclusion of haematoma should always be considered, if perineal pain is increasing or the woman is anxious.

Bladder function

Immediately following the birth, a full bladder will prevent the uterus from fully contracting and can cause heavier vaginal blood loss and increase severity of afterpains. Women should be encouraged to pass urine as soon as possible after the birth and to micturate every two to three hours in the first day or two. There may be stinging during micturition due to grazes around the vulval area or perineal damage. There may also be some oedema around the urethra, giving the woman less control when passing urine or making it difficult to pass urine. Asking women about frequency and control will identify urinary problems and will often lead to discussion of pelvic floor exercises, perineal healing and adequate fluid intake.

Gastrointestinal system

Food is often associated with caring and nurturing as well as social occasions. Women need to be well nourished following the birth, so regular meals and fluids will help to promote health and a feeling of wellbeing. Most women will resume eating their normal diet and should eat when hungry. Breastfeeding requires an increase in calories, so women will often have an increased appetite during lactation. Bowel movement can occur within 24 hours of the birth but can also be delayed for up to three days following the birth. This is due to the pregnancy hormones aiding bowel evacuation prior to labour. Constipation can continue to be a problem for some women, but increased dietary fibre is recommended, with laxatives prescribed only when fibre and dietary interventions have failed (Bick et al 2002).

Haemorrhoids are the result of swollen veins around the anus becoming prolapsed and causing pain (Bick et al 2002). Following birth, haemorrhoids can become worse due to pressure and can take some time to resolve. There is an increased incidence of haemorrhoids following a forceps birth, a longer second stage and vaginal births of heavier babies (Bick et al 2002). Hartley (2003) suggests that pain caused by haemorrhoids in the postnatal period is drastically underestimated and that midwives rarely ask about haemorrhoids, assuming that pain in that area is due to perineal trauma and healing. There are a variety of treatments ranging from topical applications to homeopathy, herbal remedies, hot or cold compresses, and acupuncture (Hartley 2003). There are no trials to show which of these treatments are most effective. Avoidance of constipation is important as it can make haemorrhoids more extensive and painful. Some midwives advise women to gently push the haemorrhoids back into place while having a warm bath or by using a lubricant such as KY Jelly or olive oil (Hartley 2003). As the effects of progesterone decrease, haemorrhoids should improve, but for a small number of women haemorrhoids can continue for up to a year after the birth and will often recur and be worse with subsequent pregnancies (Bick et al 2002).

Cardiovascular system

The cardiovascular system returns to a near pre-pregnant state rapidly following the birth. If there has been excessive bleeding at any time, an assessment of haemoglobin level would be useful in determining whether iron therapy is required. Women who are rhesus-negative, and their babies, should be assessed for anti-D gamma globulin through the direct Coombs' test (level of maternal antibodies in cord blood) and the Kleihauer test (number of fetal cells in maternal blood). If indicated, anti-D should be administered to the mother within 72 hours of the birth. It can also be administered antenatally to women who are Rhesus-negative and the National Institute for Clinical Excellence (NICE) supports its routine administration prophylactically for these women (NICE 2002).

Pregnancy and birth can predispose to venous thromboembolism because of the increased coagulability of the platelets. Early ambulation helps to reduce the risk of deep vein thrombosis or pulmonary embolism. The midwife needs to be aware of the signs and symptoms of both these complications and refer to a medical practitioner if she has any concerns. It is usual to check for pain, redness or swelling in the legs on a regular basis to rule out deep vein thrombosis and thrombophlebitis. This assessment will often lead to discussions regarding ankle oedema and promotion of health through exercise and reduced levels of smoking for those women who smoke.

Assessment of general health and common discomforts

Fatigue

Many women will express concern about being tired in the postpartum period and this often lasts for many months after the birth. Tiredness and fatigue are thought to be part of a continuum and are difficult to define (McQueen & Mander 2003). Tiredness can be defined as a temporary state that can be helped by resting or sleep, while fatigue is an unrelenting overall condition that interferes with the ability to function normally (McQueen & Mander 2003).

Fatigue is felt following prolonged activity and is a protective mechanism where the body slows down or stops, so that overuse is prevented and regeneration of the body can happen (Bick et al 2002). It is individual and is affected by psychological and environmental factors, although it is expected following physical exertion or long periods without sleep (Bick et al 2002). Most women are aware that high levels of tiredness can be expected following the birth because of the physical activity of giving birth followed by interrupted sleep patterns due to the needs of the baby. When tiredness becomes overwhelming, to the point of exhaustion, there can also be a strong association with anxiety and depression (Bick et al 2002). Extreme tiredness can affect how women care for their babies, and how they relate to their partners and other children (McQueen & Mander 2003).

Tiredness and fatigue can be caused by physical factors such as anaemia (which can be remedied with iron therapy once diagnosed) or infection, thyroid disorder or depression

(Bick et al 2002). Discussing the woman's feelings about her fatigue and what she thinks may be the cause can be helpful in identifying ways to reduce it. In their review of tiredness and fatigue, McQueen and Mander (2003) suggest that postnatal adjustment could be enhanced if childbirth education focused more on realistic expectations of motherhood. They suggest that women should seek help from support people for routine household tasks and activities in the postpartum period (McQueen & Mander 2003).

Backache

Backache is a common disorder among the general population and it can be a common complaint during pregnancy that often continues into the postpartum period. It is difficult to assess whether there is an increase in complaints about backache following childbirth (Bick et al 2002). An acute onset of backache should be referred to an appropriate practitioner for investigation immediately. For ongoing postpartum backache, women can be advised to remain active and try localised applications of heat and mild oral analgesia (Bick et al 2002). If the backache does not improve or continues for up to six weeks, referral to an appropriate practitioner such as a GP, physiotherapist, osteopath or chiropractor is advised (Bick et al 2002).

Headaches

Observational studies have found that headaches are relatively common after childbirth, although headaches are also common among the general population (Bick et al 2002). No comparative studies have yet been undertaken to determine whether headaches are more common in the postpartum period (Bick et al 2002). Headaches may be due to tension, lack of sleep and increased stress; or women who previously suffered from migraine headaches may find these recurring in the postnatal period (Bick et al 2002). Methods of alleviating tension and ensuring sufficient sleep need to be explored if headaches become more frequent, and analgesia such as paracetamol may be helpful.

The importance of support after the birth

Podkolinski (1998) researched women's experiences of postnatal support from a feminist perspective and using questionnaires, interviews and diaries from 10 women. She asked the women to comment on who had supported them during the postnatal period, how they had been supported, what they felt about the support they had received, whether they had felt special because of it and whether there was anything they would have liked that they did not receive. In this study, which was set in the United Kingdom, the majority of women received a daily visit from a midwife until 10 days post partum. Podkolinski (1998) found that the women's main source of support was a combination of their partner and their mother, although all women identified the midwife as an important source of support both in the hospital and at home. The type of support the women received from midwives included information and practical advice on baby care, advice on how to cope with a crying baby, encouragement and advice on breastfeeding, and advice about pain relief and self-care. Midwives also gave praise and reassurance, which helped to increase the women's confidence. This aspect of support

Critical thinking exercise

You are visiting Kelly, who is three days post partum following a normal birth at the local birthing unit. She was discharged home this morning and appeared to be recovering well until today. During your visit she is tearful and upset. She says she feels tired and aches 'everywhere'. The baby is feeding frequently and isn't settling between feeds. Kelly's partner has gone out to get some food and do some other errands.

1 What are the issues causing Kelly to be upset?
2 What is the midwife's role in this situation?
3 When will you plan to visit again?

BOX 26.3 Helping women in a maternity facility

Practical ways of helping women within a maternity facility environment:

- Promote a restful and caring atmosphere from all staff.
- Ensure regular meals and drinks are provided; have snacks readily available.
- Promote maternal and family contact with the baby.
- Control noise so that women can sleep/rest at appropriate times (Ockenden 2003).
- Provide consistent help and advice regarding baby care; use positive feedback.
- Provide consistent help and advice regarding breastfeeding (Ockenden 2003).
- Discuss pain and provide appropriate help with pain whether it be pharmacological or non-pharmacological management (Ockenden 2003).
- Give frequent praise and reassurance.
- Promote a family-friendly facility, and encourage family and friends to visit and provide extra support.
- Many women when stressed, tired or in pain find a warm bath relaxing and refreshing. Lavender oil in the bathwater appears to aid this relaxation and may be helpful as a way of reducing stress, helping to alleviate muscle fatigue and promoting the feeling of being cared for. Research suggests that having a bath can relieve perineal discomfort and other aches and pains, but that it does not reduce high levels of pain or improve healing of the perineum (Bick et al 2002). Adding salt or a disinfectant to the bath has not been proved to have any more benefits than bathing in water alone (Bick et al 2002).

BOX 26.4 Helping women at home

Practical ways of helping women at home:

- Ask friends, partners and family to help with household tasks; foster the idea that this should be normal within our society (Bick et al 2002; McQueen & Mander 2003).
- Be flexible about visits but ensure they are regular, giving a date and time for next visit.
- Have sufficient time set aside to listen, understand, reassure and give positive feedback.
- Discuss types of social support—how much does she have, is it enough and if not, how can she recruit more.
- Encourage the woman to accept a lower standard of tidiness and cleanliness within the house.
- Discuss the benefits of exercise, which can improve mood level and reduce tension and anxiety. A short walk every day or several times a week can be helpful (Bick et al 2002).
- Encourage women to have frequent short rests during the day (Bick et al 2002).
- Encourage healthy eating and ensure that dietary needs are being met (Bick et al 2002).
- Encourage discussion of problems or other concerns, such as finances, family relationships, lack of personal time. These may affect how a woman feels and copes (Symon et al 2003).
- Explain that 'perfect mothers' are a myth and that she only needs to be 'good enough'.

was highly valued by the women. When discussing what makes support good or bad, the women stated that it was the way in which support was offered and given. Perceptions of support were individual but support was felt to be intrusive and inappropriate when assumptions were made or when women did not feel listened to or treated as an individual. Podkolinski (1998) found that women sought emotional support from other women, whether friends, relatives or health professionals. It was the sense of a shared experience and reassurance that gave the women support and made them feel that they were not alone or different. It was these supportive relationships that women valued highly (Podkolinski 1998).

McCourt and colleagues (2000) suggest that one of the concepts of care and support is feeling that you are the centre of care and that people are interested and concerned with you and your welfare. They suggest that women expect good care, support, practical help and good communication from midwives (McCourt et al 2000).

Podkolinski (1998) identified that while all the women in her study needed support, the length of time and type of support needed by each woman varied. She suggests that midwives should help women establish their own support networks as well as trying to make women feel special, nurtured and cared for. Ockenden (2003) agrees and suggests that midwives can support women by trying to make motherhood a special time in which a new mother feels valued and cared for, by providing care based on individual need with a balance between support and physical monitoring.

Munday (2003) undertook a phenomenological study of women's experiences of the postnatal period following a home birth. The women participants commented on the positive effect the home birth had had on their partners and family, but were concerned by the lack of practical assistance in the home and with looking after other children. Because a home birth was seen as 'normal', the woman and family were not seen as needing any practical help.

Conclusion

The postnatal period is the final transition, a time of major life change and of potential stress as a woman becomes a mother and a couple become a family. Support from family, friends and health professionals is important and can affect the emotional wellbeing and coping ability of each individual. How a woman adjusts to her new role will depend on her previous experiences, her family and social roles as well as the birth itself. Postnatal care should help women achieve a smooth transition into motherhood with as much attention given to women's psychological and emotional adaptations as to their physical recovery.

Assessment of maternal wellbeing is based on knowledge of the physiological, psychological and social changes in the postnatal period and how these may affect the woman's recovery. Sharing knowledge and experience with women enables and supports them to monitor their own health. There is need for flexibility, sensitivity and understanding from midwives when providing postnatal care.

Women have traditionally helped each other following childbirth by helping with domestic chores or caring for other children. There should be a focus on encouraging women to seek practical help and support at home from family, friends and community support groups, so that women are not expected to manage alone. As women go through each phase of the postnatal period in their own time, the focus of the midwives' visits will change. Providing support to women is about giving practical help, advice, positive feedback and praise. It needs to be done in a sensitive and caring way, which is individual to each woman and her family. Women value the support of a midwife whom they know and who has established their confidence and trust.

Becoming a mother is challenging, exciting and difficult; it involves physical, social and emotional changes that women can manage successfully when provided with good care and support.

Review questions

1. Identify and describe the physiological changes that occur during the postpartum period.
2. What are the aims of postnatal care?
3. How can a midwife promote these aims?
4. How often should a midwife visit during the postnatal period?
5. Identify and describe the four phases of the postpartum period.
6. Discuss the physical assessment that a midwife should undertake during a postnatal visit.
7. Describe the range of emotions that could be felt by a woman in the postpartum period.
8. Identify the emotional and social adaptations that a woman and her partner make in the first few weeks after the birth of a baby.
9. What is support?
10. How can midwives support women during the postnatal period?

CHAPTER 27

Supporting the newborn infant

Jackie Gunn

Key terms

Barlow's test, birthmarks, brown adipose tissue, centile charts, core temperature, developmental dysplasia of the hips, ductus arteriosus, fetal breathing movements, fetal haemoglobin, foramen ovale, grasp reflexes, hyperthermia, hypogastric arteries, hypoglycaemia, hypothermia, hypoxia, immunisation, jaundice, lung fluid, meconium, neonatal examination, neurological examination, non-shivering thermogenesis, Ortolani's test, plagiocephaly, skin variations, sleep–wake state, thermogenesis, thermoregulation, vitamin K deficiency bleeding

Chapter overview

This chapter provides an overview of neonatal physiology and the transition to extrauterine life. It explains the knowledge and skills that midwives need for assessing neonatal wellbeing, including puerperal assessment. It concludes with an overview of the most common minor complications that affect the neonate's health.

Learning outcomes

Learning outcomes for this chapter are:

1. To promote understanding of neonatal physiology and the transition to extrauterine life
2. To promote understanding and assessment of physiological and social development of babies in the first weeks after birth
3. To develop assessment skills to monitor infant health, wellbeing and responses to physiological changes (including neonatal screening tests)
4. To enable midwifery practice that informs, educates and supports the baby's mother related to normal baby behaviour patterns, daily care and the minor complexities of the neonatal period
5. To promote understanding of evidence for midwifery care that supports the newborn infant
6. To describe how to undertake a comprehensive physical assessment of the newborn infant
7. To explain specific examination techniques
8. To outline the normal ranges for growth and development of newborns
9. To discuss the assessment of infant wellbeing and how to recognise a sick baby
10. To explain the minor complexities of the neonatal period
11. To discuss how to assist mothers to identify and manage baby emergencies.

Introduction

The neonatal (or newborn) period lasts from birth until 28 days of age (London et al 2003). Midwives care for women and their new babies for up to six weeks post partum. In Australia the period of postnatal midwifery care varies between states and between urban and remote settings. In New Zealand, women and babies are generally discharged from midwifery care at four weeks post partum, although visits may continue up to six weeks if there is a clinical requirement. Initial and ongoing monitoring of the health and wellbeing of the newborn infant is one of the primary purposes of ongoing midwifery care.

While much midwifery care for newborn infants involves information sharing, maternal support and day-to-day observations of normal growth and development, there are times when individual babies show behaviours or signs that are not quite as expected. At these times, midwives must use professional knowledge and judgement to assess the baby and to implement care that may include continued observation, midwifery intervention and/or referral to a medical practitioner. Women and their families expect that the midwife's practice and the information they receive is current and supported by available evidence.

Midwives are part of families' lives for a very short period. One of their major roles is to support and enable women to be confident mothers. Having knowledge of her baby's behaviour and development, understanding how to care for her baby, and reinforcement that she is a capable mother, all help to engender the mother's confidence.

Caring for newborn babies is not always part of young women's experiences before they have their own children, and therefore midwives are often in the position of supporting and guiding women as they learn to care for their new infant. In these circumstances, it is tempting for professionals to regard the baby as 'theirs' and to give women information in an instructional fashion that relegates the baby's mother to the role of 'outside' caregiver afraid to use her own common sense or to do things for her baby. At all times the midwife's client is the woman. The woman is the baby's mother. She generally knows whether her baby is doing well or not. Midwifery care is provided in partnership with the baby's mother, and therefore all midwifery observation, care, treatment and referral are undertaken only in consultation and agreement with her.[1]

Neonatal physiology and the transition to extrauterine life

This section explores neonatal physiology and the transition to neonatal life, in sections related to body systems.

Respiratory system

While functional at birth, the alveoli continue to mature until about eight years of age (London et al 2003; Michaelides 2004a). A term baby has approximately 8% of the adult numbers of alveoli (Hand et al 1990). Pulmonary, vascular and lymphatic structures differentiate during the first 20 weeks gestation. Alveolar ducts have begun to develop by 24 weeks of pregnancy and primitive alveoli appear by 28 weeks gestation. There are two types of alveolar cells: type I cells necessary for gas exchange, and type II cells for the synthesis and storage of surfactant (London et al 2003).

Surfactant

Surfactant is produced in the lungs in increasing amounts from 32 weeks gestation. It comprises phospholipids and specialised protein molecules that reduce the surface tension of the alveolar fluid at the air/alveolar interface, and contributes to the elasticity of lung tissue (London et al 2003; Varney et al 2004). As gestation increases, the lining of alveoli becomes thinner, increasing the surface area for eventual gas exchange and effectively fusing the capillary endothelium and alveolar basement membranes (Michaelides 2004; Novak 2005a). At term, the alveoli are lined with surfactant. Because surfactant reduces the surface tension in the alveoli, it reduces the tendency of the alveoli to collapse with each breath due to the elastic recoil of the lungs. Surfactant increases lung compliance and thus reduces the pressure required to inflate the lungs for inspiration (Michaelides 2004; Novak 2005; Varney et al 2004). Synthesis of surfactant is thought to be affected by acidosis and/or hypothermia (Michaelides 2004a).

Fetal breathing movements

Breathing after birth can be seen as a continuation of an intrauterine process. From as early as 11 weeks gestation, fetal breathing movements occur in order to develop the chest muscles and diaphragm (London et al 2003). As the fetus grows, the frequency and strength of breathing movements increases, until they reach 30–70 breath movements per minute and are present 40–80% of the time (Davis & Bureau 1987, cited in Michaelides 2004a, p 530).

Lung fluid

Lung fluid is not surfactant. It is a clear fluid that facilitates cell proliferation and differentiation. At birth the lungs' function changes from secretion of fluid to the absorption of gases. It is likely that the catecholamine surge at birth is the final trigger for this change (Milner & Vyas 1982, cited in Michaelides 2004a, pp 529). At birth the remaining fluid is either expelled through the upper airways or absorbed via the pulmonary lymphatic system (Michaelides 2004a). Within two hours of the birth of a healthy term neonate, about 80% of the fluid has been reabsorbed and is completely absorbed from the alveoli within 12–24 hours. The fluid is absorbed from the interstitial tissue into the pulmonary vasculature and lymphatic drainage over the next few days (Novak 2005a).

Clinical point

Monitoring 'wet' lungs

Occasionally audible rales and/or rhonchi may be present at birth. These sounds may be associated with lung fluid that has not yet been reabsorbed.

Observation and management:

- If:
  - the baby is full term, healthy and alert
  - respiratory rate is normal
  - colour is pink and maintained
  - the baby has good muscle tone
  - heart rate is within normal range and not increasing,

  recheck in 15 minutes.
- If the sounds are diminishing in audibility and harshness at this time: continue to check every 15 minutes.
- If the baby remains well and the sounds continue to diminish: continue to monitor until they have gone. They should have substantially cleared within an hour of birth.
- Refer to a medical practitioner if there are any or all of:
  - persistent or fluctuating colour change (dusky, cyanosis)
  - tachycardia
  - tachypnoea
  - reduced muscle tone
  - lethargy
  - lung sounds getting worse or not clearing.

(Source: London et al 2003)

Note: Transient tachypnoea of the newborn can occur in otherwise healthy babies (see Ch 38).

Clinical research

Oropharyngeal suctioning at birth

Routinely suctioning lung fluid from the baby's nose and oropharynx at birth was abandoned in most places more than a decade ago. However, where meconium is present in the liquor amnii, suctioning is practised, especially before the baby has taken the first breath.

Recent research has shown that even in the presence of meconium, routine suctioning a healthy newborn's oropharynx and nasal passages is contraindicated and may even be harmful (Vain et al 2004) (see Ch 36).

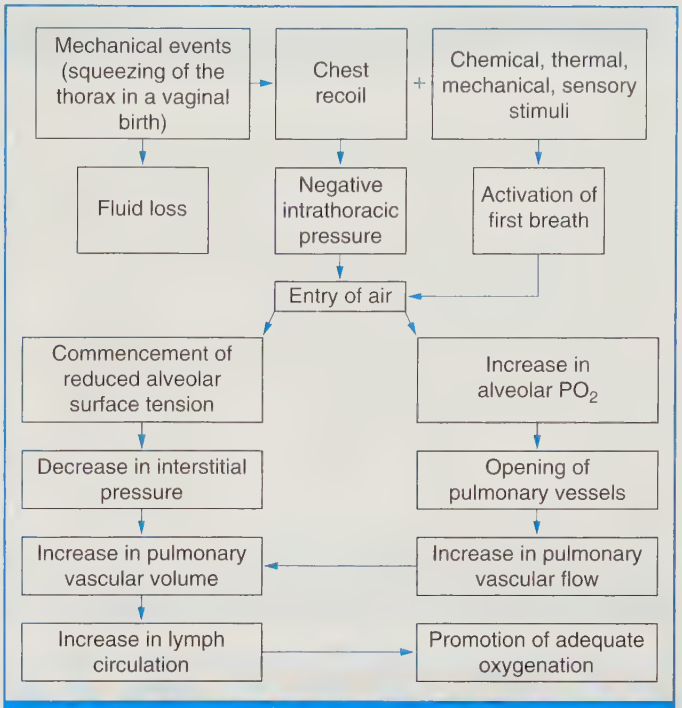

Figure 27.1 Initiation of respiration (based on London et al 2003)

First active breath

Most babies gasp and establish respiration at birth. The lungs are expanded within the first few breaths. Alveolar inflation is complete a few hours after birth, resulting in a fairly consistent lung volume of 25 mL/kg body weight (Coad & Dunstall 2001; Novak 2005a).

Factors initiating the first breath and lung expansion are:

- *compression of the chest wall during birth and the recoil of the chest wall immediately after birth.* Chest compression and recoil expand intrathoracic capacity, stimulating the baby to take a breath. Lung fluid is displaced through the nose and mouth or across the alveolar walls into the interstitial space, and the mechanism essential for effective respiration and pulmonary gas exchange is triggered (Novak 2005a). Significant negative intrathoracic pressure of up to 9.8 kPa (100 cm of water) is produced as the lung fluid is emptied and the pulmonary tissue and vasculature expand. Much less pressure is needed for subsequent breaths (Farrell & Sittlington 2003a).
- *chemoreceptor stimulation by reduction in oxygen and increase in carbon dioxide in the blood.* Normal labour results in mild hypoxia, hypercapnia and acidosis, which stimulate respiration. Physiological hypoxia and hypercapnia trigger the establishment of the respiratory drive in the respiratory centre in the medulla oblongata (Farrell & Sittlington 2003a; Novak 2005a). The chemoreceptors are less responsive in the first few days after birth (Blackburn 2003), emphasising the major role of chest recoil and absorption of fluid in facilitating the first breaths.
- *other external stimuli* such as cold, light, noise, touch and pain are secondary triggers for the baby to take the first breath.

Neonatal breathing patterns

At birth the respiratory system is immature. Neonates have shallow, irregular breathing and breathe through the nose for the first two to three months. 'Babies are obligatory nose breathers and do not convert automatically to mouth breathing when nasal obstruction occurs' (Farrell & Sittlington 2003a, p 729). On auscultation, breathing may sound noisy and wet during the first one to two hours while any remaining fluid is cleared from the lungs (Varney et al 2004) (see 'wet lungs' Clinical point).

The normal baby has an average respiratory rate of 40 breaths/minute (range is 30–60 breaths/min; see Table 27.1). Breathing is diaphragmatic—the chest and abdomen rise and fall together. Such symmetry confirms that the lungs and diaphragm are functioning correctly. Newborn babies commonly have periods of irregular breathing, particularly during REM sleep. The irregular gaps between breaths are termed apnoea. Apnoea of less than 20 seconds is not usually of clinical concern.

Clinical point

Assessing neonatal respiratory rate

- Record when the baby is quiet or asleep.
- Always count for a full minute.
- Assess the baby's colour
- Observe for any signs of respiratory difficulty (see Table 27.1).

Counting respirations when the baby is clothed can be difficult. The following methods are practical ways to count the rate without disturbing the baby.

- Listen through the diaphragm of a stethoscope held a few centimetres from the baby's nose.
- Feel the rise and fall of the baby's abdomen through a hand placed on the baby's abdomen.

While an elevated respiratory rate is a sign that the baby is unwell, tachypnoea cannot be assessed without taking the baby's other behaviour into account, such as recent crying, feeding or sleeping (Farrell & Sittlington 2003a; Michaelides 2004a). A baby's cry is loud and of medium pitch. Over time, mothers learn to distinguish variations in crying and to attach meaning to them (e.g. hungry, wet, in pain).

Cardiovascular system

Note that respiratory and cardiovascular changes occur simultaneously and are mutually dependent (Farrell & Sittlington 2003a).

Cardiovascular adaptations at birth

Cardiovascular adaptations that occur at birth are outlined in Table 27.2.

Pulmonary oxygenation of blood

In uterine life, 5–10% of cardiac output enters the pulmonary circulation to meet pulmonary cellular growth and nutrition needs. High pulmonary vascular resistance and the patent ductus arteriosus ensure that the remainder of the cardiac output enters the arterial system. At birth, adjustments must be made to the baby's circulation so that deoxygenated blood can go to the lungs for oxygenation. This involves several mechanisms. The expansion of the lungs and lowered pulmonary vascular resistance that occurs with the first breath enables virtually all the cardiac output to enter the pulmonary circulation. The oxygenated blood returning to the heart via the pulmonary veins increases the pressure within the left atrium (Farrell & Sittlington 2003a; Michaelides 2004a).

Closure of foramen ovale

The foramen ovale is an opening in the atrial septum created by a flap of tissue that is kept open in fetal life by the higher pressure of the blood in the right atrium. At birth, the vessels in the umbilical cord constrict, the cord is clamped and the

TABLE 27.1 Neonatal breathing patterns

	Normal variations	Outside normal variations (any or all of these)
Rate	40 breaths/minute average Range 30–60 breaths/min (sleeping or in quiet alert state)	More than 60 breaths/minute (sleeping or in quiet alert state)
Rhythm	Regular and irregular periods Apnoea < 20 seconds	Irregular breathing Apnoea > 20 seconds
Chest/abdominal movement	Synchronised diaphragm and abdominal movement	Subcostal and /or intercostal in-drawing
Nose	Breathes through the nose, no nasal flaring	Flaring of nostrils
Sound	Silent	Expiratory 'grunt'
Colour	Pink	Pale/cyanosis

(See Ch 38 for respiratory distress syndrome.)

TABLE 27.2 Fetal and neonatal circulation

System	Fetal	Neonatal
Pulmonary blood vessels	Constricted, with very little blood flow; lungs not expanded	Vasodilation and increased blood flow; lungs expanded; increased oxygen stimulates vasodilation
Systemic blood vessels	Dilated, with low resistance; blood mostly in placenta	Arterial pressure rises due to loss of placenta; increased systemic blood volume and resistance
Ductus arteriosus	Large, with no tone; blood flow from pulmonary artery to aorta	Reversal of blood flow; now from aorta to pulmonary artery because of increased left atrial pressure. Ductus is sensitive to increased oxygen and body chemicals and begins to constrict.
Foramen ovale	Patent, with increased blood flow from right atrium to left atrium	Increased pressure in left atrium attempts to reverse blood flow and shuts one-way valve.

(Source: London et al 2003)

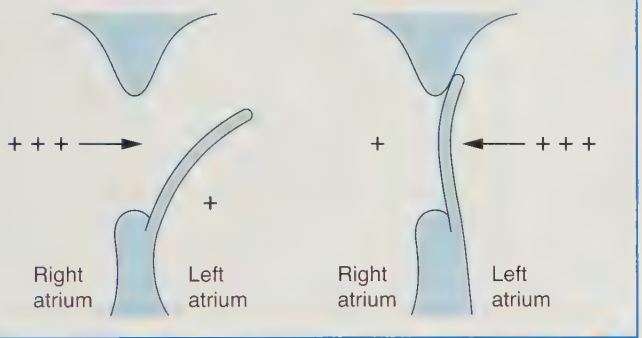

Figure 27.2 Closure of the foramen ovale (based on Coad & Dunstall 2001)

Clinical point

Temporary cardiovascular structures in fetal life

The following structures are not required for neonatal life, and become non-functional after birth:

- umbilical vein
- ductus venosus
- foramen ovale
- ductus arteriosus
- hypogastric arteries
- umbilical arteries.

pulmonary vasculature expands. These events result in a fall in right atrial pressure and a rise in left atrial pressure. The pressure alterations, especially the higher left atrial pressure, cause the flap of the foramen ovale to be pressed flat against the septum and therefore to functionally close. Flow murmurs in the first 24–48 hours post partum may be the result of incomplete closure of the foramen ovale and persist until the pressures stabilise and the foramen stays closed. In the first days after birth, closure is reversible; if pulmonary vascular resistance is high—for example, when crying—transient cyanotic episodes may occur as a result of the foramen temporarily reopening. The foramen anatomically closes within the first year of life (Farrell & Sittlington 2003a; London et al 2003).

Closure of the ductus arteriosus

In fetal life, the ductus arteriosus is nearly as wide as the aorta. Blood is shunted directly from the pulmonary artery to the aorta via the ductus arteriosus, thereby avoiding the lungs. At birth, the pulmonary vascular resistance falls and the amount of blood being shunted to the aorta via the ductus arteriosus is substantially decreased. Contraction of the muscular walls of the ductus arteriosus occurs almost immediately after birth. Decreasing levels of maternal prostaglandin (previously supplied by the placenta) and rising arterial oxygen tension trigger vasoconstriction. The ductus arteriosus is usually functionally closed by 8–10 hours after birth, but not anatomically closed for several months. Before pressures stabilise, a temporary reverse shunt through the ductus arteriosus may persist for a few hours. In some babies the ductus has been shown to be intermittently patent up to three days after birth (Farrell & Sittlington 2003a; Michaelides 2004a; Novak 2005a).

Adaptation of other temporary fetal cardiovascular structures

Clamping the cord causes the foramen ovale and hypogastric arteries to functionally close almost immediately. Anatomical closure occurs within two to three months. The resulting fibrous structures are known as the ligamentum venosum and ligamentum teres. The superior vesical arteries are the vestiges of the hypogastric arteries (Farrell & Sittlington 2003a).

Characteristics of neonatal cardiac function

- Heart rate—in the first week after birth the average heart rate is 110–150 beats per minute in a quiet, healthy, term neonate. However, wide fluctuations occur when the baby is active, feeding or asleep (Farrell & Sittlington 2003a; London et al 2003).

- Peripheral circulation—the healthy term baby's hands and feet are mildly cyanosed (acrocyanosis) for several hours after birth until peripheral perfusion is complete.
- Blood volume and blood pressure—systolic blood pressure varies with gestation, birthweight and neonatal activity such as crying. It is not usually assessed in healthy term infants (London et al 2003). At birth, the total circulating blood volume is 80 mL/kg of body weight (i.e. 280 mL for a 3.5 kg baby) (Blackburn 2003). The relatively low total circulating blood volume means that quite small quantities of blood represent a large blood loss for the neonate (e.g. 10% of adult blood volume is 800 mL; 10% of a 3.5 kg baby's blood volume is 28 mL).
  Attentive concern is required when assessing blood loss from the cord or the amount of blood taken for laboratory analysis.

Heart murmurs

Heart murmurs are sounds that may be heard as blood flow is disturbed as it crosses an abnormal valve, as it flows under pressure through a defect in either the atrial or ventricular septum, or sometimes when there is increased flow as it crosses a normal valve. In neonates, 90% of all murmurs are transient and not associated with anomalies (London et al 2003).

Clinical point

Neonatal heart murmurs

Murmurs are not heard if there is nothing to make the flow turbulent. Many serious cardiac malformations are silent, and therefore midwives need to always be observant for systemic signs of cardiac compromise—colour, respiratory rate, muscle tone, feeding problems and so on (see Ch 38).

Clinical point

Why large cardiac septal defects are usually silent

Flowing fluid does not make a noise if it is not under a lot of pressure. Think of the absence of noise when water flows through a wide-bore hose. When fluid is forced through a small opening, the pressure is raised and the resulting turbulence creates a noise. Think of the way water begins to hiss when pressure is increased by a thumb partially closing the opening of a wide-bore hose. Large defects in the atrial or ventricular septa allow the blood to flow through the defect with little or no change in pressure. Consequently there is no turbulence and no is sound made. Diagnosis of large cardiac anomalies is nearly always made through clinical observation of babies and their behaviour.

Thermoregulation

Newborn babies sustain life within a narrow range of core (internal) body temperature, generally 36.5–37.5°C (Blackburn 2003). The body uses a number of mechanisms to balance heat loss and heat production in order to maintain the core temperature within this range despite a wide range of environmental temperatures. Balancing heat loss and gain is known as thermoregulation. The range of ambient temperature that maintains a baby's core body temperature using minimum oxygen consumption at a minimum metabolic rate is called the thermoneutral range (Blackburn 2003; London et al 2003).

At birth, babies' thermoregulatory mechanisms are not fully developed, although they become progressively more efficient. Limited response to temperature changes in the first 24 hours of life results in babies being particularly susceptible to chilling during this time. By 24–48 hours of age, healthy term neonates are able to increase their heat production up to 2.5 times in response to cold; however, they remain susceptible to environmental temperature changes. Until the mechanisms controlling thermoregulation (and heat loss in particular) stabilise, the thermoneutral range of babies is at a higher environmental temperature than older children and adults. In the first weeks of life, warm rooms, or extra clothing and blankets if outside, are required (Blackburn 2003; Michaelides 2004b; London et al 2003).

Neonatal features contributing to heat loss:

- large surface area to mass ratio (approximately three times greater than adults). In particular, a baby's head, the major heat loss area in a clothed baby, is a larger proportion of the body than is an adult's.
- less subcutaneous fat
- thin epidermis
- blood vessels closer to the skin, so changes in the ambient temperature more readily influence the circulating blood, thereby influencing the temperature-regulating centre in the hypothalamus
- decreased ability to shiver.

Neonatal features contributing to heat production:

- decreased ability to sweat
- flexed posture, which conserves heat by reducing exposed surface area
- non-shivering thermogenesis (Blackburn 2003; London et al 2003; Michaelides 2004b).

Neonatal heat loss

Heat is very easily lost at birth, when autonomic thermoregulation is at its least efficient and the baby is wet. Hypothermia (a temperature less than 36.5°C) can occur rapidly unless active steps are taken to prevent heat loss.

There are four ways in which babies can lose heat from their body surface:

- Evaporation—heat loss occurs when water evaporates as vapour from the skin. Babies are particularly vulnerable to cooling by evaporation at birth and during bathing if the environmental temperature is too low. A birthing room temperature of at least 25–28° C is needed, to

prevent heat loss at birth. Minimising the time the baby is wet by careful drying also helps to prevent heat loss by evaporation.

- Convection—cooler air passing over a warm baby causes heat loss by convection. Preventive measures include eliminating cool air flows from draughts and air conditioning. Oxygen given by mask or by oxygen catheter can cause heat loss by convection.
- Conduction—coming into direct contact with a colder surface can rapidly cool a baby. Items such as cold hands, clothes and bedding, weighing scale trays and stethoscope diaphragms fall into this category. All such items should be warmed before coming into contact with the baby's skin.
- Radiation—radiant heat loss happens when heat is transferred from the body to cooler objects not in direct contact with the baby; for example, bassinets or cots placed against external room walls or under windows can cause heat loss by radiation (Blackburn 2003; London et al 2003; Michaelides 2004b; Novak 2005b).

Neonatal thermogenesis

Neonates rarely shiver. They generate heat by increasing their metabolic rate using muscular activity such as moving limbs and suckling, and by chemical thermogenesis (heat production), also called non-shivering thermogenesis (Blackburn 2003).

Thermogenesis and brown adipose tissue

Heat production by chemical means involves the metabolism of brown adipose tissue (BAT). Approximately 2–7 % of neonatal body weight is thought to be BAT or brown fat. It begins to be deposited in the fetus from 26 weeks gestation, steadily increasing in amount until two to five weeks after birth. At term, BAT is deposited around the nape of the neck and mid-scapular area, under the clavicles and in the axillae, around the kidneys, adrenal glands and large vessels in the neck and in the mediastinum (London et al 2003; Novak 2005b). Maternal prostaglandins and adenosine prevent non-shivering thermogenesis in utero; BAT is only activated after birth. Brown fat stores are not renewable once they have been used (Michaelides 2004b).

Clinical point

Heat loss in preterm and SGA babies

Preterm infants and small for gestational age (SGA) babies have less adipose tissue and a greater surface area to mass ratio than full-term babies. Furthermore, the lower the gestational age, the less brown adipose tissue (BAT) is deposited and the less the body and limbs are flexed. Consequently these babies are extremely vulnerable to hypothermia. They require a higher environmental temperature to maintain a thermoneutral range (London et al 2003).

Brown adipose tissue is so-named because of the colour that results from the tissue containing a more extensive blood supply and greater numbers of intracellular organelles such as mitochondria, than white adipose tissue. Neonatal cooling causes noradrenaline, other catecholamines and thyroid hormones to be released so that rapid lipolysis of brown adipose tissue and consequent heat production is induced. Oxygen and glucose are required in the metabolism of brown fat. Brown fat lipolysis uses up to three times as much oxygen as other tissue. Normal oxygen consumption, conservation of brown fat stores and maintenance of core body temperature are promoted by keeping babies in a thermoneutral range. (Blackburn 2003; Farrell & Sittlington 2003a; London et al 2003; Novak 2005b).

Maintaining temperature after birth

At birth, healthy term babies are placed against their mothers' body skin-to-skin, dried and covered with a warm blanket to maintain their temperature. A mother's body conducts direct warmth to the baby, and the blanket traps a layer of warm, insulating air around the baby (Blackburn 2003; Michaelides 2004b). Studies of preterm babies in Colombia and England showed that 'kangaroo care' (skin-to-skin between the mother's breasts) satisfactorily maintains body heat (Sleath 1985; Whitelaw et al 1988).

The following methods are commonly used to conserve heat in newborn infants.

- Place the baby in immediate skin-to-skin contact with the mother.
- Dry the baby immediately.
- Pre-warm any hats, blankets and clothing prior to the birth.
- Pre-warm the resuscitation area.
- Maintain the temperature in the birthing room at > 25°C.
- Replace wet blankets or towels after drying the baby.
- Do not bath the baby until temperature has been stable for two hours.
- Do not place the bassinet against windows, outside walls or doorways.
- In cooler environments, keep the baby's head covered and body well wrapped (McHugh 2004).

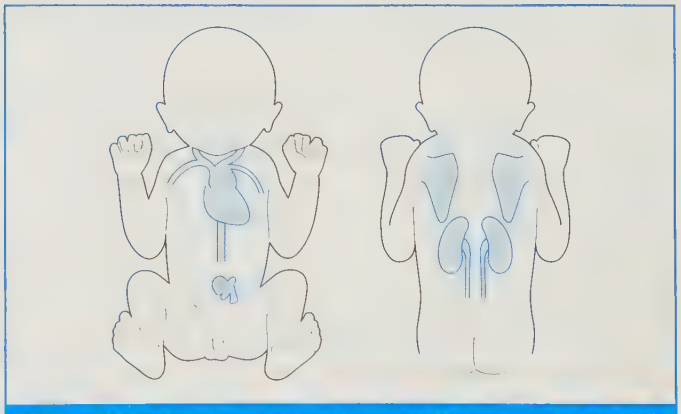

Figure 27.3 Brown adipose tissue (BAT) deposits in the term neonate (based on Stables & Rankin 2005)

Wrapping babies

While warm towels, blankets and clothing are a necessity and many babies appear to prefer being firmly wrapped, overly tight wrapping prevents the movement that generates heat. The baby's clothes should not be too tight. It is better to use several thin layers than one or two thick layers (natural fabrics 'breathe' better than synthetics). Hats, especially for small and preterm infants, have proved effective in reducing heat loss from the head in cool environments or when heat loss is a concern. When transporting small or sick babies, a thermoblanket that retains body heat is used (London et al 2004; Michaelides 2004b).

Hot water bottles and electric blankets

These items are used only for heating fabrics and must never be left in the cot with the baby. This is also true of wheat bags or anything else that retains heat in a similar way, such as gel packs.

Bathing and temperature maintenance

Babies are no longer bathed immediately after birth unless there is a risk of vertical transmission of an infection from the mother, such as hepatitis B or HIV. Bathing soon after birth increases the risk of hypothermia, and therefore it should not be undertaken until the baby's temperature has stabilised (Leveno et al 2003). Breastfeeding is more important, both to initiate feeding and to provide fuel for the baby's metabolic processes, including temperature maintenance. Although babies' thermoregulatory mechanisms become more efficient as the days pass, bathing remains a time when they can be easily chilled. The following precautions should always be taken:

- Bathe the baby in a draught-free room.
- Ensure the ambient temperature is 25–28°C.
- The baby's temperature should be within the normal range.
- Water temperature should be 36.7°C (similar temperature to skin when tested with the inside surface of an adult's wrist).
- Warm the towels and clothing.
- Do not expose the baby unnecessarily (e.g. keep wrapped in a towel while bathing the head).
- Dry the baby promptly and thoroughly, especially the hair and in the folds of the skin (London et al 2003; Michaelides 2004b; Varney et al 2004).

Impaired thermoregulatory control

Neonatal hypothermia

If the neonate's temperature falls below 36.5°C, the baby is at risk of hypothermia. *Prevention is the best treatment.* A mildly hypothermic baby (36–36.5°C) can generally be warmed without difficulty by tucking up skin-to-skin with the mother in a warm (≥ 25°C) room if stable, or by placing in an incubator set at 35–36°C. In the latter situation the baby should be clothed but not under a blanket (Blackburn 2003; London et al 2003; Michaelides 2004; Novak 2005b). Untreated hypothermia can result in generalised vasoconstriction that includes the pulmonary vessels. Pulmonary vasoconstriction results in decreased pulmonary perfusion that affects pH, PaO_2 and $PaCO_2$ levels. Increased $PaCO_2$, decreased PaO_2 and pH levels result in respiratory acidosis. Consequently the baby

Clinical point

Neonatal temperature measurement

- **Axillary temperature**
  This is the preferred site.
  Note: In a hypothermic baby, the reading will be higher than the core as the area contains large areas of brown fat (Bliss-Holtz 1991). As this may make recognition of hypothermia more difficult, behavioural and other physiological signs should also be assessed when the temperature is taken.
- **Rectal temperature**—It is considered preferable to routinely measure the temperature via the axilla; however, core temperature may be required in individual situations. The rectal temperature *measures the core temperature and is the most accurate*. It is used when the axillary temperature is abnormal; e.g. check rectal temperature if axillary temperature is < 36.5°C.
  Measuring a newborn's rectal temperature: The well-lubricated thermometer should be gently inserted no more than 3 cm into the rectum of the term baby and no more than 2 cm in the preterm baby (Blackburn 2003; Fleming et al 1983).
  The baby's legs need to be held still during this procedure and great care taken to ensure that the rectum is not damaged. For this reason, many institutions prohibit this procedure.
- **Tympanic temperature**—As the reading is often affected by environmental temperature, this site is less accurate for newborn babies and *should not normally be used*. Wells et al (1995) showed that readings were 0.5–1.0°C higher than the core temperature when the environmental temperature was > 30°C, and 0.5-1.0°C lower when environmental temperature was < 30°C.
- **Skin sites**—For a rapid general assessment of temperature, skin sites can be useful.
  - Feeling the forehead or the back of the neck with the inside of the wrist can provide a quick check, to decide whether the baby needs extra clothing for example.
    The area between the scapulae, the abdomen and the feet can fulfil the same assessment. However, it needs to be remembered that the feet are cooler than the rest of the body, which makes this assessment less valuable.
- **Commercial 'spots' or 'tapes'**—used on the skin these are a non-invasive method for taking the temperature that parents may find useful as the baby grows older.

Clinical point

Relationship between hypothermia, hypoxia and hypoglycaemia in neonates

- Healthy neonates have limited stores of glycogen and brown fat and are vulnerable to rapid heat loss.
- Preterm infants have less glycogen stores and brown fat and greater vulnerability to heat loss than term babies.
- Hypothermia leads to brown fat lipolysis to restore the temperature. The process consumes oxygen and glycogen.
- Hypoglycaemia leads to mobilisation of glycogen stores to restore serum glucose levels. The process of converting glycogen to glucose requires oxygen and heat. Glycogen stores are depleted.
- Hypoxia leads to anaerobic methods of oxygen production. These inefficient processes require heat and glucose. Glycogen stores are depleted.

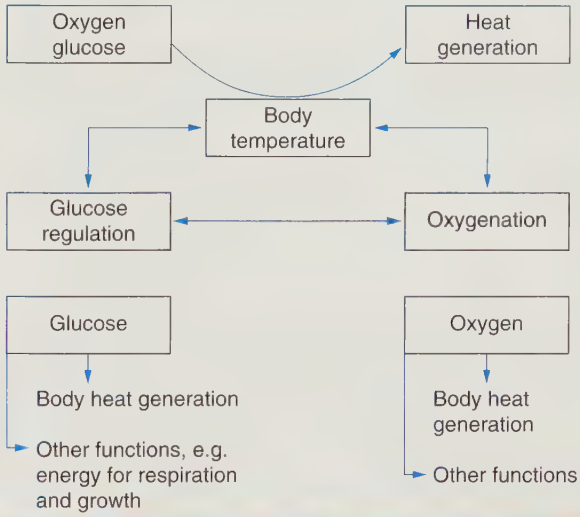

Figure 27.4 Interrelationship between temperature regulation, glucose concentration and respiration (based on Coad & Dunstall 2001)

exhibits signs of respiratory distress (Farrell & Sittlington 2003).

Underscoring the need for active steps to prevent heat loss is the fact that in newborn babies there is an interrelationship between hypothermia, hypoxia and hypoglycaemia, where the development of any one condition puts the baby at risk of the other two conditions.

Neonatal hyperthermia

Hyperthermia is a temperature above 37.5°C and is much less common than neonatal cooling. It can be as harmful as hypothermia if it is ignored. The most common cause of neonatal hyperthermia is under-estimation of the effect of the environmental temperature on the baby (e.g. putting the bassinet next to a heater). Babies can develop hyperthermia in response to an infection, environmental overheating or occasionally an underlying medical condition. Clinically discriminating between environmental factors and an infection can be extremely difficult, as babies with an infection can have a temperature below 37.5°C, while a temperature above 37.5°C can be the result of environmental factors. It is important to assess the whole clinical picture rather than rely solely on temperature as a guide.

Medical consultation is warranted when the temperature is above 37.5°C without an obvious environmental cause, such as direct sunlight in a well-heated room, or when the baby has a lower temperature but is exhibiting other signs of unwellness, such as not feeding. Similar consultation would be made if the temperature has not returned to normal within an hour of correcting an environmental cause (Farrell & Sittlington 2003a; Michaelides 2004b).

In the case of overheating due to an environmental cause, the baby should be slowly cooled by removing bootees and hat, exposing hands to the air and leaving the baby under a single blanket or sheet. Extremes such as removing all covers or cool bathing must be avoided, as rapid cooling can precipitate excessive heat loss and shock (Michaelides 2004b).

Clinical alert!

Clothed babies who become hypothermic in an appropriately warm environment need *very prompt* medical assessment and investigation, especially for infection. In these circumstances the low temperature is likely to indicate a serious illness (usually an infection) rather than an environmental cause for the hypothermia.

Referral must not be delayed.

A low (or raised) temperature may be the only sign of early onset Group B streptococcal infection. Unexpected hypothermia in an otherwise well baby is *always* abnormal.

Haemopoietic system

Haemoglobin concentration

The fetal circulation enables fetal blood to be oxygenated at the placental site and to be transported to the brain and other vital organs as efficiently as possible. This is assisted by high concentrations of fetal haemoglobin (HbF), a type of haemoglobin that has a higher affinity for oxygen than adult haemoglobin. After birth the neonate is exposed to higher oxygen levels associated with breathing air. As the red cells with fetal haemoglobin are haemolysed, they are replaced by cells containing adult haemoglobin with a lower affinity for oxygen. Neonatal red blood cells have a shorter lifespan than adult cells and as they are destroyed this produces elevated

serum bilirubin levels and physiological jaundice in some babies (Johnston et al 2003).

The haemoglobin level is initially high (130–200 g/L), and 50–85% of this is fetal haemoglobin. The levels decrease gradually, with changes apparent in the first week after birth (see Table 27.3), and fall to approximately 120 g/L by three months of age. Conversion from fetal to adult haemoglobin, which is commenced in utero, is completed in the first one to two years of life (Blackburn 2003; Michaelides 2004a).

Red blood cells, haematocrit and leucocytes

After birth the red blood cell (RBC) count gradually decreases as adult-sized red cells replace the larger HbF red cells. Neonatal RBCs have a lifespan of 80–100 days, approximately two-thirds of the lifespan of adult RBCs. In the first days after birth, the haematocrit (PCV) may increase above fetal levels as a result of placental transfusion and diminished extracellular fluid volume. The RBC count ($5–7 \times 10^{12}$/L) and haematocrit levels (55%) decrease gradually during the first two to three months of life. During this time, erythropoiesis is suppressed due to the relatively high hyperoxide environment that the neonate is exposed to after birth. Erythropoietin release is reduced due to lack of hypoxic stimulus (Blackburn 2003; Roberton 1996).

The leucocyte or white blood cell (WBC) count is initially high ($1–25 \times 10^9$/L) but decreases rapidly (Roberton 1996). Immature leucocytes, such as band neutrophils, are present in cord blood but disappear as transitional changes take place.

An elevated level of immature neutrophils is an indicator of infection.

Clotting factors

Colonisation of the intestine by the bacteria that synthesise vitamin K does not occur until milk feeding is established. Therefore, blood clotting is impaired in the first week post partum while levels of vitamin-K-dependent clotting factors II (prothrombin), VII, IX and X are low. Adult levels of platelets are present, but their capacity for adhesion and aggregation is reduced (Blackburn 2003; Michaelides 2004a).

Vitamin K prophylaxis

It is unclear why newborn infants have reduced levels of vitamin K dependent clotting factors; it has been postulated that it may be related to fetal growth regulation (Blackburn 2003). If vitamin K is not administered parenterally, the natural course is for the vitamin K levels to initially decrease as maternally acquired vitamin K is used. Neonatal vitamin K stores then increase gradually over the first month (Blackburn 2003).

Vitamin K deficiency bleeding

In some babies, the decline in vitamin K after birth leads to haemorrhagic disease of the newborn, now called *vitamin K deficiency bleeding* (VKDB). VKDB occurs in an early (< 48 hours), classic (2–7 days) or late (1 week – 6 months) form (Blackburn 2003). The natural prevalence of the classic form is 4–17 per 1000 (Greer 1995; Zipursky 1999).

The risk of late VKDB without and with vitamin K prophylaxis in Europe and Australia is shown in Table 27.4.

Breastfed babies are more at risk of haemorrhagic disease than formula-fed infants because formula contains vitamin K. Unfortunately, it is difficult to predict which babies

TABLE 27.3 Normal neonatal blood values*

	Cord blood	Day 1	Day 2	Day 3	Day 4	Day 5–14	Week 2–5
Hb (g/L)	136–196	165–215	165–215	165–215	165–215	150–200	110–185

will develop VKDB as babies without specific risk factors can develop classic VKDB (Zipursky 1999). Because of these factors, prophylactic vitamin K at birth is recommended to prevent VKDB (Blackburn 2003; NZCOM 2001).

Routine vitamin K prophylaxis

The need for routine prophylaxis for all babies has been questioned since Golding et al (1990, 1992) published the results of a study that linked administration of intramuscular (IM) vitamin K to increased risk of childhood cancer. Several later reports have not demonstrated the same relationship (McKinney et al 1998; Olsen et al 1994; Passmore et al 1998; Zipursky 1996). While some methodological criticisms have been made of some of these later studies, in places where routine use of IM vitamin K was stopped or replaced by oral doses subsequent to the Golding et al study, the incidence of VKDB increased (Passmore et al 1998; Zipursky 1996). It is probable that vitamin K prophylaxis is not needed at birth by every baby; nevertheless, because it is not possible to identify those who do need vitamin K with any certainty, prophylaxis is policy in most maternity services. The New Zealand College of Midwives Consensus Statement (2001) supports vitamin K prophylaxis. In Australia, most babies are given Konakion®. The NHMRC (2000) recommends that an IMI dose of Konakion® be given to all newborns as prophylaxis against VKDB. A selective policy of vitamin K administration after screening is not appropriate, because a relatively high incidence of late VKDB occurs without prophylaxis. However, there is sufficient evidence to show that oral regimens are effective.

Informed consent

Depending on local policy, IM or oral vitamin K is given at birth. Maternity care providers have a responsibility to provide access to information and discussion. Parents need time to consider the information related to vitamin K prophylaxis. It is preferable that they receive written information and an opportunity to discuss their choices during pregnancy so that their decision can be recorded in their plan of care.

Dosage

After the Golding et al report, several studies were carried out comparing different dosage regimens (Cornelissen et al 1992; Greer et al 1998). The conclusions drawn from these studies are as follows:

- IM or oral vitamin K improves the neonate's coagulation status in the first week (Farrell & Sittlington 2003a).
- A single dose (1 mg) of IM vitamin K at birth effectively prevents classic VKDB.
- The effectiveness of intramuscular vitamin K in the prevention of late VKDB has been established (Loughnan et al 1999, cited in NZCOM 2001).
- The effectiveness of oral vitamin K in the prevention of late VKDB has been not established (Zipursky 1999).
- Local policies relating to the administration of oral vitamin K may differ. The three-dose regimen is common. The doses are usually spread across the first six weeks of life (e.g. at birth, one week and six weeks) (NZMOH 2004).

Immunological adaptations

Functional immaturity of the immune system and lack of exposure to common microorganisms at birth means that babies are very vulnerable to infections, particularly respiratory and gastrointestinal infections. Antibody-mediated and cell-mediated immunity, the inflammatory response and complement factors are different in newborn infants. Neonates cannot localise infections very well, and so an infection is more likely to become systemic. The immaturity of the gut defence mechanism increases the likelihood of both gastrointestinal infection and later development of allergies (Blackburn 2004; Farrell & Sittlington 2003b; Novak 2005b; Varney et al 2004). Both commensal and pathogenic microorganisms begin to colonise the baby during birth. Colonisation occurs first from the maternal genital tract, then from the mother's skin, and finally from other people and the general environment (Novak 2005b).

Specific immune responses

Antibody-mediated immunity

At birth the neonate has 55–80% of the adult total immunoglobulin values (IgG, IgA and IgM) (Blackburn 2003).

- Immunoglobulin G (IgG)—the baby's levels of IgG are equal to or slightly higher than those of the mother as maternal IgG is transferred across the placenta. Transfer increases progressively until term. The maternal IgG gives the baby some degree of passive immunity to the diseases to which the mother has antibodies, for approximately six months. After birth, levels fall gradually as the transferred IgG is used. The baby does not develop significant production of IgG until after six months of age. Adult levels are reached over four to six years (Blackburn 2003; Michaelides 2004a; Novak 2005b).
- Immunoglobulin A (IgA)—newborn levels of IgA and IgM are low, as the molecules are too large to cross the

placenta. IgA is important for localised immunity in the gastrointestinal and respiratory tracts. It is found in saliva, tears, and intestinal mucosa by two to three weeks of age, although adult levels are not reached in the saliva for two months. Maternal secretory IgA is also transferred to the baby in colostrum and breast milk, affording local protection to the gut. IgA levels reach 20% of adult levels by one year (Blackburn 2003; Farrell & Sittlington 2003b; Novak 2005).

- Immunoglobulin M (IgM)—at term the baby's IgM level is 20% of the adult value, which is not reached for two years. In utero, IgM is able to be formed after 19–20 weeks gestation in response to exposure to certain antigens, such as the TORCH organisms. IgM protects against blood-borne infections and is the main immunoglobulin produced in the first four weeks of life. Half the adult value of IgM is reached by six months of age (Blackburn 2003; Farrell & Sittlington 2003b).

Cell-mediated immunity

- Lymphocytes—at birth, T cell numbers are similar to those of adults but their function is decreased for approximately three to six months (Blackburn 2003). 'The thymus gland, where lymphocytes are produced, is relatively large at birth and continues to grow until eight years of age'(Farrell & Sittlington 2003b, p 730).
- Polymorphonuclear neutrophils and complement—immaturity of the polymorphonuclear neutrophils alters the inflammatory response and phagocytosis in neonates. Neonatal polymorphonuclear neutrophils are structurally more rigid, respond more slowly to antigen stimulus, move more slowly to the antigen site and are less efficient at aggregation and phagocytosis. Neutrophil function gradually matures through childhood.

Low levels of complement components contribute to decreased opsonisation capability. Serum complement levels increase to adult values by 6–18 months (Blackburn 2003). Nevertheless, Blackburn (2003) reports that neutrophils act normally in neonates when bacterial numbers are not too large and the baby is not stressed (e.g. by perinatal asphyxia). However, significantly reduced bacteriocidal activity for Gram-positive and Gram-negative organisms has been shown in stressed babies (Blackburn 2003).

Gut defence mechanism

In humans the gastrointestinal (GI) tract is part of the natural immune system. Defences in the GI tract include acidity, digestive enzymes that break down large molecules and secretory IgA that lines the small intestine (Varney et al 2004). At birth, the epithelial lining of the GI tract is immature and relatively permeable. Development of the epithelium and the mucosal surface as an impenetrable barrier against pathogenic microorganisms and other antigens is known as gut closure. Gastric acid, peristalsis and the mechanical barrier properties of the gut mucosal surface are some non-immune factors that contribute to the gut defence mechanism (Blackburn 2003).

Clinical point

Prevention and assessment of neonatal infection

Prevention:

- Practise standard precautions at all times.
- Teach parents to prevent infection through general hygiene measures such as hand washing, keeping equipment used for the baby in closed containers and by encouraging commonsense precautions such as keeping the baby away from people with colds etc.

Assessment:

- Recognise any risk factors for development of infection and monitor for signs of onset.
- Understand the subtle signs of infection in neonates and particularly note that fever is rarely a sign of infection.
- Know and teach parents the signs of illness in their baby.
- Understand normal neonatal laboratory findings and recognise changes that are associated with neonatal infection.

Role of breast milk in gut colonisation

Breastfeeding promotes gut colonisation because it provides a large amount of secretory IgA and stimulates the proliferation of intestinal enzymes. Colostrum and breast milk contribute to the development of protective gut flora by creating an acidic enteral environment, which favours growth of *Lactobacillus* and *Bifidobacterium*, thereby preventing growth of acid-sensitive organisms such as *Bacteroides* and enterobacteria. Breast milk also contains the protein lactoferrin, which binds with unabsorbed iron in the intestine, making it unavailable for bacterial metabolism (Blackburn 2003).

While there are fewer differences in gut colonisation when formula closely resembles breast milk, an alkaline environment is produced when babies are fed formula. In an alkaline environment, enterobacteria outcompete bifidobacteria, resulting in Gram-negative enterococci becoming the dominant organism in the intestine (Blackburn 2003).

Renal system

At birth the kidneys are structurally complete but functionally immature. There are limitations in the glomerular filtration rate capability and the ability to concentrate or dilute urine. Newborn babies have little renal reserve to cope with increased levels of solutes, which may occur in physiologically stressed or ill neonates (Farrell & Sittlington 2003b; Michaelides 2004a; Novak 2005a; Varney et al 2004). The total body water content in newborn babies is a larger proportion of body fluid than in adults. The shift of intracellular fluid into the extracellular compartment after birth results in a diuresis that causes loss of 5–10% of birthweight over the first week (Novak 2005a).

Urine is first passed within 24 hours of birth. Initially the newborn baby excretes only a small quantity of urine; as little

as 30–60 mL is passed in the first 48 hours of life. Volume and frequency increases with rising fluid intake. The urine has a low specific gravity, is straw-coloured and odourless. There should be no protein or blood in the urine. Until fluid intake increases, the urine may be cloudy from the presence of mucus or urates. Urates may cause pink or brick-red staining on the nappy. While common in the first few days of life, the presence of urates in the urine of babies more than a few days old may indicate dehydration (Farrell & Sittlington 2003b; Michaelides 2004a; Novak 2005a; Varney et al 2004).

When the bladder becomes full it is palpable abdominally. The kidneys may also be palpable. On micturition the direction and force of the stream of urine should be noted (Farrell & Sittlington 2003; Michaelides 2004; Novak 2005a; Varney et al 2004).

Gastrointestinal system

Mouth

The mucous membrane is pink and moist, and both the hard and soft palate are complete. The teeth are buried in the gums, but occasionally a tooth may be present in the mouth. Small epithelial retention cysts, called Epstein's Pearls, are sometimes found along the midline of the palate and occasionally elsewhere in the mouth. They disappear over time. The sucking pads in the cheeks give a rounded, full appearance to the face (Blackburn 2003; Farrell & Sittlington 2003b; Michaelides 2004a; Varney et al 2004).

Swallowing and sucking

At birth the term baby has mature gag, cough, suck and swallow reflexes. As well as sucking fingers and thumbs, in utero the fetus swallows amniotic fluid from 10–14 weeks gestation to prepare the oesophagus to move food into the stomach by peristalsis. The swallowing reflex is mature at approximately 34 weeks gestation. The mature pattern of coordinated sucking–swallowing–breathing is seen as three to four bursts of sucking–swallowing followed by a pause for breathing. This pattern may not appear fully synchronised for a day or two after birth. The burst–pause pattern of sucking, swallowing and breathing seems to occur earlier in breastfed babies. Neonates cannot draw food from the lips to the pharynx, and therefore the nipple is drawn deeply into the mouth to enable suckling to occur (Blackburn 2003; Farrell & Sittlington 2003b; Michaelides 2004a; Varney et al 2004).

Stomach

At birth the capacity of the stomach is approximately 6 mL/kg of body weight (i.e. 21 mL in a 3.5 kg baby) (Blackburn 2003). However, capacity increases rapidly over the first few weeks. Gastric emptying time averages two to three hours, with breast milk emptying more rapidly than formula. When food enters the stomach, the ileo-caecal valve opens in response to a gastrocolic reflex. The contents of the ileum pass into the large intestine, and rapid peristalsis means that feeding is often accompanied by a bowel motion.

During the first 24–48 hours, gastric emptying time can be delayed by mucus in the stomach. Older neonates may swallow air from the nasal passages when feeding especially from a bottle. The competition for space can cause regurgitation of milk or the appearance of satiety before adequate intake. This can be prevented by release of the air when the baby burps, either spontaneously or as a result of 'winding' by rubbing or patting the back while holding the baby upright. Breastfed babies appear to swallow less air and rarely require winding in the first days of life (Blackburn 2004; Farrell & Sittlington 2003b; Novak 2005b).

At birth the cardiac sphincter and nervous control of the stomach are immature. The cardiac sphincter has transient episodes of relaxation that predispose to possetting (regurgitation). Sphincter muscle tone improves rapidly during the first week, while final maturity may take up to 12 months (Blackburn 2003; Michaelides 2004a). Projectile vomiting, especially appearing from approximately the end of the first week, may indicate congenital pyloric stenosis.

Liver

Physiological immaturity of the liver results in low production of hepatic glucuronyl transferase for the conjugation of bilirubin. This may result in transient physiological jaundice after 48 hours. Glycogen stores are rapidly depleted, and therefore early feeding is needed to maintain normal blood glucose levels and compensate for used glycogen. Liver function and colonisation of the intestine, both of which assist in the formation of vitamin K, are stimulated by feeding (Farrell & Sittlington 2003b).

Digestion

Between 6 and 16 weeks of fetal life, polypeptides that regulate the gastrointestinal tract appear. At term the baby can digest, absorb and metabolise simple carbohydrates, proteins and emulsified fats. After birth, maturation of the gastrointestinal tract is stimulated by specific peptides. Breast milk assists this adaptation as it contains many gastrointestinal trophic factors. Oral feeding stimulates the epithelial cells lining the newborn's small intestine to mature by promoting rapid cell turnover and producing gut enzymes such as amylase, trypsin and pancreatic lipase (Blackburn 2003; Farrell & Sittlington 2003b; Michaelides 2004a). Supporting early feeding aids maturation of intestinal capabilities. Colostrum is non-irritating and enhances the passage of meconium. As well as promoting gut closure, breastfeeding stimulates intestinal enzyme proliferation (Blackburn 2003; Varney et al 2004).

Intestine

Intestinal villi begin developing between 14 and 19 weeks. The gut is sterile at birth but is colonised within hours of birth. Bowel sounds can be heard one hour after birth (Farrell & Sittlington 2003b; Novak 2005). 'Absorption of water by the colon is less efficient than in adults hence the propensity for serious water loss when neonates contract gastrointestinal infections' (Varney et al 2004, pp 68–69).

Clinical point

Alterations to bowel motions

Breastfed babies:

- Stool generally has little or no odour.
- Day 1 to 2/3: meconium (dark green, sticky and unformed).
- Day 2/3 to 3/4: meconium → transitional stool (i.e. copious greenish-brown, loose stool). The baby's mother may need reassurance that this is not diarrhoea.
- Day 3/4 to approx 10/12: mustard yellow, very loose, unformed stools, often only yellow fluid containing seed-like solid waste. Passed at almost every feed.
- Approx. day 10/12 onward: mustard yellow, soft, loosely formed stools. Solids retain a seed-like appearance.
- After the first fortnight, breastfed babies generally pass a bowel motion 2–3 times a day. However, some exclusively breastfeeding babies may only pass a stool once every 3–5 days. As long as the baby is content, gaining weight, feeding well and passing normal amounts of urine, the baby is not constipated. These babies pass a large quantity of soft, non-constipated stool when they do have a bowel motion.

Formula-fed babies:

- Stools have a sharp, distinctive odour.
- Meconium and transitional stool are passed as for breastfed babies.
- From 3–4 days onward, stools are pale yellow, well-formed and solids do not have a seed-like appearance.
- Formula-fed babies pass 2–3 stools a day.
- They do not exhibit the irregular pattern seen in some breastfed babies. If a formula-fed baby does not pass at least one bowel motion each day, the baby should be assessed for constipation.

Bowel motions

Initially all babies pass meconium. Meconium is found in the colon from 16 weeks gestation. It is generally passed within the first 24 hours of life and fully excreted within 48–72 hours. Meconium is an unformed, sticky, greenish-black stool made up of intestinal debris including fatty acids from swallowed amniotic fluid, vernix caseosa, epithelial cells, lanugo, bile and other intestinal secretions. 'Most term infants pass meconium by 12 (69%) to 24 (94%) hours, almost all (99.8%) by 48 hours of age' (Blackburn 2003, p 444). Passing meconium indicates that the baby's lower bowel is patent, although there are exceptions (e.g. an ano-urethral fistula in the presence of an imperforate anus). The bowel motion changes to a greenish-brown colour (transitional stool) as residue from oral food mixes with the meconium. The change to transitional stool indicates a patent GI tract. Once lactation and breastfeeding are established, soft, yellow stools are passed.

Clinical point

Signs of neonatal hypoglycaemia

Signs of neonatal hypoglycaemia are often vague and non-specific. They can include:

- jitteriness
- cyanosis
- apnoea
- weak cry
- lethargy
- lack of muscle tone ('floppiness')
- refusal to feed.

(Source: McHugh 2004)

Glucose regulation

During pregnancy the fetus is in an environment in which glucose levels are consistently 60–70% of maternal levels. Glycogen stores are laid down in the third trimester, primarily in the liver. After birth the healthy term baby naturally stabilises glucose levels through feeding and by using glycogen stores. Feeding within an hour of birth conserves glycogen and minimises the risk of hypoglycaemia. While healthy term babies are at low risk of developing hypoglycaemia, any situation before or after birth that has either prevented the accumulation of glycogen stores (e.g. preterm birth or fetal growth restriction), or has caused abnormal consumption of glycogen (e.g. fetal distress or hypothermia), increases the risk of hypoglycaemia. Satisfactory early feeding is particularly important for these babies and blood glucose levels may need to be monitored (see Ch 38).

Neurological system

Nervous system activity develops progressively in fetal life; however, while term babies are able to receive and process stimuli appropriate for neonatal development, the nervous system is still quite anatomically and physiologically immature. The brain is approximately a quarter of adult size and myelination of nerve fibres is incomplete. Such immaturity results in brain stem and spinal reflex activity predominating in the early months. Healthy term babies are capable of social interaction, which continues to develop as the brain continues to grow rapidly (Blackburn 2004; Farrell & Sittlington 2003b; London et al 2003; Michaelides 2004a).

The baby's autonomic nervous system maintains homeostasis; however, temperature instability in the early days and uncoordinated muscle movement reflect the incomplete state of neurological development. The presence of a wide range of reflex activities at varying ages is an indication of the normality and integrity of the neurological and muscular systems (Roberton 1996).

Midwives can gain information about the baby's neurological state from observation and by asking the mother

Clinical practice

Collecting a neonatal capillary blood sample

For estimation of blood glucose, serum bilirubin, full blood count, and Guthrie test.

- The sample is collected from the heel.
- Foot must be lower than body.
- Warm the heel by wrapping warmed gauze or muslin cloth around the foot to improve peripheral vascular perfusion and thus prevent falsely low results.

SAFETY ALERT!

- *Test* the heat of the gauze/cloth against the inside of the wrist. It should feel a similar temperature to that of the skin.
- *Never* put the baby's foot in warm water. It is very easy to seriously scald a neonate's sensitive skin.

Procedure:

1. Clean the heal with an alcohol wipe. Allow to dry. Alcohol-impregnated swabs should never be used prior to collecting a blood sample for a Guthrie test (neonatal screening test) or glucose readings, because the alcohol can affect the accuracy of the results (Johnston & Taylor 2000).
2. Avoid sensitive areas of the heel (see Fig 27.5).
3. Puncture the outer aspect of the heel with a sterile disposable lancet. Automated lancets are preferable to manual ones.
4. Wipe away the first drop of blood with dry sterile gauze.
5. Gently fill the microcapillary collection tube or press collection filter paper against a large drop of blood.
6. Apply gentle pressure with gauze or cotton ball until bleeding stops.
7. Label specimen appropriately and send for analysis.

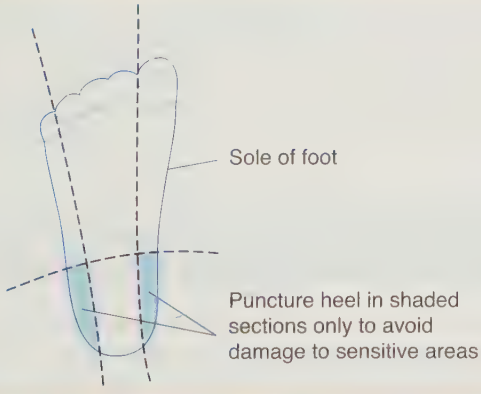

Figure 27.5 Heel puncture sites for neonatal blood sampling

about latching and sucking on the breast, how much the baby cries and sleep–wake patterns (Johnston et al 2003). The term baby lies with the limbs flexed and limb movements are uncoordinated and purposeless. No two newborn babies behave in exactly the same way but there is a broadly predictable pattern of behaviour that is regarded as normal. At first, it is a relatively simple pattern of sleep, wakefulness, semi-purposeful movements and reflex reaction to stimuli such as sucking and swallowing.

Senses and perception

Habituation is the process whereby there is an initial response to a visual or auditory stimulus such as a loud noise, followed by diminishing response with repetition until the response disappears. Being able to ignore a noisy environment is a newborn defence mechanism. Orientation is the neonate's ability to be alert to, follow and fixate on appealing, complex visual stimuli. Self-quieting ability refers to babies' capacity to quiet and comfort themselves (e.g. fist sucking) (London et al 2003).

Vision

Babies are sensitive to bright lights, which make them blink or frown. They focus at a distance of 15–20 cm and show a preference for the shape of the human face and bold black and white patterns. They can briefly track a moving object by the end of the first week and can differentiate their mother's face from a stranger's by two weeks. Over the first two months, interest in colour and variety of patterns develops (Blackburn 2003). Interaction with the mother is developed through eye-to-eye contact.

Hearing

Newborn babies turn towards localised sound. High-pitched sound makes them blink or startle. They are comforted by low-pitched sounds such as the crooning noises mothers make to comfort a crying baby. They prefer the sound of their mother's voice to others' and prefer the human voice over other noise. After a few weeks, neonates mimic the patterns of human speech by moving in response (Blackburn 2003; Farrell & Sittlington 2003b).

Smell, taste and touch

Babies prefer the smell of human milk and can differentiate their mother's milk within a few days. They prefer a sweet taste and turn away from unpleasant smells.

Babies respond to being picked up, stroked and talked to. They can mimic facial expressions and hand movements made by adults by 12 days of age. They enjoy skin-to-skin contact, immersion in warm water, rocking, cuddling and stroking (Blackburn 2003; Farrell & Sittlington 2003b; Michaelides 2004a). 'Pain in babies is expressed by brow bulging, eyelid squeezing, nasolabial furrowing and open lipped crying' (Farrell & Sittlington 2003b, p 732).

Sleep–wake states

From the moment of birth, infants are alert and aware of their surroundings, and able to respond to their carers and

the environment. Understanding the baby's sleep–wake state can help both the mother and the midwife to provide care that works with, rather than against, the baby's state of consciousness, thereby conserving energy.

Behavioural observation of sleep–wake states in the newborn:

- Sleep states:
  - deep sleep—eyes closed, no eye movements, respirations regular, hard to wake, occasional jerky movements
  - light sleep—eyes closed, rapid eye movements seen, respirations less regular, may be sucking movements, easier to wake, occasional random movements.
- Awake states
  - drowsy—eyes open or closed, eyelids may flutter, occasional smiling, smoother limb movements but may startle, minimal response to sensory stimulus and minimal motor activity
  - quiet alert—eyes open, alert and focuses on source of stimulus, minimal motor activity, may or may not be fussing
  - active alert—eyes open, alert, generally active and reactive to a variety of stimuli and the surrounding environment, may or may not be fussing
  - crying—actively, may be hard to console, much muscular activity. Difficult to get a response, need to bring baby down to active alert state to feed (Brazelton 1984; Brazelton & Nugent 1995).

Initially the baby is wide-eyed, alert and hungry. Approximately an hour after birth the baby falls asleep for a few minutes or several hours. The importance of initiating breast feeding in the first period of reactivity is evident. Successive sleep–wake patterns are very individual and the baby will take some time to demonstrate a consistent pattern. At first the baby wakes because of hunger, but longer periods of wakefulness unrelated to hunger, that meet the baby's social interaction needs, begin to occur in the succeeding weeks.

At times during the day, the baby will be active and crying, or will lie quietly awake. Newborns sleep for 16–20 hours each day, although the depth and duration of sleep vary considerably from one baby to another. Some wake only to be fed and changed, others are easily disturbed and wakeful even though well fed (London et al 2003; Farrell & Sittlington 2003b; Johnston et al 2003; Michaelides 2004a).

Crying

Term neonates usually cry without tears and generally for reasons of hunger, thirst or discomfort, although sometimes there is no obvious reason. Parents are able to differentiate the cry as they gain experience with their baby. Midwives have a role in supporting parents as they grow to understand the baby's individual pattern of communication and learn to comfort him or her.

Mother–baby relationship

It is important to keep mother and baby together. Emotional care is just as important as physical care for the baby's ongoing health and development. Unless ill and requiring intensive care, the baby should stay with the mother so that she can enjoy and get to know, love and care for her baby (Johnston et al 2003). The mother examines her baby minutely in a predictable pattern at birth. The father is also involved in this early exploration. Apart from their pre-understandings, the parents' response is affected by the baby's appearance and response. Close contact in the first hour after birth fosters the attachment process and promotes later neonatal development. The mother examines the baby first by using her fingertips to explore the baby's head, fingers and toes. She then strokes the baby's body with her hand before cuddling the baby into her arms with the baby facing her. She establishes eye contact and talks to her baby, looking for support from her partner and the midwife. Sometimes the father's overt responses are stronger than his partner's. Some fathers are surprised at the depth of their emotional response to the birth of their baby. They also feel a sense of deep satisfaction and self-esteem, are elated and eager to touch and hold their baby and their partner (Barclay & Lupton 1999; Farrell & Sittlington 2003b).

The baby's responsive behaviours induce further responses from the parents, which calls forth a response from the baby. These interactions develop the bond between parents and child that is essential for the baby's ongoing development (Farrell & Sittlington 2003b).

Fostering the process of attachment

Studies suggest that physical contact between the mother and baby encourages attachment between them, and research evidence shows that the chances of successful breastfeeding are enhanced when the baby is put to the breast immediately after birth (Johnston et al 2003). Midwives can foster the process of parental attachment by keeping the baby with the parents, fostering privacy for the parents to be alone with their baby and to talk with each other, providing information and reassurance about the range of normal baby behaviour, reassuring the parents that attachment to the new baby is not always instant and is commonly a gradual process over the first few months. When the father is encouraged to be involved in discussions and decisions and to share responsibility for baby care, it is thought that the parent's relationship is enhanced. Both parents need opportunities to voice their feelings and reactions about their baby. Sensitive and supportive midwifery care can foster confident parenting for both parents (Farrell & Sittlington 2003b; Johnston et al 2003).

Neonatal assessment

Assessment of the neonate is a continuous process. Many of the assessments undertaken in a formal neonatal examination are continuously assessed by both the mother and the midwife on a daily basis (see Ongoing assessment, this chapter). The general principles that apply to the full neonatal examination also apply to ongoing assessments.

Formal neonatal examination

A full examination of newborn babies is undertaken at birth, at the end of the first week and at discharge from midwifery care. It is generally accepted that it is good practice to undertake a comprehensive physical examination of the baby within 24 hours of birth (Hall 1999). The initial examination allows observation of the baby as a whole, forms the baseline for future checks and provides an alert to areas of concern (Johnston et al 2003). The examination also gives parents an opportunity to ask questions and to express any concerns.

Scope of practice

The formal examination of healthy term neonates is within the midwife's scope of practice. In New Zealand it forms a standard part of the Ministry of Health contract specifications for the provision of primary maternity care (Regulations to the NZ Public Health and Disability Services Act 2000, s.88). Mitchell (2003) found in a UK study that the examination is most appropriately undertaken by the ongoing caregiver, and that efficacy and quality of the assessment is improved if it is undertaken by the midwife. Wolke and colleagues (2002) found that there was no difference in maternal satisfaction levels whether the examination was undertaken by midwives or junior paediatricians. They also found that satisfaction levels were increased if information about behavioural and healthcare issues was provided at the time of the examination. Glazener and colleagues (1999) found no evidence of health gain from a policy of two examinations in hospital.

General rules for examining newborn babies

- The examination should always be undertaken with the consent of the baby's mother and in her presence. The assessment findings are communicated to the baby's mother or both parents at the time of the examination.
- The baby should be in a quiet, alert state.
- Be firm but gentle. Babies feel insecure if not handled confidently. Smooth, gentle handling will give maximum information with minimum disturbance to the baby.
- Without compromising the thoroughness of the examination, minimise the time during which the baby is unclothed, to prevent chilling and disturbance.
- *Use the same process every time* so that nothing is missed.
- Examine the baby generally in a 'top-to-toe' direction.
- Pay particular attention to symmetry. Each side should be the same—sounds, length, size, creases, muscle tone, flexion.

Exceptions to the 'top-to-toe' process:

- Observe as much as possible before the baby is fully undressed. All of the head, the baby's general muscle tone and some of the reflexes can be observed while the baby is still clothed.
- It is usual to start with examination of the baby's heart and lungs while the baby is least disturbed and less likely to cry. Nearly all babies cry when naked for any length of time, so it is sensible to listen to the heart and lungs before removing the napkin.
- Examination of the hips for developmental dysplasia is uncomfortable for the baby and should be carried out at the end of the examination. Similarly, weighing the baby should be reserved until near the end of the examination (Farrell & Sittlington 2003b; Johnston et al 2003; London et al 2003; Michaelides 2004a; Varney et al 2004).

History

Factors to take into account from the clinical record and the baby's parents include:

- the parents' appearance/stature—a small baby may merely reflect the size of the parents, for example
- genetic—any known family history
- environmental—known maternal exposure to teratogenic agents, smoking, recreational or prescription drugs etc
- social factors, maternal blood group, medical conditions
- pregnancy and intrapartum variations—such as intrauterine growth, liquor volume, fetal distress, maternal analgesia, intrapartum complications
- neonatal factors—Apgar score, birthweight (Varney et al 2004).

General measurements

The crown–heel length, head circumference and weight are assessed and used as a baseline for assessment of growth over time. Observe the whole baby for symmetry and proportion, and in particular note general length-to-leanness proportion.

Crown-to-heel length

Local policy applies as to whether calibrated measuring equipment or a tape measure is used to assess length in the first few weeks of life. When a tape measure is used at the early examinations, this assessment is only an approximation. Calibrated equipment is required for accurate and reliable length measurement. For reliability the length needs to be serially assessed by the same person (Doull et al 1995).

To use a calibrated box or mat, the baby's head and feet must be flat against either end, which is quite difficult to achieve with new babies. Whichever method is used, the mother is usually asked to assist by holding the baby's leg(s) straight while the measurement is taken.

The average crown–heel length of a term baby at birth is 50 cm. (In the New Zealand population the 3rd–97th centile range is 48–53 cm (NZMOH 2004).)

Weight

Weigh the baby toward the end of the examination. To improve reliability it is preferable to use the same set of regularly maintained scales for serial weight measurements.

Babies are generally weighed at birth, sometime towards the end of the first week, then weekly until four to six weeks old. The average birthweight of a term baby is 3500 g and the New Zealand 3rd–97th centile range is 2500–4500 g (NZMOH 2004). Healthy term babies can lose a maximum of 7–10% of their birthweight due to physiological diuresis (Blackburn 2003). In practice, 7% loss is generally regarded as the alert

point at which feeding patterns need to be reviewed and intake increased. The baby should regain her or his birthweight by 10–14 days. As the baby grows older, mothers usually know if their baby is gaining weight by assessing whether the baby's clothes are fitting better or getting tighter. They also notice that the baby's face and tummy are starting to fill out. Generally term infants gain 30 g/day for the first three months (Blackburn 2003). However, the emphasis is on healthy term babies and normal urinary output—that is, babies who are feeding well and having six to eight wet napkins in 24 hours. Babies who are not term, and/or not feeding well, and/or not exhibiting normal urinary output, need to be identified and individually assessed. An appropriate plan of care needs to be implemented (see Chs 29 and 38).

Head circumference

Measurement is taken round the occipito-frontal diameter (not the ears). The average head circumference for a term baby is 35 cm. The New Zealand 3rd–97th centile range is 34–39 cm (NZNOH 2004). There may be a discrepancy between the measurement at birth and the end of first week assessment, as moulding can make an accurate initial assessment difficult.

Gestational age assessment

Gestational age is formally assessed using either the Ballard or the Dubowitz gestational assessment tools (see Ch 38). While ultrasound scanning has confirmed the gestation of most pregnancies, occasionally the scan result is incorrect; also, some women choose not to be scanned, and some women arrive at the birthing unit without prior care from that service. Midwives make a general assessment of gestational age at the time the baby is born so that unexpectedly preterm infants can be readily identified.

General assessment of gestation for healthy term neonates:

- resting posture—fully flexed extremities (see Fig 27.6)
- creases cover the whole of the sole of the foot (see Fig 27.7) (Note: this is reliable only in the first 12 hours.)
- breast tissue of 6–7 mm diameter is present
- ear cartilage and curves of the pinna are complete. The ear promptly returns to the normal position when folded forward and released.
- genitalia well developed. Male: scrotum covered in rugae and testes usually descended. Female: labia majora completely cover the clitoris and labia minora.
- elbow does not reach the midline when the scarf sign is assessed from 40 weeks gestation onward (see Fig 27.8).

Temperature

Take and record the baby's temperature. This is especially important at the initial examination when the baby is most vulnerable to hypothermia.

Examination of specific areas

Lungs

- Count the respiratory rate, and observe the rise and fall of the chest and abdomen—they should rise and fall together.
- Babies' heart sounds can be heard in many parts of the chest, so auscultate the lungs toward the lateral side of the chest to diminish the volume of the heart sounds. Focus on the breath sounds until the heart sounds are backgrounded. Then the breath sounds can be assessed.

Figure 27.7 Plantar surface of the foot (Thureen et al 2005)

Figure 27.6 **(a)** Term posture (flexed) **(b)** Preterm posture (extended) (Thureen et al 2005)

Figure 27.8 Scarf sign **(a)** Full-term infant **(b)** Preterm infant (Thureen et al 2005)

- Listen for air entry into both lungs. Note whether each side sounds similar.
- Listen for rales or rhonchi. If present, record which lung(s), volume and how it sounds (e.g. moist, rattly, dry, breezy).

Heart

The heart is examined for rate, regularity, heart sounds and the presence of murmurs. The baby is assessed for general signs that may indicate a cardiac anomaly—that is, variations in colour, raised respiratory rate, lethargy, poor feeding.

Auscultate with the stethoscope diaphragm (high pitch), then the bell (low pitch). Focus on the heart sounds, backgrounding the breath sounds. Listen carefully until the heart sounds have your full attention. The cardiac cycle can then be assessed.

- *Count*: rate and note regularity
- *Listen* to:
  - systolic (first) heart sound S_1 (lub)
  - diastolic (second) heart sound S_2 (dub)
  - the spaces in between the sounds:
    lub-space-dub-space-lub-space

Neonates sometimes have a third heart sound. Carefully assess whether there are any murmurs (other sounds in the cardiac cycle). Murmurs in newborn infants are usually flow murmurs. These can be either physiological (e.g. from a partially closed foramen ovale) or pathological (e.g. from a septal or valvular defect). Physiological flow murmurs are the most commonly heard murmurs at the initial examination. These should be reassessed in 24 hours. They have generally resolved by the examination at the end of the first week. However, until significant experience is gained, if any sound other than the normal systolic and diastolic sounds are heard, consultation with a medical practitioner is warranted.

Clinical point

Auscultation of the lungs and heart

- Use a paediatric stethoscope. The small diaphragm makes heart sounds in particular much easier to hear. Warm the diaphragm in the hand prior to placing on the baby's chest.
- Use smooth, gentle actions. If the baby is disturbed and cries, the sounds will not be audible.
- Focus on the sound being listened to, backgrounding other sounds.

Clinical point

Telephone consultation related to cardiac variations

Initial consultation and referral is often via the telephone and the doctor may be some distance away, so it is important to ensure that she or he can make an assessment of the urgency of the situation. The following information should be given and recorded in the clinical notes:

- General condition of the baby, especially colour, respiratory rate and feeding behaviour. (Major cardiac anomalies are either very soft or inaudible. These anomalies announce themselves as more general signs and symptoms.)
- Heart rate (normal 110–150 bpm)
- The extra sound(s):
  - nature—rumbling, breezy, whistling, creaking, rubbing
    volume—soft (grade 2), easily heard (grade 3), loud (grade 4)
    where the murmur is audible—all over the chest, in the back, a specific place on the chest or back
    in which part of the cardiac cycle the murmur is audible (e.g. with the systolic sound)

Midwives and women need to be aware that non-specific signs and symptoms such as pallor or failure to thrive may be the only indication of a silent cardiac defect that will become apparent at a later time.

Head

After measuring the head circumference, examine the scalp for cuts and abrasions, fetal scalp electrode or blood sample sites. Assess the head for general shape, presence and shape of moulding, microcephaly, macrocephaly, caput succedaneum, cephalhaematoma, 'chignon' from vacuum delivery.

Palpate the sutures, which should be clearly felt unless overriding of the bones associated with moulding is present at the initial examination. Note width, overriding or premature fusion. Note distribution and texture of hair. Hair is usually silky and fine. Coarse-textured hair is abnormal.

Examine the anterior and posterior fontanelles. The posterior fontanelle is often not palpable as an opening from shortly after birth but does not anatomically close for 6–8 weeks. The anterior fontanelle slowly closes over by approximately 18 months. The anterior fontanelle should be flat; a sunken fontanelle is a late sign of dehydration, whereas a bulging fontanelle may indicate hydrocephalus or intracranial haemorrhage.

Plagiocephaly

Some babies always lie with their head in one position. This can lead to flattening of the occiput that becomes more noticeable after three to four weeks (Johnston et al 2003). It is important to differentiate plagiocephaly from unilateral premature closure of the coronal suture (craniosynostosis). According to Cowan (2000), Glasson, a plastic surgeon, states that there is growing evidence that plagiocephaly does not completely self-correct. In the early stages it is easily preventable and also treatable by varying the baby's head position. Mothers are encouraged to turn their baby's head to one side during the day and to the other side at night. However, Glasson goes on to state that helmet treatment may be necessary if the condition is undetected and untreated in the early stage, but that helmets are ineffective after one year.

Face

Examine for symmetry, placement of features, expression and shape.

Eyes

Examine to ensure the eyes are present, note symmetry, any discharge or swelling. The eyes should move; the baby will follow movement and gaze at the mother's face when held. The iris may be dark blue at birth but the colour may gradually change over the first three to six months. Tears are not usual for the first two months, although some babies have tears from birth.

Check for presence of subconjunctival haemorrhages (treatment not usually required), and epicanthic fold (skin fold over the medial aspect of the eye). This fold may be familial but is also seen in some congenital syndromes including Down syndrome (Hernandez & Glass 2005).

Examination for the red reflex with an ophthalmoscope confirms the clarity of the lens and the presence of the retina. The red reflex may be seen as the red pupils in photographs taken without the red eye reduction button on. If the red reflex is not assessed by the examiner, it is important to record that it has not been done in the health record so that the assessment can be undertaken at the next examination.

Nose

Check that the nostrils are patent by observing that the rate of respirations is normal and the baby is having no difficulty breathing. Note any swelling of the tear ducts. A small amount of saline drops can be used to clear the nares if the baby is 'snuffling'. Do not insert cotton buds.

Mouth

The mouth opens symmetrically but is usually held closed at rest. The lips are complete and the philtrum present. A receding jaw is sometimes associated with feeding difficulties. Elicit the rooting reflex by brushing the baby's cheek with a finger to encourage the baby's mouth to open. Use a pencil torch to view that the palate is complete, followed by palpation with a gloved finger. Assess the soft palate carefully, as small clefts can easily be missed. Check for complete gum lines and exclude premature dentition. Note the presence of tongue tie. Treatment is not required unless the tongue cannot move upward or cannot protrude over the bottom gum line.

Observe the sucking reflex (preferably when feeding). At subsequent examinations, examine the mouth for signs of *Candida* infection (thrush). Oral thrush is seen as white plaques on the gums, inside of the cheeks or a white film over the tongue. The white film left by milk is easily wiped away, whereas *Candida* plaque is not.

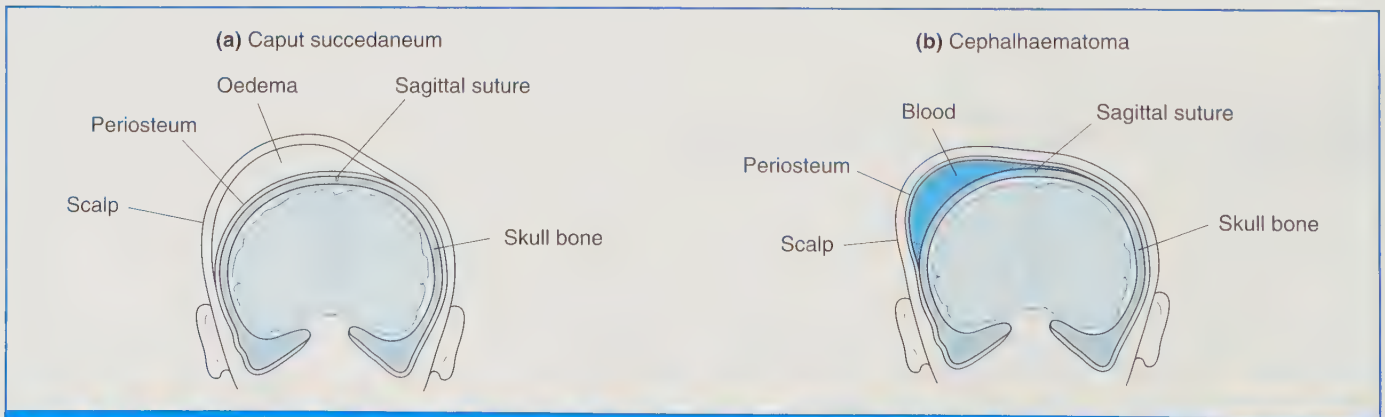

Figure 27.9 Characteristics of **(a)** caput succedaneum and **(b)** cephalhaematoma (based on Thureen et al 2005)

Ears

The auditory canals should be patent and the pinna should be flexible and cartilaginous. The upper edge of the pinna should be above or level with the outer corner of the eye. Moulding may affect these proportions at birth. Re-check at the first week examination. Low-set ears should alert for other anomalies.

Check for skin tags and spots, most commonly in front of the ear lobe but may be behind the ear. Skin tags may be benign or associated with a bone deficit under the tag and may contain meningeal tissue; they may also be associated with renal anomalies. Medical consultation is warranted when skin tags are noted. Never insert objects such as cotton buds into the auditory canal.

Hearing

A general assessment for sensitivity to noise can be made at birth, but hearing is better assessed more fully at a later date. 'Almost half of newborns with hearing impairment have no risk factors associated with this impairment' (Narrigan 2000, p 368). Routine screening for hearing using acoustic emission testing (AET) occurs in some Australian states, and trials are currently being undertaken in others and in New Zealand. Where routine AET testing is not undertaken, midwives should ask the parents if their baby is 'disturbed by loud noises—that is, jumps or blinks, stirs in sleep, looks up from sucking or stops sucking for a moment or cries' (NZMOH 2004, p 85). Note that babies can have a variable response to loud background noise in the early months.

Neck

Elicit the rooting reflex bilaterally to examine range and symmetry of movement. The head should move freely, creases should be symmetrical. Note any webbing or cystic growths, check creases for skin lesions.

Skin

Assess colour: pink, peripheral acrocyanosis at birth, jaundice, duskiness, pallor. Note the amount of vernix caseosa, lanugo and peeling. Examine creases for heat rash and pustules, the buttocks for nappy rash (bright red), or *Candida* rash (bright red, excoriated, sometimes roseate, associated with *Candida* lesions in the mouth and painful maternal nipples). Examine for common variations and birthmarks.

The full term baby's skin has few veins visible and has limited pigmentation at birth; all babies experience changes in skin pigmentation as they grow and develop. Because of the reduced pigmentation and the fact that capillaries are close to the skin surface, all healthy term neonates have a pink tinge to the skin. When the baby is first born, the skin is reddish and crinkly. The redness disappears within a few hours and the skin unfurls over the first few days. The skin is smooth and soft to the touch (Blackburn 2003; Farrell & Sittlington 2003b; London et al 2003; Michaelides 2004a; Thureen et al 2005).

The neonate's skin is thin and easily blistered or excoriated by friction, acid or alkaline substances and pressure. The epidermis is nonetheless an effective barrier preventing infection, especially as the skin pH falls from an average of 6.4 at birth to a mean of 4.9 over the first few days. Bacteriostatic capability is a feature of skin that has a pH lower than 5.0. Preterm infants are vulnerable to infection for a longer period as they take longer to form this acid mantle (Blackburn 2003; Farrell & Sittlington 2003b; London et al 2003; Michaelides 2004a; Thureen et al 2005).

There is a varying quantity of fine hair called lanugo particularly on the shoulders and upper arms. Lanugo is more noticeable over a larger area and found in greater quantities as gestation decreases. Before birth the skin is covered with varying amounts of vernix caseosa, a thick white, creamy substance that is thought to protect the skin. By term the amount has reduced so that it is primarily found in the creases of the axillae, elbows, neck and groin. Vernix does not need to be removed. If necessary it may be massaged into the skin. During the first week the skin on the hands and feet may peel, particularly if the baby is post term. Peeling requires no treatment; application of oils or creams is not necessary (Blackburn 2003; Farrell & Sittlington 2003b; London et al 2003; Michaelides 2004a; Thureen et al 2005).

Common skin variations

The following skin variations are common and clear spontaneously without treatment. Parents may need reassurance that they are normal skin variations.

- Acrocyanosis is the transitory bluish colour of the hands and feet seen in the first 2–6 hours after birth, before peripheral perfusion is fully established. Hand and foot colour is not sufficiently reliable to use for assessment of satisfactory neonatal oxygenation, and therefore assessment of the face and mucous membranes of the mouth is used to detect cyanosis.
- Superficial capillary naevi (see Fig 27.10) are pale reddish marks commonly called 'stork bites', seen on about a third of babies, on the eyelids, brows, between the nose and at the nape of the neck. They mostly disappear over the first year, although the marks at the nape of the neck sometimes persist.
- Mongolian spots (see Fig 27.10) are bluish/black or bluish/grey areas primarily seen on the buttocks or lower back, although they can be found anywhere on the body. They are more readily visible in babies with darker skins. They usually fade over the first year of life. Parents may need reassurance as the marks can look very like bruising.
- Milia are exposed sebaceous glands on the face. They look like raised white spots and can be quite profuse particularly on the nose. They disappear in the first four to six weeks after birth.
- Erythema toxicum is the term given to a transient rash that frequently comes and goes mostly on the body, in the first week of life. The baby is otherwise well. The spots are most commonly small, erythematous lesions with a white centre that look like pimples. They are not an infection; the fluid in the spots contains eosinophils,

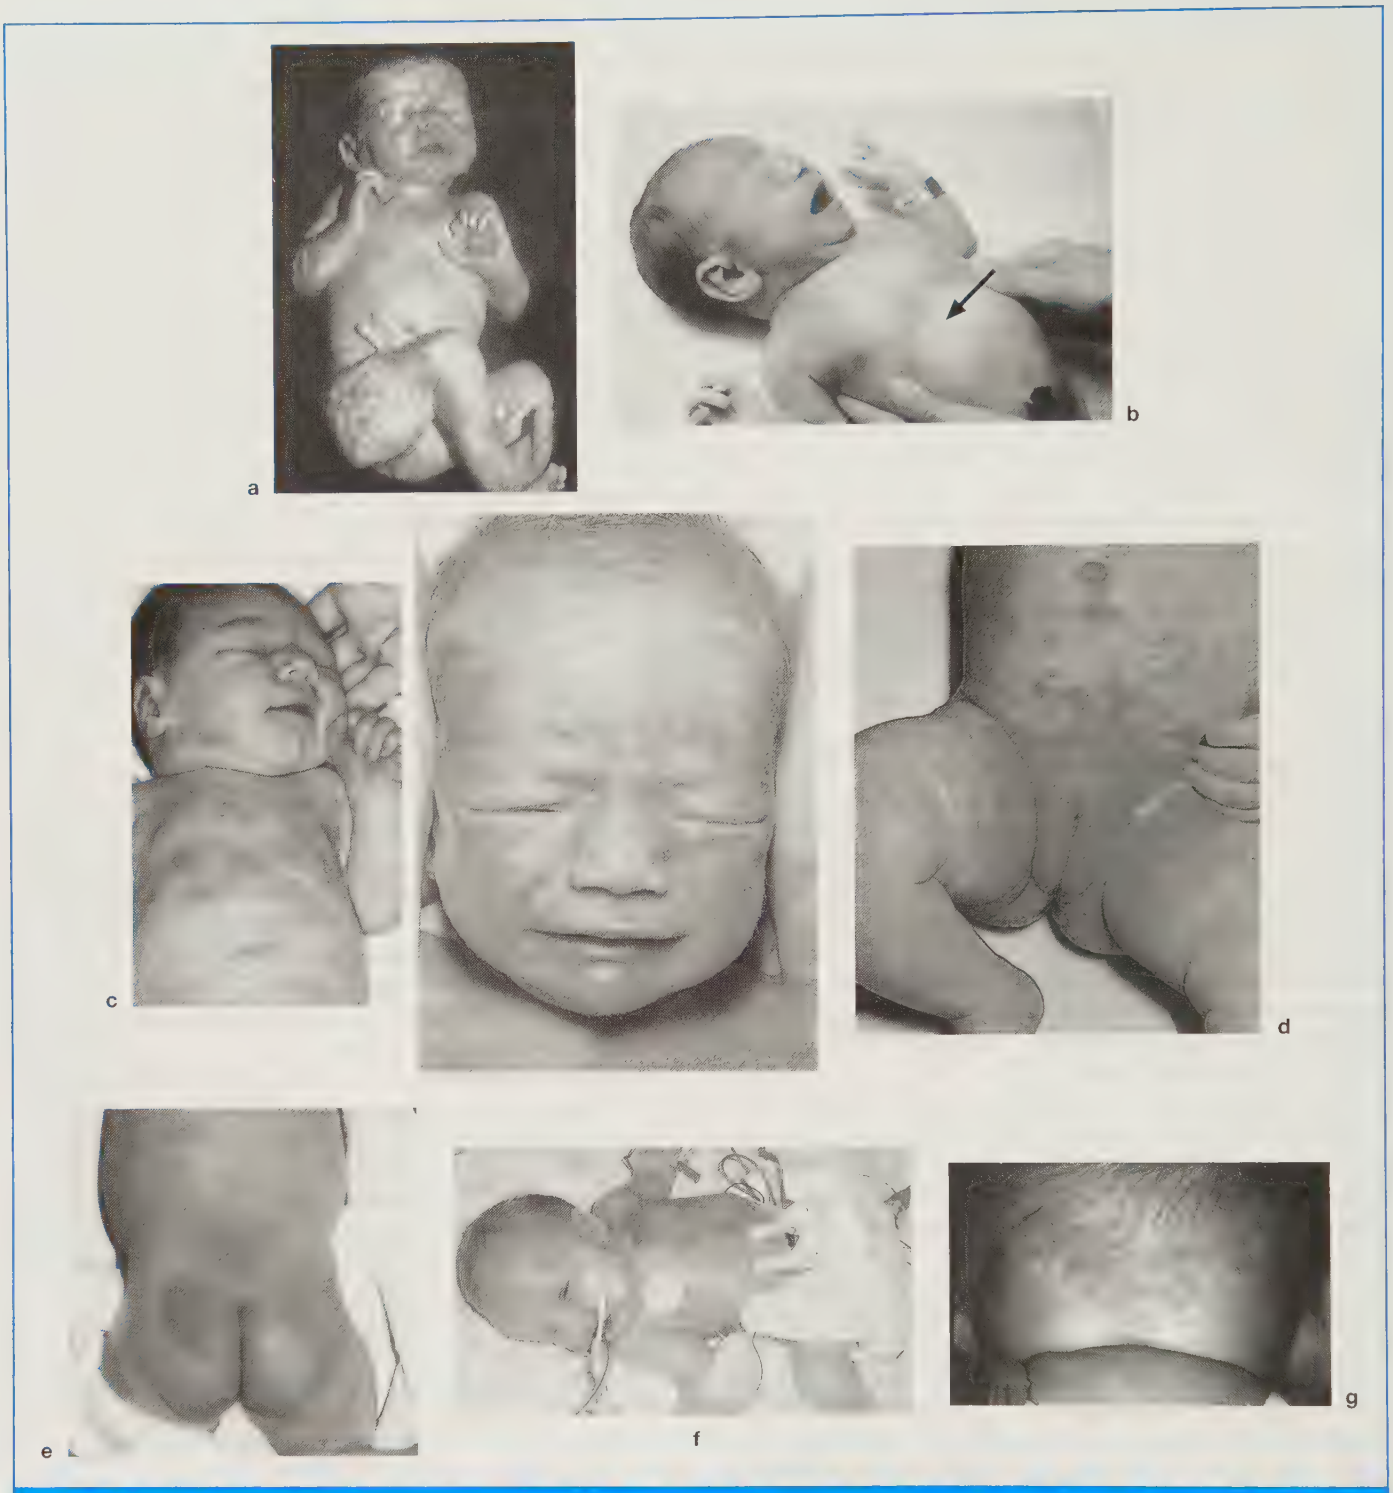

Figure 27.10 Skin variations **(a)** vernix caseosa **(b)** plethora **(c)** erythema toxicum **(d)** *Candida* dermatitis **(e)** Mongolian spots **(f)** harlequin sign **(g)** 'stork bites' (Thureen et al 2005; photograph (g) Dr AMM Oakley)

not pathogens. The rash can be quite extensive and the spots can run into each other making large blotchy red patches on the baby's skin. The rash is usually aggravated by heat. It can be unsightly and cause anxiety for parents. The rash usually clears in a few days.

- Petechiae, sometimes called traumatic cyanosis, are small, pinpoint haemorrhagic skin lesions, giving a dusky (bluish/grey) appearance to the face and head when there are multiple tiny petechiae in the skin. It is commonly seen when the head has been congested

during birth, most commonly by the cord tightly wound around the neck. The mucous membranes of the mouth and the baby's body are not affected and remain pink. It disappears within 48 to 72 hours.

- Subcutaneous fat necrosis is a localised area of induration that is reddish and blotchy with a hardened area of fat underneath. Usually spontaneous, it can follow a forceps delivery when it is usually found over the zygomatic process. It gradually disappears over several months (Burden & Krafchik 1999).
- Harlequin colour change (see Fig 27.10) is an intermittent transient colour change lasting from a few minutes to half an hour more commonly seen in preterm infants. There is a clear line of demarcation between an area of redness and one of paleness. The line of demarcation may run from the head to the abdomen. It is caused by temporary imbalance in the skin vasculature. Although it may occur up to three weeks of age, it is not significant (Farrell & Sittlington 2003b; Johnston et al 2003; London et al 2003; Michaelides 2004a; Thureen et al 2005).

Birthmarks

Birthmarks need obstetric or paediatric assessment so that a treatment plan and ongoing parental support can be initiated.

Capillary haemangioma

Port wine stain (naevus flammeus) (see Fig 27.11) is a flat, dark, reddish-purple capillary haemangioma that occurs in about 1 in 3000 births. It is commonly seen on the face and may vary in shape and size. It is twice as common in girls. It does not fade or shrink over time. Parents and child will need significant support. Laser treatment and cosmetics can be used later in life to reduce the appearance. Meningeal anomalies (Sturge-Weber syndrome) should be suspected if the haemangioma follows the distribution of the trigeminal nerve (Johnston et al 2003; Thureen et al 2005).

'Strawberry mark' (naevus vasculosus) (see Fig 27.12) is a capillary haemangioma that becomes apparent during the first few weeks as a small, bright red, raised lesion that continues to enlarge over one to three months. They can be very distressing for parents and the older child as they are often on the face and can grow quite large. However, they regress spontaneously and usually disappear by five to eight years of age. Treatment is not required unless the haemangioma is in an awkward place, such as obstructing the vision (Johnston et al 2003; Thureen et al 2005).

Pigmented naevi

Pigmented naevi are rare but can be multiple, large and/or hairy. They are brown and can be flat or raised. The impact on parents can be significant. They are formed from abnormal dermal melanocytes and become malignant in approximately 30% of cases, and therefore surgical excision and skin grafting in childhood is often recommended as a preventive measure. Treatment is not usually undertaken in the neonatal period (Johnston et al 2003; Thureen et al 2005).

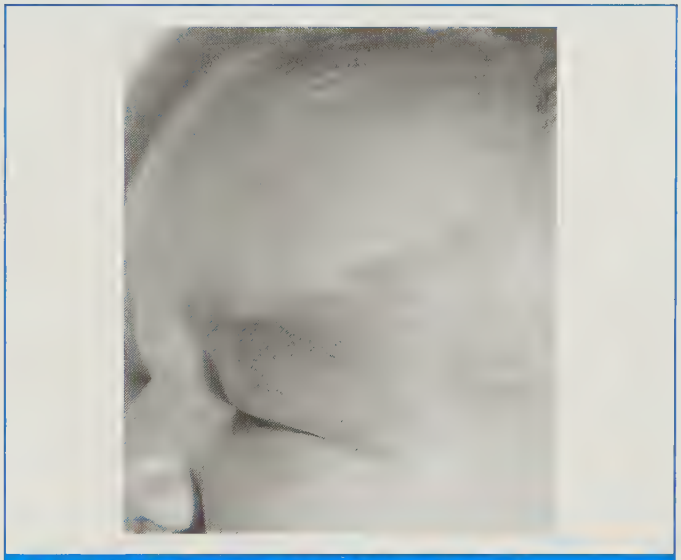

Figure 27.11 Port wine stain (Callen et al 2000)

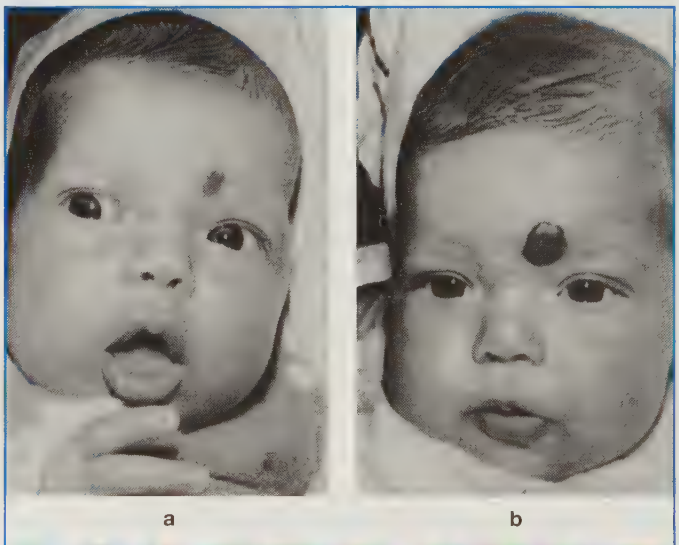

Figure 27.12 Strawberry naevus **(a)** four days after birth **(b)** six weeks after birth (Thureen et al 2005)

Chest

In a term infant the nipples should have approximately 6–7 mm of breast tissue (Leveno et al 2003). Hormonal swelling of breast tissue in both boys and girls may occur naturally and occasionally a milk-like substance may be seen. This is not an infection and will resolve naturally over one to two weeks as the level of maternal hormones decreases. Parents and health professionals alike need to be actively discouraged from squeezing the tissue, as it is easily damaged (Hernandez & Glass 2005).

Umbilicus

The cord should not be bleeding. Check that the clamp is properly fastened. Examine the cord for the presence of

three vessels. A small number of babies with one umbilical artery have one or more associated congenital anomalies, usually cardiac, pulmonary or renal, especially renal agenesis (Thummala et al 1998). At birth the cord is bluish white and contains a variable amount of Wharton's Jelly. As it dries out, the cord shrinks and darkens to a yellow-brownish colour. The umbilical cord separates by dry gangrene at any time between three and seven days, most commonly at four to five days. The cord clamp remains on the cord stump for 48 hours, after which it is removed.

Serous, purulent or sanguineous drainage is abnormal and may indicate a patent urachus or omphalitis (Hernandez & Glass 2005). Observe the area at the base of the cord for redness. Redness or umbilical 'flare' is usually associated with an infection and must be medically treated *very promptly* as neonatal septicaemia can be a rapid consequence. Check for umbilical hernia. This occurs when the abdominal muscles have not completely closed around the umbilicus. Unless very large it does not usually require treatment and closes spontaneously by two to three years of age (Hernandez & Glass 2005).

Abdomen

Auscultate each quadrant of the abdomen for bowel sounds, which are present from approximately one hour after birth.

Liver

The inferior border of the liver should be palpable 1–2 cm below the costal margin in the mid-clavicular line and extends across the midline; the normal edge is 'sharp and soft' (Hernandez & Glass 2005, p 141). Start palpation at the iliac crest and work upward towards the liver to come on to the liver border. It is sometimes easier to use the edge of the thumb rather than the fingertips for this palpation. The spleen is not usually palpable.

Kidneys and bladder

The kidneys are usually palpable in the first 24–48 hours. They are moderately firm and approximately 4.5–5.0 cm long. The right kidney may not be easily palpable. The kidney is palpated by placing the hand under the baby's flank and using deep, smooth abdominal pressure over the renal area (Hernandez & Glass 2005).

The bladder becomes an abdominal organ when full and may be palpable 1–2 cm above the symphysis pubis. There should be no other masses in the abdomen. The groin should be examined for any sign of palpable hernia or undescended testicle.

Femoral pulses

Palpate the femoral pulses. Assess each pulse individually and then together. The pulses are normally present on both sides and should beat in unison when palpated together. Compare the femoral pulse with the brachial pulse. Difference between brachial and femoral pulses, absence of femoral pulse(s) or asynchronous pulsation (rate or pressure) may indicate congenital cardiovascular anomaly, in particular coarctation of the aorta (Hernandez & Glass 2005). Any finding other than synchronous pulsation should be assessed by a medical practitioner.

Clinical point

Umbilical cord care

The cord stump separates by saprophytic action. Using antiseptics to clean the base of the cord interferes with this process. Umbilical cords do not require any special cleaning or treatment. There is no increase in infection when the cord is not treated with hexachlorophene powder and alcohol wipes (Dore et al 1998). Application of powders, antiseptic or alcohol wipes has been shown to delay cord separation (Barr 1984; Lawrence 1982). The cord should be washed in the bath and dried carefully. It is preferable to fold down or cut a small 'v' in the waist band of disposable napkins so that the cord is outside, where it is exposed to the air and protected from contamination by urine and faeces. If cloth nappies are used, they should be fastened so that the cord is outside the nappy. As the cord begins to separate it can become quite sticky around the base; the sticky material should be gently removed with a damp cotton bud and carefully dried. As the cord comes off there may be a *very small* amount of dark blood seen. This is normal and is only present for one or two nappy changes. Fresh blood is not normal. Occasionally the centre of the umbilicus has a small piece of raised, granulomatous flesh where the cord has separated. Occasionally this rubs on the baby's clothing and does not heal over. If this is the case, the stump can be easily and painlessly cauterised by the baby's general practitioner.

Clinical point

Palpating the abdomen

The baby's abdomen is examined in the same way as that of an adult. However, the quadrants are much smaller, so the flat surface of the fingertips is used. The palpation moves from light to deep, watching the baby's face to detect discomfort. The examiner's other hand is placed in the back of the baby to provide a firm support. The baby's hip may need to be flexed to relax the abdominal muscles during palpation.

Limbs

Upper limbs

Examine symmetry of length, creases, flexion and muscle tone. Check axillae and elbows for abnormalities. Open the hands to check for extra digits (polydactyly), skin tags or webbing

Clinical point

Palpating femoral pulses

With the baby lying flat, draw an imaginary line between the umbilicus and the normally flexed knees. The pulses are palpable where the line crosses the groin, in the groove between the leg muscle tendons.

between the fingers. Examine palms for single palmar (Simian) crease (may be associated with Down syndrome) (London et al 2003; Thureen et al 2005).

Confirm symmetry and normal range of movement in the joints. (***Do not force the joints.***) The hands are normally held as loosely clenched fists.

Lower limbs

Examine symmetry of length, creases, flexion and muscle tone. The term baby has creases over more than two-thirds of the sole of the foot (see Fig 27.7). Check for polydactyly, webbing and skin tags. Examine groin and popliteal spaces for abnormalities. Confirm symmetry and normal range of movement in the joints. Note that the knee joints often cannot be fully extended for the first few days (Johnston et al 2003).

The term baby's feet should easily dorsiflex so that the upper surface of the foot almost touches or touches the shin. (Preterm infants' feet do not fully dorsiflex.) Examine for signs of talipes equinovarus. ***Do not force the foot***. If it will not naturally flex, refer the baby for paediatric or orthopaedic examination.

Spine and back

Turn baby over and examine the spine. Palpate the length of the spine to feel all the vertebral spinous processes. If there appears to be a gap, a hairy patch, or an area of thickened or differently textured skin over the spine, refer to a paediatrician for exclusion of spina bifida.

Examine the cleft in the buttocks; about 1% of babies have a dimple, usually at the top of the cleft (Johnston et al 2003). Ensure that the base of the dimple is sighted and that it is closed. The dimples are usually benign; however, very occasionally they are open to the meninges at the base, or it may be a congenital pilonidal sinus. If the base cannot be clearly seen or the dimple is deep, paediatric consultation is indicated. Dimples elsewhere on the spine should always be medically assessed (see Ch 38).

While examining the back, note the baby's posture when held in ventral suspension (see neurological section and Fig 27.13, below).

Visually check that the anus is patent and correctly positioned.

Genitalia

Female

The labia majora covers the clitoris and labia minora. The labia should be parted to examine the clitoris for appropriate size. The hymen should be perforated, confirmed by whitish vaginal discharge. There may be a small quantity of bloodstained discharge in the first few days, which is a pseudo menstrual period caused by the withdrawal of maternal hormones at birth (Johnston et al 2003; London et al 2003; Thureen et al 2005).

Male

The foreskin should completely cover the glans penis. As it is normally adherent it should not be retracted. By three years of age, 90% are retractable (Johnston et al 2003; Thureen et al 2005). Examine the penis for hypospadias by ensuring that the urethral opening is at the end of the penis and that the tissue is intact along the full length of the inferior surface.

The scrotum should be soft and covered in rugae. Hydrocoele (collection of fluid in the scrotum) is not uncommon and should be identified. While most resolve spontaneously, consultation is appropriate (London et al 2003) as inguinal hernia should be excluded. Strangulated inguinal hernia is a surgical emergency (Thureen et al 2005).

Gently palpate the scrotum between the thumb and forefinger for the testes. They are firm, pea-like structures 1.5–2 cm long (Johnston et al 2003). The testes are sensitive to temperature and may move back up the inguinal canal when cold. It is not uncommon for one or both testes to have not descended. It they are not palpable in the scrotum, palpate the groin from the iliac crest to the external inguinal ring, where undescended testes are sometime palpable. Babies with undescended testicle(s) need medical follow-up as it can take several years for the testes to descend. Testes that fail to descend are treated surgically in childhood (Johnston et al 2003; Thureen et al 2005).

Ambiguous genitalia

Gender should not be ascribed if there is any doubt. Medical referral is required if the genitalia appear ambiguous, as it is important that gender is correctly ascribed. Chromosomal analysis may be required. Ambiguous genitalia are almost always associated with an underlying abnormality (Johnston et al 2003).

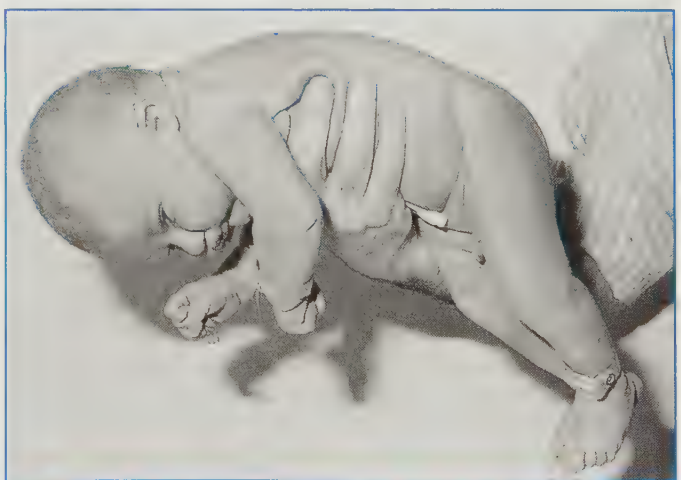

Figure 27.13 Ventral suspension (Fraser & Cooper 2003)

Elimination

Note whether the baby has passed urine or meconium.

Neurological examination

Movements and reaction to stimuli change as gestation progresses. What is normal at 34 weeks is not normal at term. When interpreting the neurological examination, the baby's gestational age and state of arousal need to be taken into account (Johnston et al 2003). The baby needs to be in a quiet alert state. The integrity and normality of the neurological system is tested by assessing the baby's posture and reflexes. Weak or absent responses may indicate immaturity or an abnormality.

Posture

- Supine—legs are semi-flexed and the head turns to one side. The arms and legs recoil readily if extended and released. The elbow should not cross the midline when the arm is drawn across the chest and up to the neck (scarf sign, see Fig 27.8).
- Prone—legs are more flexed and tucked up under the abdomen; the arms are held to the chest in a flexed position.
- Ventral suspension—when the baby is held up by the examiner's hand under the chest (see Fig 27.13), the body is semi-flexed, the head is briefly extended in line with the spine, and the limbs are momentarily flexed.
- hAll limbs move spontaneously.

Rooting, sucking and swallowing

These are easily observed when the baby commences feeding. The rooting reflex is easily stimulated by brushing the baby's cheek or upper lip with a finger. The baby will turn toward the stimulus and open the mouth ready to suck. The suck–swallow–breathe pattern is coordinated and strong enough for adequate feeding from 36 weeks.

Grasp reflexes

These can be elicited in both the hands and feet. It is strong enough in term neonates to briefly lift the baby away from the examination surface.

Traction response

When the baby is pulled forward by the hands from supine to a sitting position, the elbows, knees and ankles flex (see Fig 27.14). The head comes with the body with minimal lag. When the baby reaches the sitting position, the head falls onto the chest. The response reflects the development of flexor tone, which occurs at about 37 weeks.

Asymmetric tonic neck reflex

The head is turned to one side while the baby is supine. The limbs on the side the baby is facing extend, while the limbs on the opposite side flex (see Fig 27.15). It is strong from 30 to 36 weeks, may not be seen in the early newborn period, and returns four to six weeks after birth. A very strong response at birth needs a medical consultation (Johnston et al 2003, London et al 2003).

Moro reflex (startle reflex)

In response to a loud noise or suddenly lowering of the head into the examiner's hand, the baby extends the arms, hands and fingers outwards and the knees flex (see Fig 27.16). The arms slowly return into the chest (like a hug). The baby may cry.

Stepping response

When the baby is supported in a standing position with the soles of the feet on a firm surface, the infant will simulate walking. The presence of this reflex indicates mature extension and flexion mechanisms (Farrell & Sittlington 2003b; Johnston et al 2003; London et al 2003).

Hips

Developmental dysplasia of the hips (DDH) is a condition that has serious consequences for the child if not diagnosed and treated very soon after birth (see Ch 38 for treatment). Screening babies for this condition is non-invasive and effectively diagnoses most babies requiring orthopaedic assessment. Clinical examination using Ortolani's and

Figure 27.14 Traction response (Fraser & Cooper 2003)

Figure 27.15 Tonic neck reflex (Thureen et al 2005)

Figure 27.16 Moro reflex (Fraser & Cooper 2003)

Barlow's tests is universally used to screen newborn babies. When examiners are experienced, sensitivity is significantly improved. The tests have high specificity but a low sensitivity, resulting in a false positive rate and subsequent over-treatment and a false negative rate resulting in late detection (Eastwood 2003). Ultrasound is used for screening in some centres in Europe and Britain. Two recent reviews of the research concluded that there is as yet insufficient clear evidence for or against general ultrasound screening of neonates for DDH (Eastwood 2003; Woolacott et al 2005).

Examine the hips for:

- symmetry of thigh and buttock creases
- equal leg length
- range of abduction
- dislocation or laxity of the hip joints ('clicky hips').

Symmetry of thigh and buttock creases, leg length

The thigh and buttock creases should be symmetrical when the baby is lying prone. (Note these when examining the baby's back, to minimise handling.) The legs should be of equal length. When the baby is lying flat with knees flexed, the height of both knees should be equal. Asymmetry and/or limited range of abduction may be signs of DDH. These assessments are unreliable alone and must be accompanied by the abduction tests.

Abduction tests

Each joint should be physically assessed separately for dislocation or laxity. Two tests are normally used:

- Ortolani's test (Fig 27.18) examines for the presence of a dislocated hip.
- Barlow's test (Fig 27.17) examines the joints for laxity and the capability for the joint to dislocate with ease (see Clinical point above, for procedures).

Findings:

- Normal finding—no movement is felt in the joint.
- Joint laxity—on examination the joint feels lax or unstable (i.e. 'gives' a little) but does not clunk. It may 'click' during the examination. Joint laxity at birth is the result of the breech position in some babies or may be related to a hormonal effect on the joint capsule, especially in baby girls. In most cases the joint capsule tightens over several days and the laxity disappears. Persistent joint laxity is abnormal. *All* babies with joint laxity are referred for medical assessment so that the state of the joint can be monitored and treatment commenced where necessary.
- Dislocated or dislocatable hip(s)—if a distinct 'clunk' is felt and/or heard when either test is carried out, the femoral head is dislocated or dislocatable. Immediate orthopaedic referral is required so that treatment can be commenced without delay (see Ch 38).

Clinical point

Examining the hips for developmental dysplasia

In all cases *be gentle*. The pressure you apply to the baby's legs should the same as you would apply in holding an egg. Excessive force is not needed. If the hip joint is unstable, it will move as the test is carried out. Normal hip joints are stable.

Preparation:

- consent from mother
- warm, relaxed baby lying flat on a warm, flat surface
- napkin off.

Do *not* attempt the examination if the baby is distressed.

Ortolani's test

Joints are assessed separately.

1. Stabilise the pelvis with the non-examining hand.
2. Hold each leg, place thumb on inner surface of the thigh, and the index and middle fingers over the greater trochanter of the femur.
3. Flex the knees and the hips 90 degrees.
4. Lifting the thigh slightly, abduct the leg gently, applying pressure over the trochanter with the fingers. (The aim is to slide a dislocated head of femur over the rim and back *into the acetabulum*.)
5. A positive result is a palpable clunk.

Barlow's test

Assess each hip separately.

1. Hold the knee and hip in a flexed position.
2. Gently pull the thigh upward, Adduct the thigh *slightly* and push downward toward the bed, then abduct the thigh. (The aim is to slide a dislocatable head of femur over the rim and *out of the acetabulum*.)
3. A positive result is a palpable clunk.
4. Record findings.

(Sources: Johnston et al 2003; Thureen et al 2005.)

Record of neonatal examination

Although there is no single way to record the findings from the examination, it is essential that the assessment is fully recorded. Table 27.5 shows some commonly used symbols for recording selected assessments. These records usually form

Figure 27.17 Barlow's test (Thureen et al 2005)

Figure 27.18 Ortolani's test (Thureen et al 2005)

part of a total record for the baby at birth and at subsequent assessment points.

Care of the newborn infant

Growth and development: birth to six weeks

Newborn infants communicate verbally by crying. Non-verbal communication is initially by reflex, such as the sucking and rooting reflexes. By the time they are four to six weeks old babies can also communicate by smiling in response to an adult and exhibit the beginnings of random 'cooing' when content. Random smiling may occur quite early but smiling socially in response to an adult does not usually appear before four weeks, and it is often closer to six weeks before it occurs.

Restlessness when hot or uncomfortable begins to be seen as the baby grows.

Initially, babies move their arms and legs and can turn their head from side to side as they seek the breast. By four to six weeks, babies can generally turn their head from side to side and raise their head from the cot when in the prone position. They have developing neck strength.

At birth, babies are usually quiet and wide-eyed, have a crinkled skin and some degree of head moulding. They lie in their mother's arms or in the bassinet generally in the same flexed position as they were in utero. They unfurl like flowers opening over the first one to two weeks of life. Head moulding disappears and the head shape becomes round. The face appears to 'open up' as the head shape changes, the crinkly reddish appearance present at birth disappears and the skin smoothes out. Their bodies also unfurl. While babies' bodies stay quite flexed while sleeping, there is a gradual straightening of the body when the baby is awake. For parents, watching this gradual unfurling is one of the precious joys of new parenthood.

Ongoing care

Everyday assessment for mothers and midwives

The thriving baby:

- *The baby should be content between feeds and have a wet nappy every feed.* In the first 24 hours the baby must pass urine, usually 2–5 times; thereafter 6–8 wet nappies every 24 hours, regular bowel motions, usually 2–3 every 24 hours (the pattern varies).
  Note: Disposable nappies are designed to pull the moisture away from the baby's skin. It is sometimes quite difficult to tell whether the baby has passed urine just by looking at the nappy. Feeling the weight of a dry, unused nappy and the one removed from the baby helps to determine this. Disposable nappies full of urine feel heavy when 'weighted' in the hand.
- *The baby should look well.* That is, the baby has a pink colour, and feels warm to the touch, including extremities. Breathing is not very noticeable (see section on normal variations in breathing, this chapter). Arms and legs are flexed and feel firm, with good muscle tone, content expression, not grimacing or frowning (although babies do have these expressions when passing a bowel motion). There should be no signs of infectious skin lesions and the umbilical cord should be clean and dry (see box, umbilical cord care, earlier).
- *When asked, the mother says the baby is well.* It is imperative that the midwife asks the baby's mother how the baby is, and *listens* to the answer. The mother has much more knowledge of the baby than the midwife. If the mother expresses concern, listen and look carefully. Babies can become seriously ill *very* quickly and do not show signs of illness in the way that adults and older children do. Signs are often subtle and/or global—examples are: (i) a baby with a urinary tract infection will not necessarily have a high fever and cannot say where the pain or discomfort is; (ii) a baby that has been feeding well, stops feeding; (iii) significant or persistent jaundice (see Box 27.2 for danger signals).

Ongoing assessment of growth

Every baby in all Australian states and in New Zealand has an individual health record book that is maintained by all providers of healthcare during the first two to five years. The record books have a variety of local names (e.g. the Blue Book, the Plunket Book, the Well Child Health Book). The books include an ongoing record of assessments by midwives and well child healthcare providers, and information for parents about age- and stage-related issues such as making the house safe when the child begins to crawl and walk. The books also keep an ongoing record of the baby's growth and

BOX 27.1 Decision points in the first six weeks

1st decision point (immediately post partum up to and including the first 24 hours)

Physical:

- full physical assessment of the baby including heart sounds, hip examination, weight and measurements

Possible tests:

- blood group, Rhesus factor, Direct Coombs test

Possible treatments:

- respect the birth plan developed with the woman in relation to administration of vitamin K, hepatitis B immunoglobulin and vaccination
- facilitate BCG vaccination as appropriate

Health information and education:

- information for baby care related to: feeding, breathing, passing urine and meconium, umbilical cord care, crying, warmth, safety
- national immunisation register
- information about developing parenting skills
- legal requirements
- birth notification.

Subsequent decision points in postnatal period

Every 24–48 hours until the woman feels confident in her home environment

Information shared:

From history:

- Discuss lactation and ongoing feeding.
- Discuss parental and baby's wellbeing.

From examination:

- full physical examination of the baby

Possible tests:

- Guthrie test; consider need for serum bilirubin estimation

Consider additional care if:

- feeding problems, congenital abnormalities, parenting problems

Six-week or final postnatal visit

Information shared:

From history:

- feeding and behaviour patterns

From examination:

- developmental assessment, full physical examination

Health information:

- immunisation
- community agencies and other health professionals for referral as appropriate or necessary

Well child health service:

- information, referral and expectations

Discuss consumer feedback and midwives' standards review process.

(Source: NZCOM 2005)

Critical thinking exercise

Baby Matt is examined at birth.

1. Plot weight, head circumference and crown–heel length on a centile chart for newborn boys.
2. Determine whether Matt is large, appropriate or small for gestational age.
3. Use a Ballard assessment score sheet to assess Matt's gestational maturity from the following features that have been observed:
   - Weight: 3000 g
   - Head circumference: 35 cm
   - Length: 50 cm
   - Skin is peeling, lanugo is in patches
   - The ears are formed, firm and show instant recoil
   - Creases cover two-thirds of the soles of the feet
   - Breast has raised areola, 3–4 mm bud
   - The scrotum is covered in rugae and contains both testes
   - Limbs are flexed at shoulders, elbows, hips and knees
   - 0° square window; arm recoil 90–100°; popliteal angle 90°; scarf sign at the midline; heel to ear scores 4 on the Ballard scale.

development up to two to five years of age. Weight, length and head circumference are measured regularly to assess growth.

Centile charts

Assessment of growth generally involves the use of standardised centile charts (see Fig 27.20). Consult the Well Child record book or the local area Department of Health website, as centile charts usually reflect the growth patterns of each country's population and therefore vary a little. Serial measurements of weight, length and head circumference are recorded in the clinical notes and/or on the centile charts in the baby's health record book. The centile charts provide a visual record that enables comparison of growth in the three measurement dimensions. Different centile charts are used for boys and girls. In healthy term babies, all three measurements parallel each other along the same centile curve (e.g. all following the 50th centile curve). Babies who have an initial measurement below the 3rd or above the 97th centile are carefully assessed to exclude underlying causes, as are babies with ongoing measurements that begin to fall below the initial centile curve.

Growth rate

Babies double their weight by five to six months and treble it by the end of the first year. After six months babies gain 100 g per week on average. The average length at birth is 48–52 cm. By six months, 8–10 cm is gained, and another 10 cm by the end of the first year (Sweet 2000). (See Ch 29 for feeding and weight gain.)

BOX 27.2 Child sickness danger signals

Get help from a doctor *quickly* if your baby or young child shows any of these signs.

General:

- Cannot be woken or is responding less than usual to what is going on around them.
- Has glazed eyes and is not focusing on anything.
- Seems more floppy, drowsy or less alert than usual.
- Has a convulsion or fit.
- Has an unusual cry for one hour or more.
- Has been badly injured.
- There is a bulge in the groin which gets bigger with crying.

Temperature:

- Feels too cold or too hot (temperature 38.3°C or higher).
- Circulation and skin colour.
- Body is much paler than usual or suddenly goes very white.
- Nails are blue or big toe is completely white, or colour does not return to toe within three seconds of a squeeze.

Breathing:

- Goes blue or stops breathing.
- Breathes more quickly than normal or grunts.
- Is wheezing when breathing out.
- In-drawing of the chest [is] visible with each breath.

Vomiting and diarrhoea:

- Has vomited at least half the feed after each of the last three feeds.
- Has green vomit.
- Has taken less fluid then usual.
- Has passed less urine then usual.
- Has a large amount of blood in nappy.

(Source: New Zealand Ministry of Health 2004)

Warmth and hygiene

One of the pleasures for new parents is bathing their baby. This is a time when parents can get to know their baby. Babies enjoy a deep bath, which can be a relaxing time for parents and baby. There is no 'right' way to bath a baby as long as the baby does not get cold in the process. Common-sense precautions such as warm room, towels and clothes, getting all necessary equipment ready before starting, and drying the baby thoroughly, are simple ways to prevent chilling. Soaps and shampoos should not contain strong detergents or perfumes, as the baby's skin is easily irritated.

Parents are frequently encouraged to dress their baby in many layers of clothing. Generally, it is sufficient to use one layer more than the other people in the room are wearing. Babies do not sweat very effectively and become overheated. Out of doors, especially in extreme climates, care should be taken to protect the baby's head and extremities from cold and to protect the face from cold winds (Varney et al 2003). Conversely, in hot weather keep the baby out of direct sunlight and protect the skin with light clothing.

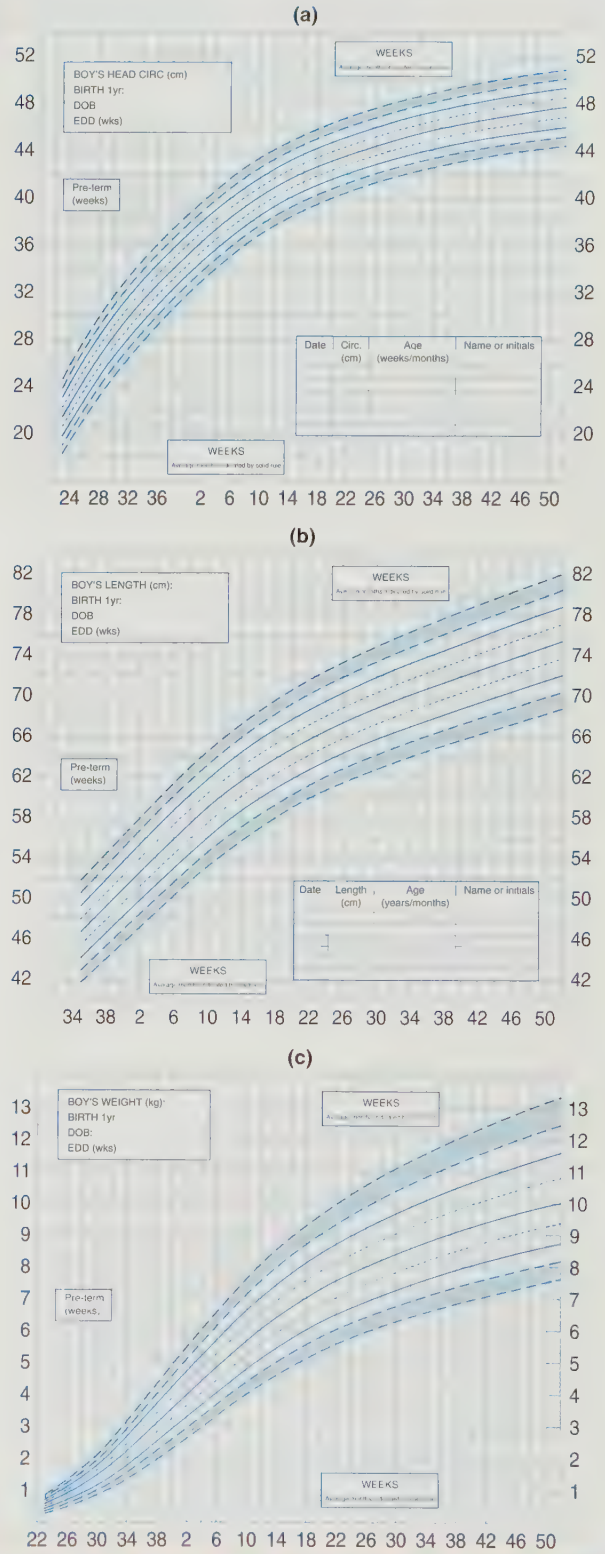

Figure 27.20 Growth charts (a) Head circumference from preterm (24 weeks) to one year (male). (b) Length from term birth to one year (male) (c) Weight from 23 weeks to one year (male) (adapted from Henderson & Macdonald 2004)

Prevention of injury or accident

Commonsense precautions should be observed by midwives and parents, to prevent injury. Babies should not be left unattended in cots with the sides down or on beds, chairs or tables. Pillows are not required in bassinets. Bath water should be tested before bathing the baby. Care needs to be taken with polythene bags and wrappings, and waterproof mattress covers need to be tightly fitting to avoid loose covers that may suffocate the baby (Farrell & Sittlington 2003b).

Car safety

There is evidence that death or injury in a car accident can be prevented or minimised by appropriate restraint for age. In Australia and New Zealand it is illegal for any person to be unrestrained in a car. Newborns are restrained in car seats that are the correct size for newborns. In many areas, local health authorities or well child services provide an affordable hire service. Local availability should be sourced so that women can be given the required information.

Prevention of sudden infant death syndrome (SIDS)

- Sleeping position—there is strong evidence that babies should sleep on their backs. Parents may need to be reassured that it is safe to do so. Since the introduction of the 'back to sleep' programs in Australia and New Zealand, the death rates from sudden infant death syndrome (SIDS) have fallen substantially.
- Maternal smoking—maternal smoking in pregnancy significantly increases the risk of SIDS. Ongoing smoke-change programs are working with women to reduce smoking in pregnancy. The new baby's environment should also be smoke-free.
- Bed sharing—bed sharing between a mother and her baby is a traditional and treasured practice in many places. Some situations make bed sharing less safe for young babies. The biggest risk is when there has been smoking in pregnancy. Bed sharing is also less safe when the adult is under the influence of drugs or alcohol, or is a smoker. Bed sharing should also be avoided with preterm babies (< 36 weeks gestation), low birthweight babies (< 2500 g) and babies exposed to smoking.
- Safe bedding—providing a firm sleeping surface (no soft surfaces, chairs, sofas, bean bags or waterbeds) and keeping the baby's face clear of loose bedding reduces the risk. There should be no pillows or stuffed toys in the cot while the baby is asleep (Cowan 2000).

Immunisation

Australia and New Zealand have similar standard immunisation schedules. However, the vaccines offered at birth and the timing of the vaccinations is different. The Immunise Australia Program website states that 'Immunisation providers are responsible for advising patients and parents/caregivers of available vaccine choices at the time of consultation, including those provided free under the National Immunisation Program' (DHA 2004). Each state and territory health authority has an Immunisation Infoline. The immunisation schedule and information about current vaccines are also available in *The Australian Immunisation Handbook* (DHA 2003).

The New Zealand Immunisation Schedule and information about current vaccines is available on the NZ Ministry of Health website (http://www.moh.govt.nz) or from the Immunisation Advisory Centre (http://www.immune.org.nz). The Ministry of Health also publishes a print version of the *Immunisation Handbook*. Midwives and other LMCs are required to provide parents with timely information about both the risks and benefits of immunisation and about the immunisation schedule so that an informed choice can be made. The information is usually discussed by the midwife at the four-week discharge visit, so that the parents or sometimes a child health nurse have made a decision by the six-week visit when the schedule commences.

Screening for inborn metabolic and endocrine disorders

Blood tests such as the Guthrie test are available to screen for a variety of inborn errors of metabolism and some endocrine disorders. A blood spot collection is made onto an absorbent card. For some tests the baby must have had a minimum of 48 hours of milk feeding prior to specimen collection. The conditions tested for vary in each population and with Health Department policy. They are rare conditions where very early diagnosis and treatment can prevent brain or other organ damage or prevent other serious complications.

Conditions commonly screened for can include:

- biotinidase deficiency
- congenital adrenal hyperplasia
- cystic fibrosis
- galactosaemia
- hypothyroidism
- maple syrup urine disease
- phenylketonuria
- sickle cell disease
- thalassaemia.

Population screening such as this raises ethical issues about consent, especially in relation to the addition of tests to the screen and about the long-term storage of blood samples. Murray and Clarke (2002) hold the view that 'while personal autonomy must be respected . . ., especially the need for informed consent, population screening will often be justified on the basis of benevolence' (p 447). There is no doubt that early diagnosis of hypothyroidism, for example, prevents the development of cretinism—babies treated early lead a normal life with no brain damage. However, the issue of stored blood samples has been considered by the New Zealand Privacy Commissioner (2003). The issues of explicit consent for storage, length of storage, the increasing list of items that the stored specimens can be tested for, and protection against access by other organisations or individuals, were the subject of the Commissioner's report. Storage varies between countries, from instant destruction (France), to two years (Western Australia), to indefinite (New Zealand). The information leaflet provided to New Zealand mothers prior to obtaining consent now makes the storage information explicit.

Clinical point

Bedsharing

(By Sally Baddock)

Bedsharing between babies and their mothers (and sometimes other family members) is a traditional practice in many cultures and is becoming more common again in Caucasian families (Arnestad et al 2001). Bedsharing is often chosen as a way of facilitating breastfeeding, and the majority of infants who bedshare are breastfed. However, bedsharing is not a single coherent practice. Families follow varied practices and choose to bedshare for different reasons, and this may affect the safety or otherwise of their sleeping arrangements (Baddock et al 2000).

Parents who choose to bedshare report ease of breastfeeding, reduced tiredness, emotional benefits, and having a more settled baby (Baddock et al 2004; Ball et al 1999; McKenna et al 1994). This is supported by observational studies that record increased breastfeeding, increased maternal interactions, and synchronisation of mother–baby sleep patterns during bedshare sleep. Mothers and babies are also found to sleep facing each other, in close proximity, and with the baby most often at the level of the mother's breast, facilitating breastfeeding (McKenna et al 1997; Young 1999). Fathers, if present, do not usually interact with the baby overnight.

While observational studies show that bedshare babies wake more often, their total sleep time is similar to that of cot-sleep babies, as cot sleepers tend to wake for longer at each waking (Baddock et al 2004). Waking and feeding poses less disruption in the bedsharing situation as mother and baby remain in bed, often with the mother feeding in a drowsy state. Maternal checks are sometimes prompted by infant movements, but equally the mother self-initiates many checks through the night (Young 1999). Mothers report an awareness of their babies even during sleep.

The benefits of bedsharing seem to stem from the mother–baby partnership and the facilitation of breastfeeding. As such it is a strategy incorporated into UNICEF Baby-Friendly Hospital Policies (FSID UNICEF 2003). It has been reported that non-breastfeeding mother–baby pairs do not adopt the same orientation in bed and may not derive the same benefits from bedsharing (Ball 2002). This is supported by a study of high SIDS risk, low-income families in inner-city Chicago, where bedsharing was common but breastfeeding was not (Hauck et al 2003). Bedsharing is also associated with a high rate of SIDS in cultures such as New Zealand Maori (Mitchell et al 1993), and Australian Aborigines (Panaretto et al 2002). In other cultures, however, bedsharing is common but the rate of SIDS is low—for example, Japanese (Sawaguchi & Namiki 2003), Bangladeshi infants in Wales (Gantley 1994) and infants from Pacific Island cultures (Mitchell et al 1993).

The difference in risk may be linked to high rates of maternal smoking in ethnic groups with higher SIDS rates. Bedsharing with a mother who smoked during pregnancy has consistently been identified in international studies as increasing the risk of SIDS (Carpenter et al 2004; Mitchell et al 1993). The risk from maternal smoking is greater for bedshare infants than for infants who sleep in a cot. It is possible that infants compromised by maternal smoking may not have adequate ventilatory (Campbell et al 2001) or thermal (Tuffnell et al 1995) responses to particular stresses arising in the bedsharing environment. The increased risk may be from increased head covering that inadvertently occurs during bedsharing due to the mobility of the bedding, or it may be connected with the warmer environment during bedsharing, associated with thicker adult bedding (Baddock et al 2004). The close maternal contact in bedsharing may also expose the bedsharing infant to more effects from passive smoking—for example, nicotine has been shown to accumulate on furniture surfaces and bedding, even if the mother smokes only outside the house (Matt et al 2004).

Other risk factors associated with bedsharing include recent maternal alcohol consumption or illicit drug consumption, maternal overtiredness, excessive bedding, household overcrowding, and infant age younger than eight weeks (Blair et al 1999; Carpenter et al 2004). Sleeping on a couch, chair or waterbed with a baby increases the risk of SIDS, possibly due to the likelihood of the baby becoming trapped between adult and furniture. Pillows or situations that might lead to wedging or trapping of the baby (e.g. between the bed and wall or between two mattresses) also pose a risk.

Thus the risk factors are grouped around a vulnerable baby (young age, exposure to smoking), an impaired mother (alcohol, overtired) and the physical environment (overheating, hazardous bedding). Some of these factors can be addressed, but the evidence to date suggests that a baby exposed to smoking in utero should not bedshare.

For healthy babies with mothers who are able to respond appropriately to the subtle cues of their baby, unimpaired by alcohol or overtiredness, bedsharing may offer many advantages, particularly with respect to ease of breastfeeding.

For current advice regarding safe bedsharing, check the following website: http://www.babyfriendly.org.uk/bedshare.asp

Hearing

If a universal newborn hearing screening program is not in place, the parents should be asked if they think their baby can hear before the six-week examination. Questions such as: 'Does the baby startle to loud noise?' and 'Does she turn her head in the direction of localised noise, such as the mother's voice?' are asked.

Referral to a paediatrician, otolaryngeal specialist and/or audiologist is warranted for any of the following situations:

- a close relative who has been deaf from early childhood
- rubella or contact with rubella or other congenital infection during pregnancy (e.g. cytomegalovirus (CMV))
- prematurity (< 32 weeks gestation or < 1500 g birthweight)
- malformation of head or face, or other physical findings known to be associated with deafness
- serum bilirubin levels that require exchange transfusion
- Apgar score of 0–4 at one minute or 0–6 at five minutes or more than five days ventilation
- bacterial meningitis
- received ototoxic medications (NZMOH 2004, p 76).

Vision

Before the six-week examination, parents should be asked if they think their baby can see: 'Does their baby close his/her eyes against bright light, stare at people's faces when they are up close, turn toward light, smile at the parent without being touched or spoken to' (NZMOH 2004, p 85).

Referral to an ophthalmologist or paediatrician is warranted for any of the following situations:

- close relative with an eye tumour at birth or during infancy
- close relative with a congenital eye malformation
- rubella or contact with rubella or other congenital infection during pregnancy (e.g. toxoplasmosis)
- prematurity (< 32 weeks gestation or < 1250 g birthweight)
- eye malformations (absent red reflex, bulging eye, abnormal pupil); failure to fix or follow objects/movements; abnormal eye movements
- newborn seizures, encephalopathy, certain errors of metabolism
- trauma to the eye
- conjunctivitis that worsens or does not resolve (NZMOH 2004, p 76).

Physiological jaundice

Jaundice is a symptom that either reflects the normal breakdown of RBCs that contain HbF that is no longer required or reflects an underlying pathological process. Neonates require careful assessment in the first weeks of life to exclude hyperbilirubinaemia, particularly caused by dehydration, infection or severe physiological jaundice as kernicterus is again being reported in term infants (Bratlid 2002). Jaundice may be the only sign of bacterial infection (Garcia & Nager 2002). Hannon and colleagues (2001) showed that jaundice alarms mothers—mothers were concerned about it and perceived it as serious. In their study, Hannon and colleagues found that mothers expressed misconceptions and felt guilty, as they believed that they had caused the jaundice. However, interactions with health personnel and other mothers who had personal experience reduced their concerns. Midwives work in partnership with women to keep them informed of the baby's progress, the nature of physiological jaundice and which observed signs warrant calling the midwife.

Assessing physiological jaundice

In the community, clinical estimations of the severity of jaundice are usually made without the aid of instruments such as an icterometer or bilirubinometer, although the latter have recently made a reappearance in some hospitals. Jaundice progresses from the baby's head to the toes. The further down the body the yellow colour is, the higher the serum bilirubin level. Daily assessment of skin colour, muscle tone, alertness, feeding patterns, urinary output and sleeping behaviours assists midwives to determine whether an estimation of serum bilirubin is warranted. It is very important not to rely on skin colour alone. A dehydrated baby, for example, will exhibit the lethargy and poor urine output related to the lack of fluids while still only mildly yellow, while babies who are alert, feeding well with good muscle tone and urinary output may be quite yellow-looking and be well.

Serum bilirubin estimation in a term baby is warranted if:

- the baby is jaundiced (any degree of yellowness) and sleepy and/or feeding poorly and/or has a reduced urinary output
- the baby unexpectedly becomes jaundiced for the first time after 72 hours of age
- the baby's body is quite yellow. As rule of thumb, if the jaundice is seen in the lower abdomen or below, has spread below the mid upper arm, or the sclera are yellow, the levels are likely to be in excess of 250 mmol/L and a serum estimation is warranted.

The level of jaundice in darker-skinned babies is more difficult to assess. Blanch the baby's gums with a gloved finger. The depth of the yellow discolouration provides additional information to assist with the assessment.

Note: Assess the baby in natural light where possible; pink walls and pink or yellow clothing can affect the appearance of the skin colour.

Critical thinking exercise

At an antenatal visit, a pregnant woman asks you what sort of clothes, what size and how many she needs for her baby. She also asks you whether she should use cloth nappies. Consider your reply. Where would you access the information the woman needs in your local maternity services?

Summary

- The neonatal period lasts for 28 days. Midwives work in partnership with the baby's mother for a variable time up to six weeks of age. Midwives use professional knowledge and judgement to support new parenting, share information, and provide initial and ongoing examination and assessment of the baby's health, wellbeing and development. Timely identification, treatment and/or referral for variations from normal and appropriate transfer of care to well child services are integral to contemporary, professional midwifery care of the newborn infant.
- The transition from intrauterine to extrauterine life is characterised by physiological adaptation of many of the baby's body systems. Care of the neonate is based on supporting normal transition and early identification of variations from normal for treatment and/or referral.
- A sound understanding of neonatal anatomy, physiology and development enables midwives to support women as they learn to recognise normal behaviour and growth and development of their baby.
- Information sharing about the everyday signs that her baby is thriving, commonsense precautions to prevent heat loss and infection and common variations in baby behaviours such as sleeping and crying, assists women to develop confidence as they learn to care for their newborn infant.
- Developing the knowledge and skills to undertake a comprehensive physical examination of a newborn baby is within the scope of midwifery practice, as is ongoing monitoring of growth, development, health and wellbeing.
- Knowledge and assessment skills are required to recognise the baby who is ill, not thriving or who has a variation from normal that requires referral to another health professional.
- Good record keeping and inter-professional communication ensure that healthcare providers can continue to provide individualised and contextualised care.

Conclusion

The aims of this chapter have been to promote understanding of neonatal physiology and adaptation to extrauterine life, so that assessment skills to monitor infant health, wellbeing and development can be developed; and to promote knowledgeable and skilful midwifery practice incorporating available evidence for care that supports the newborn infant. A significant proportion of midwifery care of the newborn consists of sharing information that informs, educates and supports the baby's mother to develop confidence in her own capabilities to nurture and care for her baby and to recognise and take action when her baby is unwell.

Review questions

1. In what way do prenatal fetal breathing movements assist the assessment of post-term fetal wellbeing?
2. What would be the result if one of more of the temporary structures in the fetal circulation failed to close after birth?
3. Which babies are at higher risk of developing VKDB?
4. Are there times when vitamin K would not be administered?
5. Why can persistent jaundice be a sign of neonatal infection?
6. If you work in an area where the temperatures are extreme, what advice will you give to women about protecting their baby in very hot or very cold conditions? Find out what advice is given by midwives in your area.
7. What are the procedures in your local area if a lax hip joint is detected at birth? At one week?
8. How will you differentiate a monilial rash from nappy rash on the baby's buttocks and groin? What advice will you give the baby's mother? How will you treat the condition?
9. In your area, which conditions are tested for in the postpartum blood spot test? What is the incidence? How are they treated?
10. What action will you take if one of the blood spot tests returns a positive result?
11. In your area, what happens to the blood spot cards once the tests are completed?

Note

1 Other family members such as the baby's father, grandparents or other significant people are also part of the baby's life, and as such are included in midwifery care of the family. Nevertheless, the mother and her baby are the recipients of midwifery care and the primary interactions usually take place between the baby's mother and the midwife. This chapter refers to woman/mother and baby while respecting that others are closely involved and may also be a primary adult in the baby's life.

CHAPTER 28

Supporting the breastfeeding mother

Ann Henderson and Marlene Scobbie

Key terms

ankyloglossia (tongue tie), attachment, engorgement, epidemiological research, galactopoesis, lactation, lactogenesis I, lactogenesis II, let-down reflex, mammogenesis, mastitis, positioning

Chapter overview

The purpose of this chapter is to provide an understanding of breastfeeding from both global and local perspectives. It reviews the physiology of lactation, and the benefits and properties of breast milk in establishing a natural personal and public health advantage for infants, women, families and communities. Worldwide public health initiatives that actively protect, promote and support breastfeeding provide a global context through the local application of the Baby Friendly Hospital Initiative (BFHI) and the ten steps to successful breastfeeding in healthcare services.

The chapter establishes an evidence-based framework for understanding, educating and assisting women and their families with breastfeeding. The discussion draws on research to identify benefits of breastfeeding practices and provide guidelines for midwives when working with women who are preparing, initiating and maintaining breastfeeding. Problems that may arise during breastfeeding are addressed, and evidence-based strategies for their management are discussed. Positioning and attachment are emphasised as crucial to milk production, supply and successful transfer from mother to infant. A critique of artificial feeding is presented against a background of the advantages of breast milk and breastfeeding.

Learning outcomes

Learning outcomes for this chapter are:

1. To identify the location and anatomical structures of the female breast
2. To explain the function at a cellular level of the lactating breast
3. To differentiate between mammogenesis, lactogenesis and galactopoesis
4. To identify the properties of human breast milk
5. To discuss the benefits of human breast milk
6. To discuss worldwide initiatives that promote breastfeeding
7. To identify the ten steps to successful breastfeeding
8. To describe recommended practices that assist in the preparation, initiation and maintenance of breastfeeding
9. To recognise the importance of positioning and attachment of an infant at the breast
10. To identify common problems associated with breastfeeding, and describe recommended interventions and treatments for each identified problem
12. To critically analyse artificial feeding in relation to breastfeeding.

Physiology of lactation

Breast anatomy

The mature female breast is located over the pectoralis major muscle on the chest wall, extending from the 2nd to the 6th rib and from the sternum to the axilla on each side (Stables & Rankin 2004), and is composed of glandular tissue with a branching duct structure surrounded by supportive connective and adipose tissue. Breast size, colour and shape vary from breast to breast and from woman to woman. Breast size is dependent on the amount of adipose tissue present—size is a poor indicator of breast function and breastfeeding success (Riordan 2005).

In the mature woman, each breast has 7–10 sections or lobes of glandular tissue separated by connective tissue. The gland epithelial tissue (secretory or acini cells) synthesises the breast milk, which is then stored in small clusters of sac-like spaces called alveoli. Some 10–100 clusters of alveoli cells are present in each lobe, supported by collagen sheaths (Stables & Rankin 2004). Myoepithelial (muscle) cells surround the clusters of alveoli. The breast milk passes with the aid of muscle contractions from the alveoli into small and then larger ducts as they get closer to the nipple. Several milk ducts merge close to the areola before the nipple is reached. Some 5–10 small channels or pores emerge through the nipple to the skin surface (Brodribb 2004). A diagram of the breast structure is shown in Figure 28.1.

Ultrasound technology has enabled the female breast structure and function to be more clearly visualised (Ramsay et al 2002). This research has challenged the once-familiar, well accepted and longstanding diagrams depicted in textbooks. Visualisations have indicated:

- fewer lobes (7–10, not 15–20)
- an absence of milk sinuses (reservoirs) behind the nipple and areola
- fewer openings of milk ducts at the nipple (5–10, not 15–25)
- smaller number and size of the small and larger ducts
- rapid branching of ducts close to the areola, which continue to branch and intertwine into a disorderly pattern. The assumption that there is an organised pattern of branching ducts is now obsolete.
- that the milk duct diameter increases as let-down (milk ejection) occurs
- that multiple let-downs occur during a feed.

The nipple is located in the middle of the brown pigmented area called the areola. The size and shape of both nipple and areola can vary between individuals, from large and with flat nipples and reduced or no pigmentation, to raised and small nipples with very distinctive pigmentation. Women can lactate successfully regardless of these wide variations. The nipple, which is composed of smooth muscle, becomes erect when stimulated. There are small swellings located on the areola that secrete an oily fluid that lubricates the nipple and areola surface; these are called Montgomery's tubercles. The nipple and areola also contain many nerve endings that respond to the infant's sucking at the breast and trigger the production and release of milk (Blackburn 2003).

The breast is highly vascularised via the internal mammary and lateral thoracic arteries. Arterial blood terminates in capillary networks surrounding the alveoli. Venules drain venous blood into a circular vein behind the nipple, then into the mammary and axillary veins (Stables & Rankin 2004). The lymph vessels are extensive, flowing alongside the ductal tissue and converging toward the nipple, where they form a plexus beneath the areola. Lymph glands drain into axillary nodes. The breast is innervated by the 4th, 5th and 6th intercostals, giving rise to an uneven pattern of sensation, with the areola and nipple being the most sensitive part (Riordan 2005).

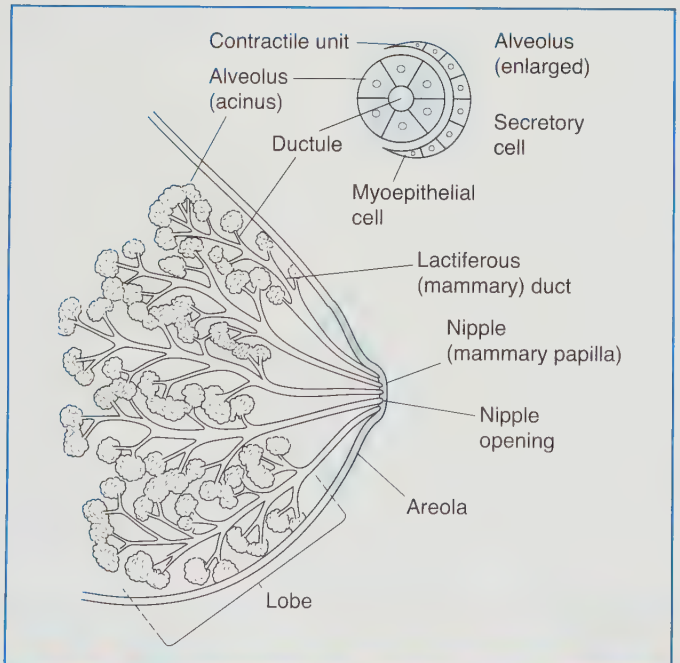

Figure 28.1 Structure of the female breast (based on Riordan 2005)

Breast physiology

The function of the breast is to synthesise and eject milk—a process called lactation. The components of milk are synthesised in the secretory cells (protein, fat and lactose) of the alveoli or extracted from the maternal plasma (minerals and vitamins) (Blackburn 2003). The secretory cells alternate between a secreting and a resting state. During infant sucking, active secretion occurs.

Breast milk production involves integration of neuronal, endocrine and autocrine processes. There are five main phases of lactation physiology.

Mammogenesis (mammary growth)

Mammary growth (mammogenesis) begins during embryonic and fetal life and accelerates at puberty under the influence of oestrogen and progesterone (Stables & Rankin 2004). Further changes occur during pregnancy and after birth, in order to

support lactation. Maturation of tissue begins shortly after conception, when there is a steady increase in breast size and weight, with a proliferation of the ducts and alveoli. Nipples become more erect, the areola pigmentation enhances and Montgomery's tubercles enlarge. Blood supply to the breast also increases, making the vessels appear more visible on the skin surface (Riordan 2005). These changes occur under the influence of oestrogen, human placental lactogen, human chorionic gonadotrophin, insulin, growth hormone, thyroid hormone, progesterone and prolactin.

Lactogenesis (initiation of milk secretion/production)

During the second half of pregnancy, the secretory cells begin milk synthesis (lactogenesis I) under the influence of prolactin, and colostrum and fat globules distend the alveoli (Blackburn 2003). Following childbirth, progesterone and oestrogen diminish in the bloodstream. Colostrum begins to change to more mature milk. At about day 2–3 up until day 8 post birth, milk production is influenced by the hormones prolactin, placental lactogen, cortisol and insulin.

When the infant sucks at the breast, mechanoreceptors (nerve endings) in the nipple stimulate the hypothalamus to suppress the prolactin-inhibiting factor and release prolactin from the anterior pituitary into the bloodstream. This initiates milk production by the acini cells in the glandular tissue (lactogenesis II). Increase in sucking and emptying the breasts leads to an increase in prolactin levels, and the prolactin receptors and milk supply increase. The breast function moves from being under initial endocrine or hormone control to autocrine or milk removal control (Riordan 2005).

The let-down (milk ejection) reflex

The let-down reflex (or milk ejection reflex) is an important process for moving milk along the system of ducts in the breast. Sucking at the breast sends messages from the nipple/areola area to the hypothalamus, which in turn releases oxytocin from the posterior pituitary gland into the bloodstream (see Fig 28.2). Myoepithelial cells around the alveoli are then stimulated to contract and push milk down the ducts toward the nipple. This same hormone stimulates uterine contractions and involution (Riordan 2005). The milk ducts increase in diameter during let-down. Multiple let-downs can occur during a breastfeed and affect the amount of milk the infant consumes (Ramsay et al 2002).

The let-down reflex can also be stimulated by the sight of an infant or the sound of an infant's cry, and inhibited by maternal pain or stress, or low milk supply. Some mothers do not notice any change in sensation during let-down but others report signs of increased thirst, a tingling sensation in the breast, a feeling of breast fullness, leaking of milk from the non-suckled breast or uterine contractions (Brodribb 2004). During let-down, the infant's sucking and swallowing pattern may also change.

Galactopoesis (maintenance of milk secretion)

The maintenance of milk production (galactopoesis) depends on active removal or non-removal of milk from the breast

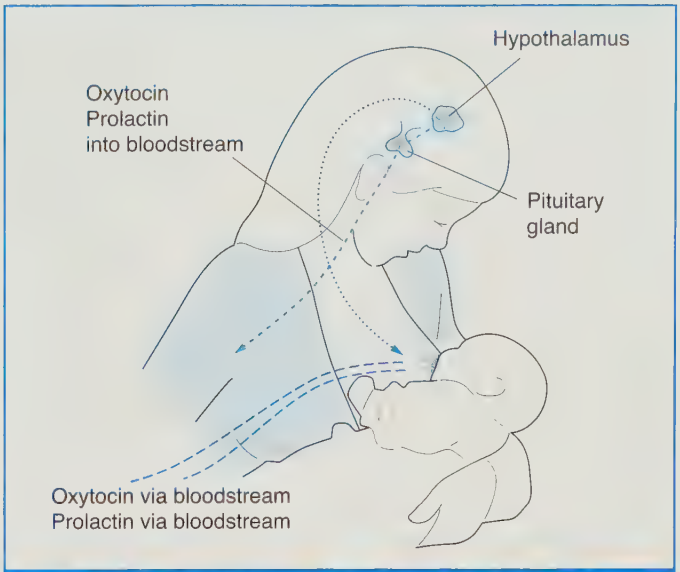

Figure 28.2 The let-down reflex (based on Day 2004)

from about day nine post birth until breastfeeding ceases. Breast function is now under the influence of a local feedback control mechanism. Production of milk depends on adequate stimulation of the breast—the more the infant sucks and the more milk is removed from the breast, the more milk is produced. The less sucking at the breast and the less milk removed, the less milk produced. As long as milk is removed from the breast regularly, the alveolar cells will continue to synthesise milk. Furthermore, the storage capacity of each breast and the quantity of milk removed at each feed influences milk synthesis between feeds (Ramsay et al 2002). The milk supply is therefore produced and influenced through the supply–demand principle as well as the functional capacity of the breast.

Weaning (involution)

If breastfeeding ceases or reduces in frequency, peptides in the milk begin to inhibit cell production and cells die, and therefore milk production decreases (Royal College of Midwives (RCM) 2002). This reduction or weaning may be infant- or mother-led. When breastfeeding ceases, involution of breast tissue occurs to the pre-pregnant state. Weaning milk begins to resemble the composition of colostrum, again with an increase in immunoglobulins, protein and sodium (Brodribb 2004).

Critical thinking exercise

Prolactin levels in the mother's blood are higher at night than during the day.

1 What are the clinical implications of this fact?
2 How would you use this fact when teaching a mother about breastfeeding?

Benefits of breastfeeding

Although instinctively known, research has clearly established the benefits of breastfeeding and the use of human milk for infants. Concomitantly, mothers, families and society can benefit from an increase in the incidence and prevalence of breastfeeding. These benefits include physiological, nutritional, health, psychological, social, economic and environmental outcomes (Bick 1999; Lutter 2000; Oddy 2002).

Physiologically, breast milk is the ideal food for infants (Bick 1999). Breast milk provides a unique fomulary of proteins, carbohydrates and fats needed for optimal cell function and growth. The breast alters the consistency of these nutrients as the infant's growth and development change over time. This balance, complexity and enhanced bioavailability of nutrients and other substances in breast milk has only recently been recognised (Brodribb 2000).

Epidemiological research has provided strong and consistent evidence of the significant association between human milk and breastfeeding of infants and the reduction in incidence and severity of acute and chronic illnesses, therefore reducing infant morbidity and mortality. Infants who receive human milk have reduced:

- gastrointestinal infections (Kramer & Kakuma 2004; Oddy 2001)
- diarrhoeal illness (Bertran et al 2001)
- necrotising enterocolitis (Bick 1999)
- otitis media (Oddy 2001)
- urinary tract infections (Bick 1999)
- respiratory infections (Bertran et al 2001).

Breast milk also:

- protects infants from sudden infant death syndrome (McVea et al 2000)
- reduces the risk of childhood asthma
- significantly enhances cell-mediated and humoral responses to antigens (Campbell 2000)
- provides immunological protection from insulin-dependent diabetes mellitus (Bick 1999), Crohn's disease and ulcerative colitis, childhood lymphomas and those of allergic origin (Saarinen et al 2000).

Breastfed infants are less likely to develop obesity (Armstrong & Reilly 2002; von Kries et al 1999) and have lower cholesterol levels in later life (Owen et al 2002). Human milk, containing vital omega-three and omega-six fatty acids needed for brain development, also enhances cognitive development (Angelson et al 2001; Horwood et al 2001; Quinn et al 2001; Richards et al 2002) and visual acuity (Anderson et al 1999; Mortensen et al 2002).

Mothers are also likely to benefit from breastfeeding. Oxytocin, released during infant suckling at the breast, contracts the uterus and hastens involution (Riordan 2005). Breastfeeding also prolongs lactation amenorrhoea, thus reducing fertility and increasing child spacing (Kramer & Kakuma 2004). A reduction in rates of ovarian and breast cancer (Zheng et al 2000), heart disease (Owen et al 2002; Singhal et al 2001) and osteoporosis (Jones et al 2000) is revealed in mothers who breastfeed. Prolonged breastfeeding also improves the return to pre-pregnant weight. Psychologically, maternal–infant bonding is enhanced by breastfeeding, due to early contact; and maternal oxytocin levels released during a breastfeed decrease maternal anxiety, and enhance calmness and social responsiveness (Day 2004).

An increase in the prevalence of breastfeeding may provide overall medical, social and economic benefits to society. This impact may flow through to improved personal health outcomes and the possibility of healthier communities through: reduced perinatal morbidity and mortality; cost savings for parents (no need to purchase infant formula articles); fewer hospital admissions; lower healthcare costs; and less absenteeism from school or work attributable to illness (Ball & Bennett 2001). Further, global enhancements have been suggested related to reduction in world overpopulation (reduced fertility), saving on fuel and energy resources, and elimination of wastes from the production of artificial milk and its leftover containers (Biancuzzo 1999).

There is significant quality clinical and ecological evidence to support the benefits of breastfeeding and human milk consumption. Therefore the World Health Organization (WHO 2001) recommends that all babies be exclusively breastfed for the first six months to promote health and reduce illness. The WHO also recommends continued breastfeeding for a further two years. See Table 28.1 for a summary of the benefits of breastfeeding for mother and infant.

Properties of breast milk

Colostrum: the early milk

Colostrum is secreted during the last trimester of pregnancy until 10 days post partum. It is a viscous, concentrated liquid of low volume (varies from 7 mL to 123 mL in 24 hours) with an average amount of 37 mL (Riordan 2005). The newborn's kidneys are immature at birth and cannot deal with large volumes of fluid. This early fluid is high in protein, sodium, minerals and antibodies, low in carbohydrates, fats and vitamins. Colostrum facilitates the growth of gut flora, limits the growth of pathogenic bacteria and viruses, protects against illnesses and aids the excretion of meconium from the gut due to its laxative effect (Brodribb 2004).

Mature breast milk

Mature breast milk is a rich, balanced brew containing 90% water and 10% solids. Bluish in colour, it is slightly alkaline (pH 7.0–7.45), with an average calorie count of 65 kcal/100 mL, although this varies depending on fat content. It is not a uniform fluid; it varies from mother to mother and changes composition during a feed, with the time of the day and from one lactation to the next (Blackburn 2003). Breast milk has nutritional, anti-infective, immunological, bioactive and anti-allergenic properties.

TABLE 28.1 Summary of the benefits of breastfeeding for mother and infant

Mother	Infant
• Hastens involution, with reduced blood loss and less anaemia. • Reduces fertility/increases child spacing. • Reduces risk of ovarian and breast cancer. • Reduces heart disease. • Reduces osteoporosis. • Possibility of improved return to pre-pregnant weight. • Enhances maternal–infant bonding. • Enhances calmness and social responsiveness. • Decreases maternal anxiety.	• Reduces gastrointestinal infections. • Reduces incidence and duration of diarrhoeal illness. • Reduces occurrence of otitis media. • Protects against respiratory infection and reduces risk of childhood asthma. • Reduces urinary tract infections. • Protects against SIDS. • Reduces the incidence of NEC. • Enhances cell-mediated and humoral responses to antigens (allergies). • Enhances cognitive development, with higher IQ scores. • Improves visual acuity • Reduces the incidence of obesity. • Protects against IDDM, Crohn's disease and ulcerative colitis. • Reduces incidence of childhood lymphomas. • Lowers cholesterol levels in later life.

(Source: WHO 2001)

Nutritional properties

The constituents of breast milk include the following:

- Fats—fat provides half the calories of an infant's energy needs. Fats are essential for development of visual acuity, help vitamin function and form cell membranes and prostaglandins (Shinskie & Lauwers 2002). Levels vary during the feed and are higher in hindmilk than foremilk. Fat globules are small and easily absorbed, with triglycerides being broken down to free fatty acids and glycerol (Blackburn 2003).
- Carbohydrates—the carbohydrate contained in human milk is mostly lactose, being broken down slowly to glucose and galactose and providing 40–45% of an infant's energy needs. Carbohydrates enhance calcium absorption, promote the growth of lactobacilli in the intestines and reduce the growth of gut pathogens. They are also essential for central nervous system development (Shinskie & Lauwers 2002).
- Protein—human milk protein contains 40% casein (soft curds) and 60% whey (a soluble liquid), and is therefore easily digested and absorbed. The whey contains albumins, enzymes, immunoglobulins and hormones (Blackburn 2003). Infants are able to use the protein constituent efficiently. Proteins are needed for cell growth and stability, all body processes, bile salt conjugation and nerve transmission (Shinskie & Lauwers 2002).
- Vitamins—fat-soluble and water-soluble essential vitamins are available in breast milk in sufficient amounts to aid cell growth and function. Specifically, vitamins are required for blood clotting, central nervous system development and skin integrity, and to protect the retina and mediate cell function (Riordan 2005).
- Minerals—human milk contains all the essential minerals needed for electrolyte balance, and infant cell and organ function. They are highly bioavailable and suited to infant growth and development (Brodribb 2004).
- Water—water is the largest component (90%) of breast milk in which dissolved solids (10%) are carried. Water also contributes to regulation of an infant's temperature.

Other properties of milk

- Anti-infective properties—enzymes, immunoglobulin and leucocytes provide protection from infection and reduce the incidence and severity of acute and chronic illnesses (Bick 1999).
- Immunological properties—immunoglobulins are proteins produced by the plasma that block adhesion of pathogens to the infant's mucosal surfaces and produce antibodies, which in turn target microbes. B-lymphocytes help destroy antigens, macrophages engulf and absorb pathogens, neutrophils ingest microbes and T-lymphocytes kill infected cells. Lactoferrin binds iron (preventing pathogens from using it) and aids T and B cell production. The bifidus factor is an intestinal flora that promotes the growth of lactobacilli and maintains the gut pH at an acid level, which inhibits the growth of *E. coli*. Lactoperoxidase is an enzyme that, when combined with IgA, increases the ability to kill streptococcus bacteria. Oligosaccharides are simple chains of sugars that intercept bacteria and block their attachment to the gut epithelium and bind to form harmless substances (Shinskie & Lauwers 2002).
- Bioactive properties—enzymes, lysosomes, lipase, amylase, interferon and fibronectin in breast milk promote growth and development, and infection control (Riordan 2005).
- Anti-allergenic properties—breast milk facilitates early maturation of the intestinal mucosa and reduces allergic responses. There is a protective effect against skin conditions and respiratory illnesses (Bertran et al 2001; Saarinen et al 2000).

Critical thinking exercise

Draw up a table with two columns. List the components of breast milk in the left column and then add the function of each component in the right column.

Hormones and enzymes

Over 70 enzymes have been isolated from human breast milk. An insulin-like factor promotes growth, an epidermal factor aids skin growth, cortisol transports fluids and salts in the gut, thyroxine stimulates the intestine, prostaglandins aid local circulation and mucus secretion, electrolytes balance and protect the gut mucosa, and taurine is a neurotransmitter that aids brain maturation (Riordan 2005).

Worldwide initiatives to promote breastfeeding

Several worldwide primary healthcare initiatives have actively protected, promoted and supported breastfeeding and campaigned against marketing of breast milk substitutes.

World Health Organization

The World Health Organization (WHO) is a specialised agency of the United Nations with a primary responsibility for public health. Its brief extends to the role of maternity services in promoting breastfeeding (Biancuzzo 1999). A joint WHO/United Nations International Children's Emergency Fund (UNICEF) statement, launched in 1989, describes the critical role of health services and outlines steps taken to facilitate the initiation and establishment of breastfeeding (WHO/UNICEF 1989).

The WHO Global Data Bank on breastfeeding developed new breastfeeding indicators and definitions to broaden the nomenclature for describing breastfeeding behaviour and to increase the coherence, reliability and comparability of data. The 'Bank' pools information drawn from surveys and studies dealing with breastfeeding prevalence and duration. This enables comparison of representative data. National, regional and local information gathered on breastfeeding and complementary feeding practices over time provides a reliable database with which to plan promotional programs (WHO 1996).

The WHO Code

An initiative of WHO and UNICEF, the International Code of Marketing of Breastmilk Substitutes (the WHO Code), adopted in 1981, emphasises the fact that human milk and breastfeeding provides an unequalled way of providing nutrients and other biological substances necessary for the growth and development of infants. It aims to protect the wellbeing of infants through the protection and promotion of breastfeeding and ensuring that breast milk substitutes are used only when necessary. Support for and adherence to the Code is an ethical choice for countries, governments, industries, health professional organisations, educators and individuals involved in maternity and newborn care (Young 2001).

The Innocenti Declaration

In 1990 the WHO and UNICEF produced and adopted the Innocenti Declaration, which recognises the uniqueness of breastfeeding and the need to reinforce a breastfeeding culture and mobilise to stop the competition of a bottle-feeding culture. The Declaration stated that all women should be enabled to practise exclusive breastfeeding for four to six months following childbirth. It recommended that all governments implement the WHO Code and develop national breastfeeding targets and policies, and integrate them into overall health and development (Biancuzzo 1999).

In response to the recommendations, the National Health and Medical Research Council (NHMRC) developed guidelines for health workers on infant feeding (Commonwealth Department of Health and Family Services 2001). A national breastfeeding strategy was launched in the same year to provide a multifaceted primary healthcare approach to breastfeeding promotion. This was aimed at health professionals, community agencies and the general public (Commonwealth Department of Health and Aged Care 2001).

International Baby Food Action Network

Growing public and professional concern over commercial and advertising promotion of breast milk substitute foods, feeding bottles and teats encouraged development of the International Baby Food Action Network (IBFAN) (IBFAN 1993).

The network is a coalition of voluntary organisations in industrialised and developing countries working for better health through the promotion of breastfeeding and the elimination of the marketing of artificial infant foods. The IBFAN provides a written guide for health workers about the WHO Code (WHO 1993) and also monitors Code compliance. Code-breaking promotional materials and tactics are still used in systematic and blatant ways by companies that continue to undermine health in pursuit of profits (Advisory Panel in the Marketing in Australia of Baby Formula (APMAIF) 2000).

World Alliance for Breastfeeding Action

In 1990 the United Nations held a world summit for children, at which heads of state promised to work towards the rights of children, including the right to breastfeed. In 1991 groups working on maternal and child health launched the World Alliance for Breastfeeding Action (WABA). IBFAN was one founding member. The WABA group mobilised social support for the Innocenti Declaration and implemented international breastfeeding week activities on an annual basis (IBFAN 1993).

Baby Friendly Hospital Initiative

The UNICEF and the WHO jointly launched the Baby Friendly Hospital Initiative (BFHI) in 1991. This global initiative aims to provide a positive environment that promotes breastfeeding as a natural and normal primary healthcare practice and is based on the role of maternity services in protecting, promoting and supporting breastfeeding.

Ten steps to successful breastfeeding have been articulated to encompass education and counselling of new mothers, unrestricted mother–infant contact, demand and exclusive breastfeeding and maternal support in the postpartum period. Hospitals are challenged and motivated to adhere to these 10 steps when working with mothers and their families. The BFHI aims to increase the worldwide prevalence and duration of breastfeeding (Naylor 2001). The BFHI philosophy is applied universally irrespective of whether a country is developed or developing, or a society Western or traditional (WHO 1992).

BOX 28.1 The 10 steps to successful breastfeeding

Every facility providing maternity services and care for newborn infants should:

1. Have a written policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within an hour of birth.*
5. Show mothers how to breastfeed, and how to maintain lactation even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in—allow mothers and infants to remain together—24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers (also called dummies or soothers) to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from hospital.

* When written in 1989, this step required breastfeeding initiation within the first half-hour. Research in the 1990s showed that the natural sequence of behaviour is for suckling to occur within the first hour. Therefore this step has been modified in some countries.

(Source: WHO/UNICEF 1989)

Critical thinking exercise

Think about breastfeeding practices that you have seen or implemented in your hospital/health facility. Compare them to the 10 steps listed above.

1. Do they support the 10 steps to successful breastfeeding?
2. How might you initiate a review of those practices?

The ten steps to successful breastfeeding

Hospital practices are very influential when a new mother and her family are initiating and establishing breastfeeding. Support and encouragement by informed healthcare workers, the reduced influence of artificial feeding practices, keeping mother and infant together and feeding early and frequently by infant-led demand are practices promoted by the BFHI. Successful long-term breastfeeding depends on a successful beginning. Through compliance with the 10 steps to successful breastfeeding, hospitals give mothers the best chance of establishing and maintaining breastfeeding (Philipp & Merwood 2004). The 10 steps are listed in Box 28.1.

Preparation for breastfeeding

Breastfeeding education

Successful breastfeeding depends on the mother's acquisition of basic skills and accurate information. This success is strongly influenced by the quality of help and support provided during the pregnancy, childbirth and the postpartum period. Despite the evidence of the benefits of breastfeeding, many women may choose to use artificial formula, indicating that their decision not to breastfeed may be unrelated to health factors (Earle 2000; Hodinott & Pill 1999).

The maternal decision to breastfeed is based on multiple factors, including knowledge about breastfeeding, personal attitudes and beliefs about breastfeeding, role models and support of significant others. A positive exposure to breastfeeding and observing breastfeeding as a normal event increases a commitment to and confidence in maternal ability to breastfeed. Decision-making is also related to a favourable attitude by significant others to breastfeeding (Hodinott & Pill 1999).

Antenatal care should include discussion on breastfeeding by the lead carer, covering aspects of attitudes to breastfeeding, expectations, knowledge and experience (family background). A positive attitude to breastfeeding by the health professional can enhance the duration of breastfeeding (Riordan 2005). Women should be informed of the benefits of breastfeeding, the disadvantages of not breastfeeding (that is, using artificial formula) and given the opportunity to discuss their feelings about their breasts and breastfeeding. Teaching mothers the practical skill of positioning and attachment can prepare new mothers and their partners for breastfeeding. (See positioning

Reflective exercise

1. Locate resources in your local community that support breastfeeding. You may need to visit your local council and/or community health centre to help you get started.
2. List resources and contact details. This will become a useful resource.

and attachment below.) The management of breastfeeding, from initiation to maintenance and weaning, infant's normal feeding cues and behaviours, and coping with problems that may arise, should also be covered. Written resources and community services that support breastfeeding are important components of any formal and/or informal breastfeeding education activities. It is also important to include partners in education, as their support and encouragement facilitates successful long-term breastfeeding (Brodribb 2004).

Positioning and attachment

Positioning and attaching a newborn at the breast is a learned and mostly manual skill that is acquired via education, observation and practice (Woolridge 1986). The mother can learn this skill by watching other breastfeeding women. However, breastfeeding is less overt in public and family environments in current times; therefore many mothers have been deprived of this experience (Biancuzzo 1999; RCM 2002). Hospital practices that provide education in and support of positioning and attachment increase the prevalence of breastfeeding (Enkin et al 2000).

Mothers can produce milk and let it flow from the breast when the infant needs it. Newborn infants are able to search for the breast, open the mouth, attach to the breast, suck, swallow and digest the milk for growth and development. The full-term healthy infant comes equipped with three specific, innate reflexes to help obtain breast milk: rooting, suckling and swallowing. The rooting or searching reflex occurs when the infant turns toward a touch on the cheek and lips. The mouth opens into a wide gape with the tongue down and forward, ready to receive the breast tissue. Suckling is the next reflex, which occurs by stimulation of the roof of the mouth with the nipple and breast tissue. The third reflex of swallowing occurs in response to breast milk coming into contact with the back of the throat and soft palate (Day 2004).

What is positioning and attachment?

Positioning refers to the position of the infant relative to the position of the mother. It is the interaction of the mother's and infant's body positions and the infant's mouth-to-breast position that allow for easy attachment. This does not mean that there is only one correct position. Any position that the mother and infant find comfortable that does not interfere with the infant being able to draw adequate breast tissue into the mouth, suck, swallow and breathe is acceptable. Principles of correct positioning include: a relaxed and comfortable mother, so the breasts fall naturally forward; infant at level of the breast, with support behind the infant's shoulders; neck slightly extended; chest of infant turned towards the chest of mother and chin pointed towards the breast (Inch & Fisher 1999).

Attachment refers to the bringing of the infant to the breast using the rooting reflex to open the infant's mouth widely, and the drawing of the nipple and breast tissue into the mouth to the back of the soft palate. The tongue is forward over the gums but under the areola, with the chin placed on the underside of the breast (Inch & Fisher 1999) (see Fig 28.3).

The early use of cineradiographic techniques and ultrasound by Smith et al (1985) and Weber et al (1986) has helped researchers to learn about the mechanisms of infant feeding at the breast. When an infant is positioned and attached correctly at the breast, the nipple and surrounding breast tissue is drawn into an elongated teat-like shape that extends back to the junction of the hard and soft palate (see Fig 28.4).

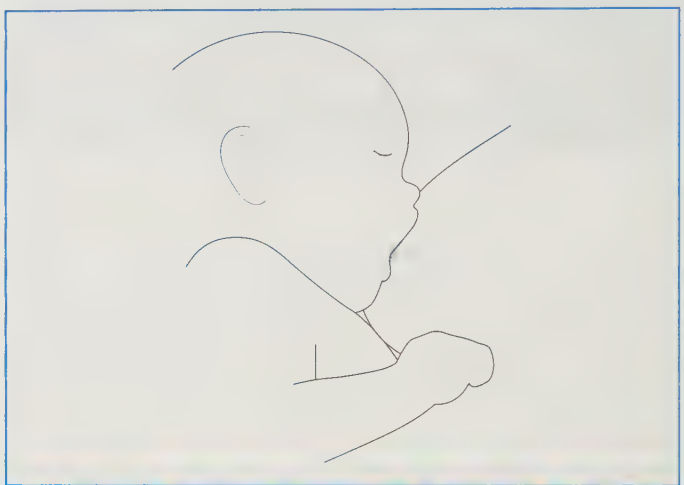

Figure 28.3 Correct attachment, external view (based on Day 2004)

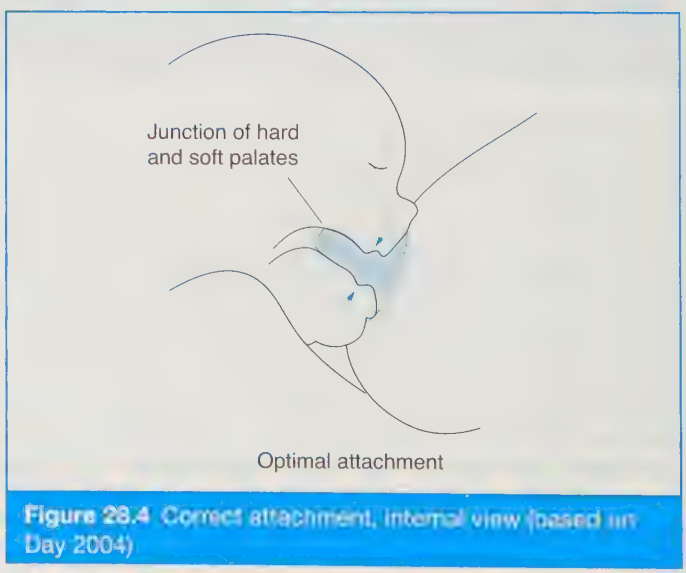

Figure 28.4 Correct attachment, internal view (based on Day 2004)

The sides of the tongue cup around the elongated 'teat', forming a central trough. A circular movement of the jaw and compression of milk sinuses milk the breast by the tongue and gums. Milk is propelled out through the nipple openings along the trough via peristaltic movement into the back of the pharynx, ready for swallowing. When the volume of milk is sufficient, swallowing is triggered. The soft palate elevates and closes the nasal area, the larynx closes over the trachea and the milk bolus moves into the oesophagus. The larynx returns to its normal position, closing off the oesophagus behind the milk, and leaves the airway open again. A fresh cycle of compression begins. When the infant is positioned and attached adequately, minimal energy is used and the breast actively ejects the milk. Suckling is free from friction, as there is little movement of the teat (Woolridge 1986).

Correct sucking technique is when the infant has a wide-open mouth, with the tongue under the areola, expressing milk from the breast by slow, deep sucks. When positioning and attachment are correct (optimal) a variation in suckling rate and pattern occurs in response to the milk flow. The first suckles are short, shallow, irregular and fast with short pauses, then the rate changes to a second stage when suckles become slower, stronger, regular and longer as the milk flows. Swallowing can be heard or seen with each or every few sucks. At this time the infant is receiving the foremilk. The third stage of suckling occurs as the feed continues when sucks are again shorter with more pauses. The infant is receiving the hindmilk at this stage. Comfort sucking occurs towards the end of the feed and the infant comes off the breast or falls asleep (Inch & Fisher 1999).

It follows that positioning and attachment plays a crucial role in the successful ejection (let-down) and transfer of milk and stimulation of milk supply. The majority of women give birth in hospital or in the home, with postpartum care provided by midwives in public, private or community settings (NHMRC 2003). Midwives can facilitate the mother's learning of correct positioning and attaching her infant at the breast through education, support and guidance. Conversely, inaccurate or inconsistent breastfeeding advice, or lack of support and guidance, may deter a new mother from breastfeeding.

Practical skills using a hands-off technique

Teaching new mothers the skill of positioning and attachment can assist in the success of breastfeeding initiation. A prevalent method involves using a hands-on technique, where midwives physically assist with positioning and attachment. This does not prepare the mother for confident and independent feeding. Health professionals can describe the process without using their hands. Using verbal and visual strategies (e.g. the use of dolls) to demonstrate these principles during the antenatal period and when initiating breastfeeding empowers mothers to 'do it for themselves' with autonomy and confidence, and this can have a positive effect on breastfeeding duration (Benjamin 1999; Fletcher & Harris 2000; Ingram et al 2002).

Clinical point

With a family member, friend or colleague, assist them (using verbal interaction and a hands-off technique) to position and attach a doll/bear ready for a breastfeed.

- Remember the principles of positioning and attachment.
- Think about the language you will use in this interaction.

Initiation of breastfeeding

Early, frequent and correct sucking aid the physiology of lactation. Early sucking occurs as soon as possible after birth using the alert responses and reflexes of the infant and enhancing maternal feelings. Frequent sucking is maintained through continuous maternal–infant contact as well as demand and exclusive breastfeeding. Correct sucking includes the optimal positioning and attachment of the infant at the breast to aid efficient and sufficient suckling. Through correct positioning and attachment, nerve messages initiate better milk production, and sufficient suckling allows the milk ejection reflex to occur and aids milk transfer from mother to infant (Riordan 2005).

The first feed

Following birth, the infant's interest and responses are at a peak to begin breastfeeding and the mother has a heightened sense of awareness and responsiveness to her infant (Anderson et al 2003). Mother and infant should remain together and not be separated unless medically indicated, in order to maximise the alertness and responsiveness of mother and infant. Weighing, bathing and examination of the infant should be delayed until after the first feed (NHMRC 2003). However, feeding immediately after birth is not essential for successful initiation of breastfeeding. If a breastfeed does not eventuate then skin-to-skin contact at this time is reported to have a significant and positive effect on breastfeeding duration (Anderson et al 2003), although a recent systematic review does not indicate such a positive effect on timing of the first feed and highlights the need for further research (Carfoot et al 2003).

Healthy newborns placed on their mother's abdomen or chest demonstrate an ability to search for and touch the breast and nipple using their five senses. Washing the skin of the mother or infant before the first feed can interfere with these senses. Mothers should be supported to breastfeed preferably within an hour of giving birth. When infant cues of mouthing, hand–mouth movements and rooting are noted, the midwife can assist the mother to encourage her infant to the breast using the principles of correct positioning and attachment. The infant's sucking reflex is very active at this time (Lawrence 1999).

Breastfeeding will stimulate the release of oxytocin and initiate the let-down reflex, with the infant receiving

colostrum. A positive experience of the first breastfeed can enhance maternal confidence (Riordan 2005). Partner presence during this time also helps establish a positive breastfeeding relationship. When the first feed is delayed (due to mother or infant needing medical attention) or if the infant is not interested in feeding due to the effect of maternal medication, the first feed should then be timed as soon as possible (Brodribb 2004).

Subsequent feeds

Following the alert period it is common for babies to be sleepy for some 24 hours as a consequence of labour and birth. Most babies begin to seek feeds frequently after their sleepy episode (NHMRC 2003). The correct principles of positioning and attachment should be reinforced at each subsequent feed, promoting the mother's confidence in her ability.

Demand feeding

Ideally, babies should be fed when they exhibit a quiet alert state of behaviour. Mothers can learn their infant's sleep–wake cycles and learn to identify the best time for feeding. It is difficult to feed an infant who is sleepy, and an infant who is crying is difficult to attach to the breast. The quiet alert state facilitates easier breastfeeding. Feeds should not be regimented by clock time, as this may not match the infant's wakefulness and may lead to reduced sucking, reduced breast stimulation and supply, and engorgement (Brodribb 2004). Demand feeding also encourages the passage of meconium and lessens the infant's weight loss (NHMRC 2003).

Unrestricted feeding

The length of a feed should be determined by the infant's needs. Variations in breast anatomy lead to variations in storage capacity and rate of milk flow. Infant-led feeding allows the infant to regulate intake according to their need (Ramsay et al 2002).

Frequency of breastfeeding for a term healthy newborn ranges from 8 to 12 feeds in a 24-hour period, with intervals varying from every hour or two during the day to a couple of times during the night. The infant will eventually develop a pattern of feeding across the day by four to six weeks of age.

Reducing sucking time or frequency of breastfeeding will reduce stimulation of milk supply and lead to engorgement (RCM 2002). Unlimited sucking at the breast also improves breastfeeding, with the infant receiving both foremilk and the higher-fat hindmilk (Shinskie & Lauwers 2002). Mothers should be encouraged to observe and interpret when their infant is satisfied. Limiting the length of a feed can result in a higher intake of foremilk and less intake of hindmilk, leading to reduced satiety and poor weight gain. It is recommended for the same reason that an infant be allowed to finish feeding on the first breast before offering the other side.

Rooming in

Keeping mother and infant continuously together from birth helps initiate breastfeeding. Mothers learn to understand their infant's cues and behaviours and how to handle the infant. This increases maternal confidence and bonding, and promotes milk supply with unrestricted access to the breast and regular stimulation (Shinskie & Lauwers 2002).

Exclusive breastfeeding

Exclusive breastfeeding ensures that the infant receives the full nutritional and protective benefits of breast milk. Full-term healthy babies do not require additional fluids. Additional fluids can interfere with sucking, and reduce the frequency of sucking at the breast, leading to reduced stimulation and inadequate initiation of breastfeeding. In addition, the mother may feel unable to provide for her infant's needs and lose confidence in her ability to breastfeed (NHMRC 2003). Infants are more likely to be weaned earlier when not exclusively breastfed. Furthermore, a Cochrane Systematic Review indicates that exclusively breastfed infants are healthier than infants who are mixed-fed, in both developing and developed countries (Kramer & Kakuma 2004).

Pacifier use

There is a strong association between daily exposure to pacifier use and breastfeeding duration (Kramer et al 2001), especially if there is frequent exposure before six weeks post partum (Howard et al 1999). Pacifier use may reduce breastfeeding episodes (frequency and duration) during a 24-hour period, therefore reducing breast stimulation and supply (Howard et al 1999). Mothers may also feel less motivated to breastfeed if a pacifier soothes a fussy baby (Bennis 2002). Pacifier use is therefore not recommended during the initiation of breastfeeding.

Maintenance of breastfeeding

Healthy newborns show signs of hunger, although the interval between feeds varies considerably. Some babies will want

Reflective exercise

1 Think about infant cues other than crying that may indicate readiness for a breastfeed.
2 How would you know if an infant was satisfied after a feed?

Reflective exercise

Take some time to reflect on your breastfeeding experiences/views of breastfeeding.

How do you think this affects the way you practise, especially when assisting a women with a breastfeed?

feeding every one and a half to two hours, whereas others may feed every four hours. During the early months, many babies do what is called 'cluster feeding', spacing feeds closer together at certain times of the day (typically in the evening) and going longer between feeds at other times of the day. When a baby suddenly wants to feed more often, it is called a growth spurt. These commonly occur around two or three weeks, six weeks and three months (Mohrbacher & Stock 2003).

Breast storage capacity is an important determinant of how often a baby's demand for milk is met. Women who have small breasts are still capable of producing as much milk over a 24-hour period as a woman with large breasts; however, the storage capacity is not as great and therefore her infant might need to feed more frequently (Ramsay et al 2002). If a mother is concerned about her milk supply, review the following points with her:

- How often and for how long is the baby feeding? Expect a minimum of 8–12 feeds in 24 hours and 15–20 minutes on the first breast, and 10–15 minutes on the second breast, but the baby may be satisfied after only one breast.
- The baby should have at least three bowel movements each 24 hours, and by day 4 these should be yellow, soft and of a watery consistency.
- The baby should have at least six wet napkins a day by day 4, and the urine should look clear, not dark and concentrated.
- Expect < 7% weight loss in the first week.
- Expect return to birthweight by day 14.
- Expect weight gain of 120–240 g a week until the baby's birthweight has doubled (International Lactation Consultant Association 1999, pp 21–22).

Many babies continue to have frequent bowel movements for as long as they are exclusively breastfed. However, some babies, from about six weeks of age, have bowel movements only once a week, and as long as this is plentiful in amount and remains soft in texture then this is not of concern (Mohrbacher & Stock 2003).

A breastfeeding mother should be encouraged to eat a well-balanced and varied diet. The recommended energy intake during breastfeeding is an additional 500 calories a day during the first six months and then reduced to 400 calories as milk production decreases (Lawrence 1999; Picciano 2003).

There is no scientific basis for the concern that gassy foods cause gas in the breastfed baby. The normal intestinal flora produces gas from the action on fibre in the intestinal tract; however, gas and fibre are not present in breast milk (Lawrence 1999). Extensive clinical experience does suggest that some babies do not tolerate certain foods in a mother's diet. If a mother questions the effect of a certain food on her baby, then Lawrence (1999) suggests that the mother watch the baby for colic for 24 hours post ingestion.

Some mothers are concerned that exercise might interfere with their milk supply. However, moderate exercise should not affect the milk supply or the baby's reaction to it (Riordan 2005).

Critical thinking exercise

Tricia is six weeks old and exclusively breastfed. Mary is concerned that she has insufficient milk supply, as Tricia is now unsettled and seems hungry all the time.

1 What may be happening here?
2 How would you help Mary?

Management of problems

With appropriate support and guidance, most common problems associated with breastfeeding can be prevented. Problems are likely to occur when the normal physiological process is interrupted, by the baby not attaching correctly to the breast, or incorrect advice, or imposed rules and regulations interrupting the normal breastfeeding process.

Early recognition and treatment of problems when they occur is required in order to preserve the breastfeeding experience for the mother and baby. For many problems, practitioners use interventions based on clinical experience rather than research; however, any interventions and treatments that are recommended should be evidence-based. Careful assessment of the situation and a plan of management should be drawn up in partnership with the mother.

Sore or damaged nipples

During the early breastfeeding experience, tenderness of the nipples is normal. As the collagen fibres are stretched in early suckling, women may feel nipple discomfort, which peaks between day 3 and day 6. Protracted nipple tenderness, or that which lasts throughout a feed, is not normal. If a mother complains of pain during breastfeeding then something is not right.

Lawrence (1999) describes common causes of nipple pain as:

- poor positioning
- nipple sucking
- nipple tipped up too much because of finger pressure above the nipple
- infant's lower lip sucked in and irritating the underside of the nipple
- taking the infant off the breast without first breaking the suction.

Riordan (2005) adds to this:

- an infant with a disorganised suck
- ankyloglossia (tongue tie)
- engorgement
- sensitivity to nipple creams
- flat or retracted nipples
- prolonged exposure to wet nipple pads
- infection or thrush.

Tait (2000) suggests that discussing latching techniques and signs of improper positioning with women during the

antenatal period and again after birth may assist them in recognising the problem before damage occurs. When skilled staff are not available to assist with breastfeeding then this knowledge would be important. Breastfeeding is a two-person activity, so both mother and infant need to be considered when undertaking an assessment to identify the cause of the nipple pain.

Management will involve supporting the mother and reassuring her that this will be a self-limiting problem. Observation of a breastfeed and correcting the positioning and attachment, if necessary, may be all that is required to correct the problem. Practical suggestions may include: applying warm compresses to the breasts before feeding to stimulate the milk flow; if the breast is engorged, hand expressing some milk to make the areola softer; beginning each feed on the less sore breast; changing breast pads frequently; and expressing milk onto the nipples after a feed.

There is little evidence that nipple creams or ointments either heal or relieve soreness of nipples. Recent research suggests that the most effective treatment is warm water (Lavergne, cited in Tait 2000). However, as most applications are relatively harmless and new mothers like to use them so they feel something is being done, it may be more harmful to deny their use if a woman wishes to do so. If women choose to use cream or ointment on their nipples, they should be advised to apply it to the nipple only, as the Montgomery glands on the areola may become blocked, inhibiting the secretion of the natural oils that help maintain elasticity of the nipples.

Resting the nipple by not feeding from the breast should only be recommended if the pain of sucking is intolerable to the mother or when any bleeding or damage is worsening. Remember that while the baby is not suckling on the breast, the milk must be removed either by hand expressing or by pumping. When the baby returns to the breast, attention must be given to positioning and attachment.

Breast fullness versus engorgement

Engorgement is almost always a preventable complication of breastfeeding. Lawrence (1999) describes engorgement as having three elements:

- congestion and increased vascularity, which is the physiological response that follows removal of the placenta and does not depend on suckling
- accumulation of milk, also a physiological response
- oedema secondary to the swelling and obstruction of drainage of the lymphatic system by vascular increases and fullness of the alveoli.

Critical thinking exercise

Jemma is three weeks old and 50 grams above her birthweight. Jemma's mother Grace has a right cracked nipple and wants to wean Jemma. You observe a blister on Jemma's top lip.

How would you respond to this situation?

When this physiological process proceeds normally, it rarely lasts more than 24 hours. During this time, the mother's breasts will be full but the tissue will remain compressible, and the infant should be able to suck efficiently without trauma to the breast or nipple (Riordan 2005). If feeds are restricted, or there is poor attachment and inefficient sucking leading to incomplete removal of milk, then what was a normal process will lead to pathological engorgement. It can also occur when breastfeeding is ceased abruptly or when weaning foods are introduced.

If the milk is not removed, over-distension of the alveoli can cause the milk-secreting cells to flatten out and even rupture. The over-distension puts pressure on the surrounding tissue, exacerbating the problem by occluding the blood capillaries. This can lead to increased arterial pressure to the breasts and compression of the connective tissue, impeding drainage of the lymph fluid from the breast, which then leads to oedema (Snowden et al 2001).

When there is milk stasis, a protein called the feedback inhibitor of lactation accumulates in the breast. The accumulation of milk in the breast and the resulting engorgement are a trigger for apoptosis, or programmed cell death, which causes involution of the milk-secreting gland, milk reabsorption, collapse of the alveolar structures, and the cessation of milk production (Smith & Heads 2002).

To prevent breast engorgement there should be no delay in initiating breastfeeding, and effective positioning. Also, transfer of milk should be ensured and unrestricted breastfeeding should be promoted.

There are many suggested treatments for engorgement, including application of heat, ice packs, cabbage leaves, massage, ultrasound and frequent feeding. The Cochrane Systematic Review of treatments for breast engorgement during lactation (Snowden et al 2001) found that anti-inflammatory drugs were the most effective treatment tested. Although widely used, cabbage leaves were found to be no more effective than gel packs in relieving symptoms.

Expressing milk may be necessary to prevent the build-up of the feedback inhibitor of lactation and decrease the risk of mastitis and compromised milk production, and to give comfort to the mother.

Blocked milk ducts (plugged ducts)

There is sometimes no obvious cause of a blocked milk duct, but it may be the result of incomplete emptying of a lobe in the breast due to ineffective positioning and attachment of the baby at the breast, or an oversupply, or external pressure on the breast. This may be from finger pressure during a feed, a tight bra, sleeping prone, or straps from a baby carrier (NMAA 1999; Riordan 2005). The mother may complain of a tender lump in her breast, which may or may not be reddened, in the absence of a fever.

Assessment should include observing the mother–infant pair during a breastfeed to ensure correct positioning and attachment. The mother should be encouraged to continue to breastfeed often, applying moist heat to and massaging the

affected area before and during breastfeeding. Positioning the baby so that the chin is pointing to the area of the lump will encourage better drainage from that area.

Lawrence (1999) describes improvement in women with repeated blocked ducts by limiting the mother to polyunsaturated fats and adding lecithin to her diet. If blocked ducts are left untreated, mastitis may develop.

Mastitis

Mastitis is an inflammatory condition of the breast, which may or may not be accompanied by infection. The initial cause of mastitis is an unresolved increase in the intraductal pressure, first causing a flattening of the secretory cells; a paracellular pathway then may occur between the cells, allowing the passage of some of the components in breast milk to leak into the interstitial tissue, resulting in an inflammatory response. This inflammatory response and the resultant tissue damage can be a precursor of infective mastitis (Smith & Heads 2002).

The WHO (2000) states that the two principal causes of mastitis are milk stasis and infection. Milk stasis occurs when milk is not effectively drained from the breast, as in untreated engorgement or blocked ducts, poor attachment of the baby to the breast, restriction or alteration of the frequency or duration of feeds, or an overabundant milk supply. Cracked or damaged nipples are thought to provide a portal of entry for pathogenic organisms.

The woman will present with sudden onset of flu-like symptoms, aches, chills, a fever and a red, hot, painful area on the breast, usually on the upper outer quadrant.

The WHO (2000) lists the main principles of treatment as:

- supportive counselling
- effective milk removal
- antibiotic therapy
- symptomatic treatment.

As mastitis is painful and the woman feels ill (flu-like chills and headache), she will require support and encouragement to continue to breastfeed. Reassure the woman that the breast milk is safe for her baby and that the breast will recover.

Effective removal of the milk

This is the essential part of treatment. If necessary, assist the mother to improve attachment of the baby to the breast and encourage frequent breastfeeding, as often and for as long as the infant is willing. If the woman is unable to have the baby feed from the breast, then breast milk must be expressed by hand or by pump until such time as the baby may return to the breast.

Antibiotic treatment

Staphylococcus aureus is the most common causative organism associated with mastitis. Antibiotics should be prescribed when:

- symptoms are severe from the beginning
- a nipple fissure is present, or
- symptoms do not improve after 12–24 hours of improved milk removal.

To be effective against *S. aureus* a penicillinase-resistant penicillin or a cephalosporin should be prescribed. Lawrence (1999) states that the antibiotic course should be 10–14 days, as shorter courses are associated with a high incidence of relapse.

Symptomatic treatment includes treating the pain associated with mastitis. Ibuprofen is considered to be effective as both a pain reliever and an anti-inflammatory.

Other measures to recommend are rest, increased fluids, and warm compresses on the affected breast to encourage milk flow. Delayed or inadequate treatment of mastitis can lead to abscess formation.

Flat or inverted nipples

Although the frequency of flat or inverted nipples is unknown, they can present a challenge to successful breastfeeding. Gunther (cited in Wilson-Clay & Hoover 2002) theorised that infants expect protractile nipple tissue that is sufficiently elastic to pull deeply into the oral cavity. Contact along the tongue and at a zone near where the hard and soft palate merge is necessary to stimulate the sucking reflex. In many cases the degree of inversion is such that it does not affect the ability of the baby to grasp the areola tissue and draw the nipple into the mouth, and so does not cause a problem.

Two commonly suggested antenatal interventions to stretch the nipples are Hoffmann exercises (stretching and pulling the nipple and areola) and wearing of breast shells (plastic discs with holes in the centre and a domed cover). Studies have failed to find any significant value in either of these interventions (Brodribb 2004).

The most effective intervention for treating flat or inverted nipples is to stimulate and shape the nipple just before breastfeeding. This can be done by hand massage, using the pump or a modified syringe. Select a 10 or 20 cc syringe, depending on the nipple diameter, remove the plunger and cut off the nozzle-end of the syringe barrel. Reinsert the syringe plunger into the barrel from the cut end, so it is away from the mother's nipple. The mother then applies the device to her nipple and pulls gently on the plunger to create suction (Kesaree et al 1993).

Pumping and breastfeeding will usually pull out flat or inverted nipples in a few days, a few weeks or sometimes months. If the baby remains unable to latch directly on to the breast despite efforts to evert the nipple, then consideration should be given to using a nipple shield.

Ankyloglossia (tongue-tie)

Ankyloglossia (commonly known as tongue-tie) is a congenital condition characterised by the lingual frenulum (the tissue that attaches the tongue to the floor of the mouth) being too short, too tight, or attached to the tip of the tongue, which causes the tongue to appear heart-shaped when protrusion is attempted. The forward motion of the tongue is restricted, causing it to thicken and turn downward, making it difficult

to initiate the characteristic peristaltic wave that milks the ductules (Riordan 2005). It is a hereditary condition and the mother, father or another close relative of the infant may also have the same condition, which is more common in boys than girls (Messner & Lalakea 2000; O'Shea 2002).

The degree of ankyloglossia varies and although it is not always a cause for concern, the condition does represent a significant proportion of breastfeeding problems. Poor infant latch, maternal nipple pain, poor milk supply, mastitis and slow infant weight gain are frequently associated with this finding. Careful assessment, followed by frenotomy when indicated, seems to be successful in facilitating continued breastfeeding (Ballard et al 2002; O'Shea 2002). However, ankyloglossia in the newborn is the subject of ongoing controversy among various professionals as well as specialty groups (Messner & Lalakea 2000).

Is artificial feeding OK? A critique

Artificial feeding is often seen as a safe, easy alternative to breastfeeding, but there are risks. However, breast milk is a living tissue that cannot be duplicated by any other means. Infants who are artificially fed are disadvantaged due to constituents of the substitutes and also by factors associated with their manufacture (Minchin 2000; RCM 2002).

Nutrients in artificial formula can be lacking, deficient or excessive (RCM 2002). Cow's milk protein is casein-dominant, and so takes longer to digest. The fat is either butterfat or mixtures of vegetable oils with fatty acid composition very different from that of human milk. Infant formula also lacks many living cells, cholesterol, free amino acids, glycosamine, polyamines, enzymes and other bioactive substances (NHMRC 2003). Long chain polyunsaturated fatty acids are important for nervous system development, specifically in the brain and retina. They are also precursors of other substances needed for renal function, allergenic and inflammatory reactions. Breast milk contains these fatty acids and precursors needed for body processes but formula-fed babies require dietary supplements to match this component (Clandinin et al 1999; Sellmayer & Koletzko 1999). The sterilisation of formula modifies the protein structure, although allergenicity of the protein is reduced (NHMRC 2003).

Breast milk constituents change constantly throughout lactation, during a feed and during the day. The high bioavailability of micronutrients ensures that the infant receives the nutrition needed at that specific time. Infants can control their caloric intake by altering their sucking pattern. The composition of manufactured milk is homogenous and cannot change and is therefore less adaptable to the infant's needs (Shinskie & Lauwers 2002).

Although the benefits of breast milk and breastfeeding are widely recognised, the hazards of artificial feeding are less so. Randomised controlled trials involving artificial feeding are not ethically appropriate with term babies (RCM 2002). The health risks of manufactured infant milks are confirmed by epidemiological research over time, by a higher incidence and severity of illnesses and diseases and increased mortality and morbidity. Gut flora can be changed as a result of ingestion of formula sensitising the infant to cow's milk proteins and gastric-related illnesses. A reduction in personal health outcomes for both mother and infant and an increase in healthcare costs results (Ball & Bennett 2001; Bick 1999).

Safe bottle-feeding requires a safe water supply, hygienic surroundings and practices for preparation, adequate refrigeration, bottles and teats and a method of sterilising the equipment, as well as the formula itself and the ability to understand the instructions for preparation. Overheating of formula can also cause burns to the mouth and throat. Although breastfeeding is the optimal infant feeding method, when there is no alternative other than using formula, the quality and composition of manufactured milk is regulated, although potentially hazardous. The artificial formula may also be contaminated with aluminium, hydrocarbons and bacteria (NHMRC 2003).

Breast milk is a convenient, inexpensive food source posing no environmental cost. Conversely, infant formula and infant feeding bottles are costly for the family and community in terms of production and energy requirements, purchase of bottles, teats and formula and waste disposal (Biancuzzo 1999; Riordan 2005).

Breast milk may be affected by maternal medications, as most pass from the maternal plasma into the milk, although there is little evidence of harm to the infant (Hale 2002). The exceptions to this are the hepatitis B and C viruses and the human immunodeficiency virus. The WHO still recommends exclusive breastfeeding in the first months when artificial feeding is not safe, feasible, sustainable or affordable (WHO 2000). Supplementation of breastfeeding with artificial formula may interfere with the establishment of breastfeeding, although the effects of established breastfeeding mixed with infant formula are less clear (Enkin et al 2000).

Review questions

1. What are the advantages of breastfeeding?
2. What are the disadvantages of artificial feeding?

CHAPTER 29

Pharmacology and prescribing

Marion Hunter and Jackie Gunn

Key terms

agonist, antagonist, bacterial resistance, bioavailability, dependent prescribing, half-life, hepatic first pass, independent prescribing, loading dose, maximum safe concentration, minimum effective concentration, NSAIDs, pharmacodynamics, pharmacokinetics, steady state, therapeutic range

Chapter overview

In this chapter, the scope of midwifery practice is discussed with respect to independent prescribing. Prescribing for women during pregnancy and lactation requires particular caution, as nearly all drugs transfer to the fetus or neonate. Pharmacological concepts are reviewed, as this understanding is essential for the administration or prescription of pharmaceuticals. Antimicrobials used during childbirth are considered in light of increasing concerns over bacterial resistance. Common conditions prescribed for in pregnancy are also discussed, and evidence-based practice is considered in order to inform the prescription of medicines. In concluding this chapter, guidelines are given for midwife prescribers and for accurate prescription writing.

Limitations of this chapter: The authors assume that readers have prior pharmacology knowledge and a comprehensive knowledge of normal and complicated childbirth. The discussion in this chapter is limited to pharmaceutical medicines and does not cover the use of complementary or non-pharmaceutical therapies. The authors acknowledge that prescription of medicines is always evolving according to research, availability of pharmaceuticals and cost. Midwife prescribers have an obligation to maintain a current knowledge of the safety of medicines in pregnancy and lactation, and of preferred pharmaceuticals for particular conditions.

Learning outcomes

Learning outcomes for this chapter are:

1. To discuss the scope of midwifery practice in relation to prescribing medicines and the legislation associated with the prescription of medicines
2. To revise pharmacological concepts that inform the prescription of medicines and discuss the safety of drugs in pregnancy
3. To review the action and use of antimicrobials in relation to midwifery practice, in particular midwifery responsibility for minimising bacterial resistance
4. To examine the evidence in relation to accurate assessment, diagnosis and prescription of medicines related to midwifery scope of prescribing
5. To accurately prescribe appropriate medicines as part of autonomous midwifery practice.

Scope of midwifery prescribing

At the time of writing, most midwives in Australia undertake dependent prescribing (prescribing according to standing orders or protocols where authority remains with the medical practitioner), although variations might occur between states. However, it is acknowledged that midwives do initiate pharmacological substances for uncomplicated pregnancies, labour and the puerperium. A project is under way in Western Australia to consider midwifery prescribing according to a formulary (personal correspondence, K Hyde, Senior Midwifery Officer, 14 September 2004).

Midwives in New Zealand undertake dependent and independent prescribing, and the Midwifery Council of New Zealand (2004) expects all registered midwives to be able to demonstrate competence in independent prescribing. Competency 2.13 (2004) indicates that a midwife must demonstrate the ability to prescribe, supply and administer medicine, vaccines and immunoglobulins safely and appropriately within the midwife's scope of practice and the relevant legislation.

Midwives in New Zealand gained lawful prescribing rights through the passage of the *Nurses Amendment Act 1990*, which included amendments to the *Misuse of Drugs Act 1975* and the *Medicines Act 1981*. There is no defined list of medicines a midwife may prescribe, but the limits as to when a midwife can prescribe are set out in an amendment to Regulation 39 of the Medicines Regulations (1984), which states: 'No registered midwife shall prescribe any prescription medicine otherwise than for antenatal, intrapartum and postnatal care'. The Misuse of Drugs Act permits midwives to prescribe pethidine, the only controlled drug that midwives can prescribe.

Following the law changes above, the New Zealand Department of Health (1990) circulated a guide to the Nurses Act Amendment stating that midwifery prescribing would not include the treatment of underlying medical conditions such as asthma or hypertension and that 'it would also not include the prescribing of medicines such as antibiotics or oral contraceptives' (1990, p 5). However, caseloading midwives found the latter restriction untenable. It imposed additional expense on women to consult a doctor in order to obtain medicines such as the progestogen-only contraceptive pill or antibiotics for an uncomplicated urinary tract infection. The New Zealand College of Midwives (NZCOM) challenged the restrictions on prescribing, and during 1995 the New Zealand Ministry of Health agreed that there was no legal basis for restricting the prescription of antibiotics and oral contraceptives and that it may indeed be appropriate for these to be prescribed by midwives during the course of providing antenatal, intrapartum and postnatal care (personal correspondence, K Guilliland, 1998).

The NZCOM Consensus Statement on Prescribing (2002) notes that midwives can prescribe for conditions commonly associated with uncomplicated pregnancy, labour and the postnatal period, up to six weeks after the birth of the baby (Campbell 2003). Midwives need to have knowledge of the effects, side-effects and contraindications of the drugs prescribed and to prescribe within their knowledge and expertise. The NZCOM strongly discourages the use of analgesics or sedatives during labour at home. The necessity for these types of medications is an indication for transfer to hospital. If narcotics are prescribed for use in labour, these must be discussed with the woman and the midwife must have the equipment and skills necessary to cope with the effects of this medication.

In the latter half of this chapter, specific conditions are discussed in relation to midwifery prescribing. The authors do not consider that all pregnancy-related conditions warrant treatment by midwives. Women requesting medication for hyperemesis should be referred to an obstetrician, as particular caution is required during the first trimester. Obstetric doctors need to prescribe adequate postoperative analgesia for women in secondary care (e.g. women who have experienced caesarean birth). Prescribing of anti-depressants, medication for asthma or hypertension/pre-eclampsia is clearly beyond the scope of midwifery practice. It is important that midwives do not issue prescriptions for medicines outside their scope of practice. Auditing identifies the named prescriber and the types of medicines prescribed. Midwives need to insist that the obstetrician or medical practitioner fax or issue a prescription for medicines associated with underlying pathology. Midwives should not prescribe antibiotics for neonates. If an infection is present, systemic antibiotics are usually necessary for newborn babies and this is beyond the scope of midwifery prescribing. Topical eye antibiotics should be used with caution and only when chlamydial infection has been ruled out. The immaturity of the neonate liver means that prescribing paracetamol should be done by medical practitioners.

Safety of drugs during pregnancy and lactation

Thalidomide is well known as the prototype for teratogens (De Santis et al 2004). Thalidomide prescribed to pregnant women in the 1960s to relieve nausea and vomiting resulted in babies born with limb malformations, and this catastrophic effect shook the perception that the placenta provides a barrier to drugs (Gardiner 2002). Drug use during pregnancy should be restricted according to necessity, and to the use of drugs for which prior clinical evidence is available. The first trimester of pregnancy is generally considered the most critical period for teratogenic effects. After the first 11 weeks, exposure to teratogens will generally have an effect on the nervous system, gonadal tissue (due to slower development than other organs) or general growth restriction (Hansen et al 2002). Vigilance is also necessary when midwives prescribe medicines during lactation. Resources should be utilised to ascertain the safety of medicines.

Studies show that many women use drugs during pregnancy. Schirm and colleagues (2004) evaluated drug types by prescription for 7500 Danish women. The authors

reported that 69% of the women used a drug during pregnancy that was not folic acid, an iron preparation or vitamins. Drugs commonly used included dermatological and gynaecological preparations, lactulose, salbutamol and paracetamol. Andrade and colleagues (2004) similarly reported that 64% of women in a study in the United States (total study $n = 98,182$) used a drug other than a vitamin or mineral supplement during pregnancy, with the most frequently used drugs being oral anti-infective medicines.

There appears to be a prevalence of drug use during pregnancy, and therefore it is important that midwives stress the safe use of medications during pregnancy, particularly with the availability of over-the-counter pharmaceuticals. The Swedish, Australian and Federal Drug Administration drug classification systems are well known for classifying drug safety and use codes (A, B, C, D, X). However, a recent evaluation showed that only 26% of drugs common to all three systems were placed in the same risk category (Schirm et al 2004). These differences in categories cause confusion for the prescriber. The Australian categorisation of drugs and safety during pregnancy provides additional narrative information to guide the prescriber with the correct choice of medicine when drug therapy is required during pregnancy. Drugs are categorised to assist the prescriber to select the 'safest' known medicine appropriate for a particular condition.

Reflective exercise

Refer to the following information and then answer the questions below.

Prescribing medicines in pregnancy: an Australian categorisation of risk of drug use in pregnancy (Australian Government, Department of Health and Ageing, Therapeutic Goods Administration), http://www.tga.gov.au/docs/html/mip/medicine.htm

Questions

1. What are the meanings of the drug categories A–X and the relevance of these categories to pregnancy?
2. Write a list of drugs commonly used during pregnancy and childbirth, and list the category of each drug.
3. What are your personal habits or friends' habits regarding the use of pharmaceuticals in relation to flu or mild infections?
4. What are your personal biases with regard to drug use during pregnancy and childbirth (e.g. women experiencing severe vomiting, women wishing to use analgesics, antacids or laxatives regularly)?

Principles of pharmacology

Some key concepts are reviewed here; for a more extensive discussion, a pharmacology text should be consulted. Pharmacokinetics is the term used to describe how drugs are absorbed, distributed, metabolised and eliminated by the body.

Absorption

In most cases, when a drug is administered to a person it has to be absorbed into the bloodstream before the molecules can be distributed around the body to the site of action. Absorption is a complex process, as age, body mass, activity and fullness of the stomach can affect both the amount and the rate at which drugs are absorbed. Decreased gastrointestinal motility can increase or decrease drug absorption during pregnancy, and vomiting could mean that the drug is not absorbed at all (Bryant et al 2003; Shargel et al 2001). Once the drug is dissolved in the gastrointestinal tract, the molecules can be absorbed. Because cell membranes primarily consist of lipid substances, drug molecules generally need to be lipophilic (having an affinity with lipids) to pass through into the capillaries (Galbraith et al 2001; Shargel et al 2001).

Distribution

Hepatic portal system

As with most other digested substances, drugs are absorbed from the intestine into the hepatic circulation via the portal vein. Therefore, before the drug molecules can reach the general circulation they must pass through the liver. This is known as the hepatic first pass. At this point, a proportion of drug molecules can be metabolised and excreted by the liver. Drugs that have a significant proportion of molecules metabolised in this way are said to have a high hepatic first pass (Galbraith et al 2001; Holland & Adams 2003).

Some of the metabolites from the liver are excreted into the small intestine via the bile duct. Bile salts are excreted in this way. The body uses intestinal bacteria to recycle bile salts. The bacteria de-conjugate the bile salts, allowing them to be reabsorbed from the small intestine so that they can be conjugated again in the liver, excreted back into the small intestine and used once again in the normal digestion process. This is known as the entero-hepatic cycle. A proportion of drug molecules metabolised in the liver on the hepatic first pass are excreted into the intestine, where they are also recycled by undergoing the process of de-conjugation, reabsorption from the gut and then passing through the hepatic circulation a second time. Oestrogen in the combined oral contraceptive pill is an example of a drug that is affected in this way (Bryant et al 2003; Galbraith et al 2001; Holland & Adams 2003).

General circulation

Once the molecules reach the general circulation, they are distributed to the site of action. Highly soluble drugs are carried in the plasma as free molecules in solution. More poorly soluble drugs are carried partially bound to serum protein molecules. Only drug molecules that are free in solution are pharmacologically active. They cannot bind to

the receptor sites in the body while still bound to the serum protein. The proportion of free and protein-bound drug molecules are in equilibrium. This means that drug molecules that are bound to protein molecules are released and become active as the free molecules are used. Therefore drugs that are distributed in the body partially bound to protein molecules take longer to be released to the receptor sites. The partially bound drug is pharmacologically active for longer than a highly soluble drug that has all its molecules available to the receptor sites and all its molecules available for metabolism by the liver at the same time.

The increase in maternal plasma volume and increase in body fat during pregnancy can affect drug distribution. This does not affect drug dosing except for loading doses, where a higher dose might be required (Gardiner 2002). The increase in body fat might affect drugs that are deposited in fatty tissue, resulting in a decrease in plasma concentration. Decreased serum albumin can decrease protein binding of drugs and can be relevant for monitoring of drug concentrations such as phenytoin (Begg 2003; Bryant et al 2003; Shargel et al 2001). Phenytoin concentrations during pregnancy are extremely complicated and specialist consultation is necessary (Gardiner 2002).

Metabolism and excretion

If the drug molecules remain lipophilic they will be reabsorbed at the nephron tubules or returned to the gut from the liver. Therefore drugs are metabolised in the liver to make them water-soluble (polar) so they can be excreted from the body. Two types of enzyme are involved in metabolism of drugs. The first type (sometimes called phase I) modifies the drug by chemical processes such as oxidation, reduction or hydrolysis to make water-soluble metabolites. The cytochrome P_{450} family of enzymes found in abundance in the hepatocytes are responsible for most of these reactions. Induction or inhibition of drug metabolism during pregnancy is dependent on the specific P_{450} enzymes involved. During pregnancy, metabolism of caffeine is decreased, whereas that of phenytoin is increased (Begg 2003; Bryant et al 2003).

The second type of enzyme (phase II) conjugate either the drug molecules, or a phase I metabolite, with a polar molecule such as glucuronic acid, which renders the molecule water-soluble for excretion. Conjugation enzymes belong to the transferase family. Midwives will be familiar with the physiological process in neonates whereby excess lipophilic bilirubin molecules are conjugated to water-soluble molecules by the enzyme glucuronyl transferase in the liver (Begg 2003; Bryant et al 2003). Drugs are mainly excreted in the bile and urine. Other routes include the lungs, sweat and saliva, and breast milk in lactating women (Galbraith et al 2001). Drugs that are very water-soluble are excreted virtually unchanged into the urine. This can be helpful when treating bacterial infections of the lower urinary tract (Bryant et al 2003; Lang 2001).

Drug clearance may be increased during pregnancy due to an increase in renal and liver blood flow (Gardiner 2002). Glomerular filtration rate increases from early pregnancy and remains elevated through the pregnancy, and therefore increased doses are used for drugs such as beta lactam antibiotics, which are eliminated through the renal system (Begg 2003; Gardiner 2002).

Bioavailability

Bioavailability is the amount of drug that is available to the receptor sites. When injected intravenously, 100% of the drug is available, but when given orally some of the drug is lost during the absorption and hepatic first pass processes. Therefore, a smaller dose is usually required when the intravenous route is used (e.g. doses of narcotics). Antibiotic therapy is the most common exception, as these drugs act directly on bacteria, not on body cells (Bryant et al 2003; Galbraith et al 2001).

Plasma concentration

The time taken after a dose of a drug to reach maximum plasma concentration is affected by absorption, distribution, metabolism and elimination rates. Drugs given orally take longer than those administered intravenously to reach peak plasma concentration. The plasma concentration is related to the therapeutic effect (Begg 2003).

Therapeutic range

In order to produce a clinical effect, a certain level of drug needs to be present in the general circulation. This level is called the minimum effective concentration (MEC). The minimum effective concentration is different for each drug. For all drugs there is also a level at which the drug will produce adverse effects on the person, known as the maximum safe concentration (MSC). The range between the MEC and the MSC that is associated with drug efficacy is known as the therapeutic range. Most drugs have a wide therapeutic range, which means that the serum levels will not normally rise to toxic levels when the usual size and frequency of dose is taken. However, a significant number of drugs, especially anti-convulsants and antibiotics from the aminoglycoside family (e.g. gentamycin) have a narrow therapeutic range. This means that it is possible for serum levels to rise to toxic levels even with normal dose and frequency regimens. People being treated with drugs that have a narrow therapeutic range have the serum levels of the drug regularly monitored so that, if necessary, the dose can be adjusted to maintain effectiveness without causing toxicity (Begg 2003; Bryant et al 2003; Galbraith et al 2001).

Half-life

The length of time for which a drug is clinically effective in the body is called its half-life. Half-life is the length of time it takes to reduce the amount of drug in the circulation by half. For example, 500 mg of a drug that has a half-life of four hours will reduce to 250 mg four hours after administration, to 125 mg after another four hours, and so on. Although there are still active molecules of the drug in the body after four hours (in this example), the clinical effectiveness of the drug has been significantly reduced. This principle is what guides

recommendations for the frequency of doses. Doses are given at the half-life interval (e.g. four-hourly in the above example) (Bryant et al 2003; Galbraith et al 2001; Shargel et al 2001).

Steady state concentration

The aim of dosing regimens is to achieve a steady state concentration—that is, to maintain a constant concentration of the drug in the plasma that is consistent with a therapeutic response in the person (Fig 29.1). When a steady state is reached, the maintenance dose rate is equal to the elimination rate (i.e. it is in equilibrium) (Bryant et al 2003; Shargel et al 2001). Drugs are given at half-life intervals to reach a steady state concentration: 'In general it takes 3 to 5 half lives to reach the desired steady state' (Bryant et al 2003, p 122). To avoid the problem of delay when the half-life is long or rapid and treatment is imperative, a loading dose is often given.

While loading doses are often twice the ongoing dose, the desired plasma concentration and the apparent volume of distribution for individual drugs are taken into account (Shargel et al 2001). The initial dose is sometimes given parenterally, followed by oral administration of maintenance doses.

Pharmacodynamics

Pharmacodynamics is the term used to describe the action of a drug on the body. Nearly all drugs act on receptors in the body (antimicrobials act on microorganisms) by binding to a protein. Most drugs have some selectivity—that is, they 'see' or 'fit' particular receptors as targets. Generally, drugs act on four main types of regulatory proteins: carriers, enzymes, ion channels and receptors (Bryant et al 2003; Holland & Adams 2003). Carriers transport ions and small, poorly fat-soluble molecules across cell membranes. Examples are carriers that uptake noradrenaline and serotonin at the nerve terminals. Drugs that target carriers usually inhibit carrier-mediated uptake of such transmitters (e.g. tricyclic antidepressants) (Bryant et al 2003). *Enzymes* are biological catalysts that control cellular biochemical reactions. Drugs that interact with enzymes inhibit or alter the biochemical reaction. The sulfonamide group of drugs, which includes the drug Bactrim, are an example (Galbraith et al 2001). Ions are transported in and out of cells through specific channels in the cell membrane so that the electrochemical gradient across the cell membrane can be maintained. Drugs that interact with receptors to block the ion channels are widely used. These drugs generally have a high selectivity. Nifedipine, used for the control of hypertension, for example, is a calcium ion channel blocker that affects the arterioles but has little effect on cardiac muscle and no effect on the transport of other ions such as sodium (Bryant et al 2003; Galbraith et al 2001).

Receptors are specific proteins that span cell membranes. They are engaged in 'chemical signalling between and within cells' (Bryant et al 2003, p 95). Drug molecules bind with receptors in a 'lock and key' effect. Drugs that temporarily bind to receptors and stimulate the cell to carry out its normal biochemical actions are known as agonists, while those that bind to the receptors to temporarily block or inhibit the normal cell process are referred to as antagonists. Drugs called 'blockers' are antagonists. The beta-blocker labetalol is an example (Galbraith et al 2001; Holland & Adams 2003).

Antimicrobials

Midwives require a thorough understanding of antimicrobials, not only for prescribing and administration purposes, but also to take every opportunity to encourage health-promoting activities in childbearing families. Opportunities to reinforce information about completing courses of antibiotics, recognising adverse effects and preventing the development of resistant bacteria arise in the course of everyday midwifery practice.

Midwives do not independently prescribe for infections that require intravenous antibiotics; referral should be made

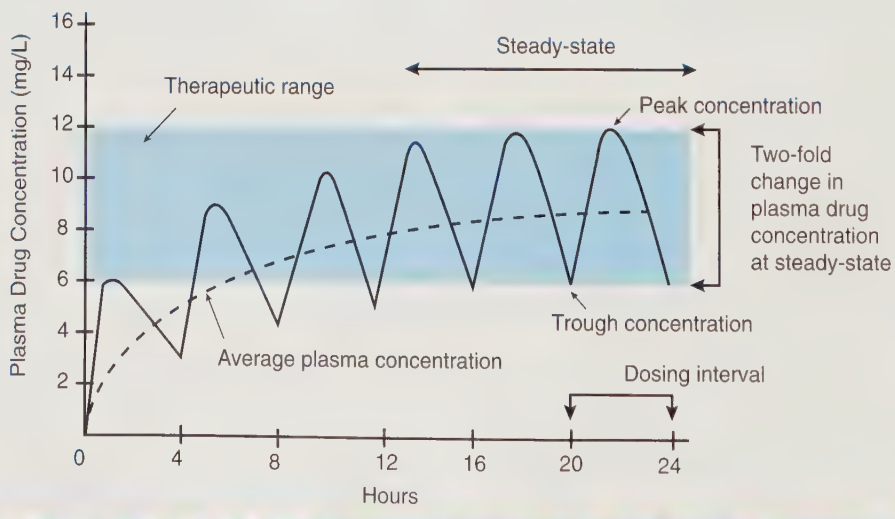

Figure 29.1 Achieving a steady state. The drug in this example has a half-life of four hours (based on Bryant et al 2003).

BOX 29.1 Barriers to distribution

Blood–brain barrier

The brain is protected from harmful substances because it has a different capillary structure from that of the rest of the body. The junctions between endothelial cells are narrower, reducing the number of pores available. Further, a web of tightly connected glial cells forms a fatty layer between the capillaries and the brain tissue. Only material that is very fat soluble or is actively transported can cross the blood–brain barrier (Bryant et al 2003; Galbraith et al 2001; Shargel et al 2001).

Placenta

Considering the size and complexity of the placenta, it is very limited barrier for many drug molecules. It does not have the selectivity of the blood–brain barrier, allowing both lipid-soluble and water-soluble drugs to cross into the fetal circulation. For example, the effect of narcotic analgesia given in labour on neonatal respiratory effort is well documented. A number of drugs can have a deleterious effect on the growing embryo or fetus (e.g. phenytoin, tetracycline).

The poor protection afforded by the placenta is the primary reason that drugs are generally contraindicated in uncomplicated pregnancies. When a pregnancy is complicated by a concurrent medical condition, medications are prescribed with caution. In these cases, the obstetrician assesses the risk/benefit of medication in each situation. Some anticonvulsants commonly used to control epilepsy in non-pregnant women pose a significant risk to the growing baby. The woman's medication may be changed to a drug that poses less risk to the baby for the duration of the pregnancy. In other medical conditions, the dose(s) of drug used to control the medical condition may need to be adjusted and plasma concentrations monitored (Bryant et al 2003).

to an obstetrician. Midwives would not prescribe for medical conditions such as pyelonephritis or prophylactic antimicrobials for cardiac conditions. Neonates with symptoms suggestive of systemic infection should be promptly referred to the paediatric service (or a medical practitioner in areas without a paediatric service). Neonates have an immature liver enzyme system and therefore have limited ability to metabolise drugs. They can also become seriously ill very quickly.

Antimicrobials are groups of drugs that destroy or restrict the proliferation of infectious microorganisms. They work by inhibiting cell wall synthesis, disrupting cell membrane permeability, interfering with the organism's metabolic processes, or by inhibiting protein synthesis in the organism (Bryant et al 2003; Galbraith et al 2001).

Bacteriocidal antimicrobials destroy the organism and bacteriostatic drugs hinder bacterial growth, giving the body a longer period in which to mobilise its own defences. Antibiotics are used to treat bacterial infections. Other antimicrobials include antiviral, antifungal and antimycobacterial agents (Holland & Adams 2003).

BOX 29.2 Prescribing antimicrobials

Bryant et al (2003, p 753) list the following important principles for prescribing antibacterial drugs:

- Use an antibacterial drug only when indicated.
- Identify the infecting microorganism.
- Determine the susceptibility of the organism.
- Use a drug with the narrowest spectrum of activity for the known or likely organism.
- Use a single drug, unless combination therapy is specifically indicated to ensure efficacy or to reduce the emergence of resistance.
- Use a dose high enough to ensure efficacy (with minimal toxicity) as this reduces the likelihood of resistance.
- Use a short duration of treatment (< one week) unless evidence indicates a longer duration.

Bacterial resistance

Midwives have a responsibility not to contribute to the development of bacterial resistance and should base practice on evidence. Good prescribing and health education practices will assist in the prevention of unnecessary exposure or under-treatment with antibiotics (Foureur 2001).

Spectrum of activity

The number of types of organisms that are sensitive to the antibiotic is what determines its spectrum of activity. Antibiotics to which only a few groups of organisms are sensitive are said to have a narrow spectrum of activity, while those that are effective against a wide range of organisms are said to have a broad spectrum of activity. This does not mean that narrow-spectrum antibiotics are of no value. A well-chosen narrow-spectrum antibiotic can be very effective. An example of this is flucloxacillin, a narrow-spectrum, beta-lactamase-resistant antibiotic, effective against *Staphylococcus aureus* and *Streptococcus sp* (Miller 2002), and used for the treatment of mastitis when women are lactating (Lang 2001).

Adverse reactions

The importance of taking a careful history relating to hypersensitivity to antibiotics cannot be sufficiently emphasised. There is a world of difference between an anaphylactic reaction, fever and rash due to allergy, and adverse effects such as diarrhoea, nausea and vomiting, candidiasis or sore mouth or tongue (*New Ethicals Compendium* 2000). Clients do not always distinguish between types of adverse reaction. Women who have a history of hypersensitivity to any antibiotic should have their notes prominently marked so that it is not overlooked. In cases of hypersensitivity, drugs should be discontinued and consultation sought. 'Hypersensitivity reactions occur in 4–8% of patients. Anaphylaxis occurs in approximately 0.2% [of clients]' (Lang 2001, p 25) (see Box 29.3). Midwives need to be particularly cautious regarding

BOX 29.3 Anaphylactic shock

Anaphylaxis is a potentially life-threatening, acute and severe systemic reaction that occurs after exposure to a specific antigen. Mast cells and basophils are the primary initiating cells of immunoglobulin E (IgE) mediated allergic reactions, causing severe bronchospasm, laryngospasm, angioedema, urticaria and cardiovascular collapse. Symptoms of anaphylaxis usually occur within seconds to minutes of exposure to the allergen and range from mild to very severe. Allergens include penicillins, anaesthetic drugs, some intravenous infusion liquids, and aspirin and other NSAIDs.

Signs and symptoms

- rapid pulse, sweating, dizziness, fainting, unconsciousness
- wheezing, chest tightness, difficulty breathing, coughing
- itchy hives, which may blend together to form larger areas of skin swelling
- swelling of the lips, tongue or eyes
- nausea, vomiting, abdominal cramps, diarrhoea
- paleness, bluish skin colour
- throat swelling, with a feeling of throat tightness, a lump in the throat, hoarseness or obstructed air flow.

Treatment

- Call for emergency assistance immediately.
- Adrenaline is the treatment of choice. The dose of adrenaline is usually 0.3 mg for an adult, to be given at the first sign of a serious reaction.
- Adrenaline given subcutaneously or intramuscularly will work for about 150 minutes.
- Following the administration of adrenaline, admit to hospital for observation for up to 24 hours, as occasionally the symptoms can return. An antihistamine or corticosteroid injection may also be administered, or given together with fluids intravenously.
- Oxygen may be given.

Side-effects of adrenaline

- Trembling, palpitations and a feeling of tension or anxiousness—these are normal effects of the adrenaline and soon wear off. Higher doses cause an extremely unpleasant feeling.

Contraindications

- high blood pressure or heart arrhythmias.

women with a history of penicillin allergy. A significant number of these clients will have adverse reactions or allergies to other groups of antibiotics, and hence referral to a doctor is indicated. The tetracyclines group of antibiotics cannot be used as an alternative, as they are contraindicated in pregnancy—there is risk to the fetus of teeth staining and inhibited bone growth (Lang 2001). Midwives need to be aware of local policy for reporting adverse reactions of medicines and to promptly refer women experiencing any adverse effects to a medical practitioner.

Types of antimicrobials

Beta-lactam antibiotics

These drugs are bacteriocidal substances that contain a beta-lactam ring in their molecular structure. They include the penicillins, cephalosporins, monobactams, carbapenems and beta-lactamase inhibitors (Galbraith et al 2001; Lang 2001; Miller 2002). Some bacteria have become resistant to antibiotics by developing the capacity to produce the enzyme beta-lactamase (penicillinase), which breaks the beta-lactam ring in the antibiotic molecule, rendering it ineffective (Holland & Adams 2003).

Penicillins

The penicillins are a large group of both natural and synthetic antibiotics (Miller 2002). They are grouped into several categories. Benzylpenicillin or penicillin G (parenteral) and phenoxymethylpenicillin or penicillin V (oral) are clinically comparable. They have been largely replaced by broad-spectrum penicillins such as amoxycillin, which does not need an empty stomach and is more reliably absorbed (Lang 2001). Penicillin V may be used as prophylaxis for women with a history of cardiac conditions such as bacterial endocarditis.

Narrow-spectrum penicillinase-resistant penicillins

These penicillins are beta-lactamase resistant (Bryant et al 2003; Holland & Adams 2003). Flucloxacillin and dicloxacillin are used to treat staphylococcal infections, particularly in soft tissues. They need to be taken on an empty stomach (Lang 2001).

Extended-spectrum penicillins

The spectrum of activity for amoxycillin/clavulanic acid, piperacillin/tazobactam and ticarillin/clavulanic acid is extended by the addition of the beta-lactamase inhibitors clavulanic acid or tazobactam. This makes these antibiotics effective against otherwise resistant strains of *S. aureus* and some anaerobes. Of all the penicillins, piperacillin and ticarillin have the widest range of action against Gram-negative organisms. Ticarillin is no longer available in New Zealand (Bryant et al 2003; Lang 2001).

Beta-lactamase inhibitors do not have much antibacterial activity in themselves, and reaction to clavulanic acid is extremely rare. They protect the antibiotic by binding with the beta-lactamase produced by the microorganisms (Lang 2001).

Patterns of bacterial resistance in local flora of the gut are an important prescribing consideration. For example, in some areas, amoxycillin-resistant *Staphylococcus* make an amoxycillin/clavulanic acid preparation more appropriate to prescribe if treatment needs to commence before sensitivities are known. It is important for midwives to follow up the results of bacterial culture sensitivities, to both fully treat the infection and minimise the spread of resistance.

Cephalosporins

Cephalosporins are a family of broad-spectrum antibiotics that are classified by their generation. The generation refers to the

timeframe over which each group was developed, rather than increasing improvement. Each generation has specific effect on different groups of bacteria. First-generation cephalosporins are active against Gram-positive bacteria. Second-generation drugs also target Gram-negative organisms, as do third-generation drugs, which have a longer duration and target beta-lactamase-producing organisms. Fourth-generation cephalosporins have similarities with the third-generation drugs (Holland & Adams 2003). Most cephalosporins are only available for parenteral use. Therefore community prescribing is limited to the few oral preparations. Cephalosporins are judiciously prescribed, as they are valuable agents in the treatment of Gram-negative organisms and are more expensive than the penicillins.

Oral cephalosporins are alternatives to penicillins for treatment of skin and soft tissue infections of *S. aureus* and streptococcal (not enterococcal) origin (Lang 2001). Cephalosporins should not be used if a person reports a serious reaction to penicillin (Bryant et al 2003; Hansen et al 2002). Adverse effects are similar to those for penicillins but hypersensitivities are much less common. Renal toxicity has been associated with earlier-generation cephalosporins (Holland & Adams 2003).

Macrolide antibiotics

The macrolides are a group of primarily bacteriostatic antibiotics with some bacteriocidal effect that include erythromycin and azithromycin. They have a broad spectrum of activity against diverse organisms. Erythromycin is the most commonly used alternative to penicillin where there is an allergy (Holland & Adams 2003; Lang 2001). Erythromycin estolate is contradicted in pregnancy because of drug-related hepatotoxicity. Erythromycin ethylsuccinate is satisfactory for use during pregnancy.

Aminoglycosides

Prescription of aminoglycosides is outside midwives' scope of practice. However, midwives administer these drugs parenterally and monitor their effects. For example, gentamycin can be used with amoxycillin as a prophylactic regimen for women intrapartum with cardiac conditions. Gentamycin can also be used to treat sensitive bacteria causing acute pyelonephritis in pregnancy.

The aminoglycosides are a group of potent bacteriocides that act by inhibiting protein synthesis. They are generally reserved for Gram-negative infections. They are: gentamycin, neomycin, netilmycin, streptomycin and tobramycin (Bryant et al 2003; Holland & Adams 2003). Adverse reactions include serious neurological, renal and ototoxicity, and therefore careful observation for signs of adverse reactions is required. If treatment is longer than 72 hours, plasma levels and renal function are monitored to determine dose regimens (Bryant et al 2003).

Nitrofurantoin

Nitrofurantoin is a broad-spectrum bacteriocide, the mechanism of which is not fully understood. It is used for the treatment of acute urinary tract infections, as it is highly soluble. Approximately 65% of the drug is excreted in the urine unchanged. Urine alkalinisers are not recommended when women are being treated with nitrofurantoin, as it has more efficacy in an acidic environment. It should not be used when labour is imminent because of the possibility of haemolytic anaemia in the neonate due to immature erythrocyte enzyme systems (glutathione instability). Nitrofurantoin is contraindicated in women with G6PD deficiency due to potential haemolytic anaemia (Bryant et al 2003; Medsafe 2003). Antacid preparations containing magnesium trisilicate should not be used when taking nitrofurantoin, to avoid the possibility of impaired absorption.

Topical antibiotics

Topical antibiotics are used for the treatment of conjunctivitis and occasionally superficial skin/umbilical cord infections in neonates. Care must be taken to only use topical antibiotics when there is actually an infection present. A significant proportion of neonatal 'sticky eyes' in the first week of life is related to an inflamed tear duct rather than an infectious conjunctivitis. Regular cleansing (associated with gentle massage of the tear duct) is usually all that is required. If an infection is suspected, a swab should be taken for culture and sensitivities prior to starting treatment. Antibiotic therapy can mask chlamydial eye infections. Midwives need to consider this condition if the conjunctivitis does not resolve quickly.

The use of topical antibiotics for minor neonatal skin infections is controversial. A mild antiseptic wash may be just as effective. The treatment of umbilical cord stumps with topical antibiotics should rarely be necessary. Most 'sticky cords' are merely the result of saprophytic action and require hygiene measures rather than antibiotics. Umbilical cord infections can rapidly spread to become serious systemic infections. Regular observation will assist early detection; referral is indicated for babies with umbilical infections.

Antivirals: acylovir

Acyclovir is used as topical or oral preparation to increase the healing rate and to decrease the pain of genital herpes lesions

Critical thinking exercise

1. How do prescribers make decisions regarding which antibiotic is appropriate for treatment of a particular infection?
2. What is the rationale for prescribing more than one antibiotic in particular circumstances? For example, an obstetrician or doctor will frequently prescribe intravenous amoxicillin plus gentamycin for women with cardiac pathology (including a history of rheumatic heart disease).
3. What pregnancy-related issues need to be considered and taken into account *before* a midwife deems that it is appropriate to prescribe a pharmaceutical?

(Galbraith et al 2001). The topical preparation is widely available (OTC), as it is primarily used for the treatment of Herpes Simplex I lesions. Diagnosis of genital herpes, follow-up of partners and treatment regimens is beyond the scope of midwifery practice. Referral to a doctor is indicated.

An understanding of pharmacology and knowledge of commonly used antimicrobials is essential for safe prescribing practices. The following section refers to common conditions during pregnancy where midwives might need to consider prescription medicines in discussion with the woman.

Other drugs and conditions prescribed for

Selected other drugs commonly used, and conditions commonly prescribed for in the childbearing year, are described below.

Oxytocin

Synthetic oxytocin is used in labour to augment uterine contractions when they are absent or incoordinate, or during induction of labour (Varney 2004). Oxytocin has an immediate onset and is rapidly inactivated in the liver. As it has a half-life of 1–6 minutes, oxytocin is administered in labour via an intravenous infusion in which the dose is incrementally titrated to achieve approximately three to four contractions every 10 minutes (Bryant et al 2003). Oxytocin is also used to prevent or control haemorrhage post partum. A single-dose injection is used for the active management of the third stage of labour, while a continuous infusion is used to control postpartum haemorrhage (Varney et al 2004). When used in conjunction with prostaglandins or inhalational anaesthetics, the action of oxytocin may be enhanced. Close monitoring of both maternal and fetal wellbeing is required. Adverse reactions include nausea, vomiting, hypotension, tachycardia and irregular heart rate. Occasional fetal bradycardia, dysrhythmias or neonatal jaundice have occurred (Bryant et al 2003).

Local anaesthetic (lignocaine hydrochloride)

Lignocaine hydrochloride is used as a local anaesthetic for perineal repair. A 1% solution without adrenaline (i.e. plain) is the usual strength employed, although others can be used. The lowest dose needed to provide effective anaesthesia should be used. Injection should be made slowly with aspiration to prevent intravascular injection, as this may produce toxic effects. The amount required for individual women will depend on the size of the woman, the extent of the perineal injury and whether the infiltration is into an intact perineum prior to birth or an injured perineum after the birth. The maximum dose is 200 mg in adults (i.e. 20 mL of 1% plain solution) (*New Ethicals Compendium* 2000). In most circumstances the dose given is significantly less than the maximum. For smaller lacerations it often does not exceed 100 mg (10 mL).

Tocolytic drugs

Tocolytic drugs have been used in the management of preterm labour to quieten uterine activity. The group of drugs most commonly used to halt uterine activity are the beta-adrenergic agonists (e.g. salbutamol). They relax smooth muscle by stimulating the beta-receptors of the autonomic nervous system. They are administered by an intravenous infusion that is titrated to achieve uterine relaxation at the minimum dose (Lindsay 2000). Common adverse effects include tachycardia, palpitations, tremor, nervousness, dizziness, malaise, nausea, vomiting, bronchospasm and hypersensitivity reactions, among others (Comerford 2003). Women receiving tocolytic drug infusions need to be carefully monitored for adverse effects. At the time of writing (2005), the calcium ion channel blocker nifedipine is used as a tocolytic agent in the management of preterm labour in some parts of New Zealand. This drug inhibits muscle contraction by interfering with the movement of calcium across the plasma membrane (Lindsay 2000).

Non-steroidal anti-inflammatory drugs

Use of non-steroidal anti-inflammatory drugs (NSAIDs) during the second and third trimester is associated with oligohydramnios and anuria. Close to term, use of these drugs is associated with premature closure of the ductus arteriosus, with subsequent pulmonary hypertension, intracranial haemorrhage and necrotising enterocolitis in the infant. During pregnancy, paracetamol is the drug of choice for analgesic, anti-inflammatory and antipyretic action (De Santis et al 2004; Gardiner 2002).

Folic acid

Supplementation with folic acid has been shown to decrease the incidence of neural tube defects (Page 2000) and is recommended for primary prevention and also for women with a previously affected baby. Stefanogiannis (2003) reported that two randomised controlled trials emphatically and rigorously confirmed that increasing the daily intake of folic acid decreases the risk of neural tube defects. The United States Public Health Service acted on this research in 1992 and recommended that women of childbearing age consume 0.04 mg of folic acid per day to reduce the risk of neural tube defects.

Other countries have adopted various approaches, such as recommending an increase in folate-rich foods, supplementation by tablets, or fortification of certain foods. The National Food Authority in Australia permitted voluntary fortification of foods with folic acid (bread, flour, breakfast cereal, pasta, yeast and fruit juices) from 1995. The Commonwealth Department of Health and Ageing recommends that women planning pregnancy take folic acid supplements of 0.5 mg per day.

TABLE 29.1 Folate recommendations for Australian and New Zealand women

Australia	New Zealand
All women planning a pregnancy should supplement their diet with 0.5 mg of folic acid/day beginning one month prior to conception until 12 weeks gestation.	All women planning a pregnancy should supplement their diet with 0.8 mg of folic acid/day beginning one month prior to conception until 12 weeks gestation.
Women with a previous neural tube defect-affected pregnancy or with close family history of neural tube defect-affected pregnancy should supplement their diet with 5 mg of folic acid/day.	
(Sources: NHMRC 1993; Ministry of Health 1997)	

Similarly in New Zealand, voluntary fortification of food has been permitted since 1996. However, evidence suggests that women still do not have a sufficient daily intake of folic acid to reduce neural tube defects (Stefanogiannis 2003). The NZ Ministry of Health recommends that folic acid 0.8 mg tablet orally be taken daily from one month pre-conception to the end of 12 weeks gestation. Women who have had a child previously affected by neural tube defect, a family history of neural tube defect, and women at risk (e.g. women on anti-convulsant medication, women with pre-existing diabetes) should take 5 mg tablet orally (Rubin 2000).

Iron supplementation (anaemia)

Iron deficiency anaemia is the most common anaemia during pregnancy; however, midwives need to be aware of other types of anaemia, including: folate, B_{12}, sickle cell, thalassemia and auto-immune anaemia. Correct diagnosis is important, to avoid inappropriate treatment regimens that might be harmful to the woman and the fetus. Iron overload can occur in women with undiagnosed haemochromatosis or ineffective erythropoiesis such as sickle-cell disease or thalassemia (Adams-Graves 2001).

Iron deficiency anaemia

Routine iron supplementation during pregnancy is not necessary in developed countries. Plasma volume increases by 40–50% during pregnancy and red cell volume increases by only 20%. Consequently, haemodilution occurs as a physiological response. The increased blood volume during pregnancy and the lower blood viscosity ensure good perfusion and oxygenation of the fetus throughout the pregnancy (McMullin et al 2003). As pregnancy progresses, there is an increase in absorption of iron from the gut. However, despite this physiological adaptation, a number of women become deficient in iron stores during the latter stages of pregnancy. It is estimated that up to a quarter of women in industrialised countries have insufficient iron in their diet to maintain sufficient intake during pregnancy (Haram et al 2001). Haem iron is the most bioavailable (absorbable) iron and is prolific in red meat. Vegetarians generally have a low intake of bioavailable iron and ingest foods with phytic acid, which decreases iron absorption (Haram et al 2001). Non-haem iron found in pulses, vegetables and fruit is not as well absorbed and can be affected by tea, coffee, excess bran and some antacids (McKay 2000). Tea is a stronger inhibitor than coffee in reducing the absorption of non-haem iron, while vitamin C can encourage the uptake of non-haem iron (Haram et al 2001).

Interpreting blood indices

It is often difficult to decide whether Hb values between 90 and 110 g/L are due to haemodilution or anaemia. Haram and colleagues (2001) considered that a 'low' Hb was 110 g/L (11.0 g/100 mL) during the first half of pregnancy and 100–105 g/L or lower after 25 weeks gestation. An Hb less than 100–110 g/L in the first and second trimester has been associated with preterm birth and low birthweight. On the other hand, a 'high' Hb (> 135 g/L) might be associated with pre-eclampsia or conditions where haemodilution has not occurred (Haram et al 2001).

When assessing a woman for anaemia, a full blood count provides initial information. Mean cellular volume increases by about 4 femtolitres in healthy pregnancy (Haram et al 2001) and is therefore not a reliable marker for diagnosing iron deficiency anaemia. Serum ferritin is the blood test of choice to determine iron stores in the body and is a reliable blood test in the first trimester of pregnancy. However, after the first trimester, serum ferritin levels will fall due to the effect of haemodilution independent of changes in iron stores. Ferritin levels can increase in response to an acute inflammatory reaction or excessive alcohol intake (the latter should not be occurring during pregnancy). A ferritin level of 15–30 μg/L indicates that iron stores are too small to cover the need for iron in pregnancy. A ferritin level of < 12–15 μg/L indicates empty stores and iron deficiency (Haram et al 2001).

How much iron supplementation is required?

Practitioners need to differentiate the woman's diagnosis to either iron deficiency anaemia or low iron stores. If the woman is iron deficient (low Hb, lower parameter mean cell volume (MCV) and almost absent ferritin) she certainly requires supplementation. If a woman has ferritin levels within the lower range, discussion needs to occur regarding increasing iron-rich foods in the diet or consideration of supplementation. Studies have shown that routine supplementation of about 60 mg iron per day *throughout* the pregnancy is sufficient to maintain iron stores during pregnancy (Haram

et al 2001). The literature is less forthcoming in relation to 'need-based' supplementation. The midwife should use her discretion as to the amount of supplementation required on an individual need basis according to the blood results and the woman's diet.

Gastrointestinal side-effects might occur with iron supplementation, yet these appear to be dose dependent. Lowering the dose of iron supplement and recommending that the dose be taken at different intervals (if tablet form permits this dosing), or taken with food, should result in fewer side-effects. Taking iron supplements with fruit juice is likely to increase gastrointestinal side-effects, and vitamin C is not essential for the absorption of elemental iron.

Women are significantly more likely to take iron supplements if the midwife stresses the importance and rationale for supplementation (Wulff & Ekstrom 2003). Intake of too much iron might interfere with the absorption of trace metals such as zinc. In certain cases, iron supplementation might increase the expansion of the red blood cell mass to the extent that the increased viscosity of the blood is an additional risk factor (Haram et al 2001).

Recommended prescribing

- Obtain complete blood count and ferritin levels (iron studies include ferritin level).
- Ensure diagnosis is iron deficiency anaemia and no other pathology.
- If haemoglobin level is < 90, referral to an obstetrician is indicated.
- If ferritin is low (e.g. 12–20 µg/L), a woman might require approximately 60 mg elemental iron per day in supplement, depending on her diet and gestation.
- If ferritin is less than 12 µg/L and diet is low in haem iron, consider prescribing a higher dose of iron supplement (e.g. up to 105 mg of elemental iron supplement per day).
- Midwives need to check the amount of elemental iron in iron preparations as this can vary substantially between products. The amount of elemental iron affects the number of tablet/s prescribed.
- The amount of ferrous iron (ferrous salts: sulfate, gluconate, fumerate and succinate) absorbed is about three times greater than that of iron in the ferric form (Engstrom & Sittler 1994).
- Midwives need to consider the cost of iron supplements in partnership with the woman, provide sound education on the rationale for use and ensure safe storage from children.
- Adding vitamins to iron generally increases the cost of the supplement. One study of 371 women, undertaken by Juarez-Vazquez et al (2002) showed that iron plus folate therapy gave a better increase in Hb, particularly for women with severe anaemia.
- Assess full blood count and ferritin level within four weeks of commencing therapy.
- If the woman requires intramuscular iron therapy (due to low haemoglobin and lack of compliance with oral iron therapy), an obstetrician should prescribe this. Iron injections can cause staining of the skin and should be administered according to the manufacturer's instructions.
- Intravenous iron therapy requires administration in a specialist unit, where the woman is monitored for adverse reactions.

Clinical scenario

Haley works in the city as a sales representative, and was having her first baby. The following were her blood results:
Immediately pre-conception: Hb 120 g/L, MCV 86
At 28 weeks: Hb 110 g/L, MCV 85, ferritin 7 µg/L
Ferritin was ascertained with Haley's consent in view of her extreme tiredness. Haley spent a lot of time driving and tended to have quick meals. She was reluctant to eat cold meats because of concern about *Listeria* infection. Haley was advised to supplement 60 mg elemental iron per day if tolerated and try to increase haem iron intake in her diet. Note that the Hb and MCV above do not indicate any significant decrease, as Haley probably has 'latent iron deficiency'.
At 36 weeks: Hb 115 g/L, MCV 84, ferritin 18 µg/L
Haley had a caesarean birth after a long labour that was augmented with Syntocinon. Haley is a small woman and her baby weighed 4.5 kg.
At 41 weeks labour: Hb 112, MCV 84, PCV .34
At 2/7 after LSCS: Hb 87, MCV 84, PCV .26
At 3 weeks pp: Hb 117, MCV 84, PCV .36, ferritin 30 µg/L
The blood loss at LSCS was documented as only being 500 mL with normal postpartum bleeding, yet there is a significant decrease in the haemoglobin and packed cell volume (PCV). Haley resumed iron therapy (60 mg elemental iron daily) from a week post partum (when she felt able to tolerate iron tablets). Blood tests were taken at three weeks after the birth. The increase in Hb and PCV (haematocrit) shows that iron therapy was effective.

Antacids

Gastroesophageal reflux is a common occurrence during pregnancy. Reflux generally bothers up to two-thirds of pregnant women by the third trimester (Tytgat et al 2003). Reflux is aggravated by spicy or greasy foods, tomatoes, acidic products and carbonated drinks. If dietary changes do not solve reflux, calcium- or magnesium-based antacids, which neutralise stomach acids, can be used during pregnancy. High-dose aluminium-containing antacids are not generally recommended due to common side-effects of constipation and altered gastrointestinal (GI) motility (Tytgat et al 2003). Combination antacids have been formulated to reduce the risk of diarrhoea or constipation. Alginic acid forms viscous cohesive foam, preventing reflux by increasing adherence of

mucus. Simethicone disperses and prevents the formation of mucous gas pockets in the GI tract, relieving flatulence (Bryant et al 2003). Antacids can bind with other medications and therefore should be taken at least an hour apart from iron preparation and other medicines. Histamine-2 receptor antagonists are also safe during pregnancy and include cimetidine and ranitidine. The latter tend to be drugs of choice prior to Caesarean birth.

Recommended prescribing

- Ensure that there is no other pathology and be aware that heartburn can mimic epigastric pain associated with pre-eclampsia. Always consider the woman's blood pressure.
- Try to encourage the woman to alter her dietary habits in the first instance before resorting to antacids.
- If reflux continues to be troublesome, advise or prescribe antacid. Recommended dose depends on which preparation is given.
- Sodium alginate: oral liquid 55 mg with sodium bicarbonate 267 mg per 10 mL (Gaviscon). Dose 10–20 mL up to four times (maximum) a day after meals and 30 minutes before bedtime.
- Simethisone: oral liquid aluminium hydroxide 200 mg with magnesium hydroxide 200 mg and activated simethicone 20 mg per 5 mL (Mylanta P).

Thrush (candidiasis or moniliasis)

Vaginal thrush is a common complaint of women and increases in prevalence during pregnancy due to changes in the vaginal flora. Predisposing factors include a recent course of antibiotics (which reduces the vaginal lactobacilli count, rendering a woman more susceptible to overgrowth of the yeast), diabetes, HIV infection, anaemia and urinary tract infection. Young and Jewell (2001) revealed that imidazole drugs (clotrimazole, miconazole) are more effective than nystatin for treating vaginal candidiasis in pregnancy. Young and Jewell also recommend treatment for a seven-day period during pregnancy (clotrimazole preparations are generally packaged for six nightly applications and this should suffice). Single-dose treatments (and four-day treatments) were shown to be less effective during pregnancy when assessed by culture and symptoms (Young & Jewell 2001). Shorter courses of antifungal therapy are stronger: 10% cream for a one-night treatment compared with 1% for the six-night course, so women are more likely to experience burning and irritation with the stronger preparations. It is possible that shorter-course treatments might contribute to non-*albicans* species such as *Candida glabrata* and *C. tropicalis*. Traditional therapy of imidazoles does not adequately treat non-*albicans* species, hence the rationale for culture of a vaginal swab (Andrist 2001). Oral antifungals are not considered safe during pregnancy (Morgan 2000). The primary mode of action of clotrimazole appears to be on the cell membrane of the fungi, damaging the permeability barrier (*New Ethicals Compendium* 2000).

There is sufficient cream in the vaginal application pack to enable women to apply cream to the vulva twice a day. Education regarding careful insertion of the applicator should be discussed, as well as hygiene to decrease the risk of re-infection. There is no evidence that treating a male sexual partner makes any difference to this episode or future episodes unless the partner already has symptoms. Douching washes out lactobacilli as well as *Candida*. Studies have shown increased pelvic infection rates after douching, so this is not a suitable treatment, particularly in pregnancy. Salt baths are helpful in reducing itching and swelling in the acute phase (Hunter & Roke 2002).

Recommended prescribing

- Treat only if the woman is symptomatic.
- While clotrimazole is classified as being safe during pregnancy, manufacturers recommend cautious use in the first trimester.
- It is advisable to confirm a suspected diagnosis with a high vaginal swab.
- Use clotrimazole or miconazole 1%. Insert applicator full of cream into vagina at bedtime for six (or seven) nights. There is sufficient cream to apply to vulva BD. Some women might prefer to use vaginal pessaries plus cream to treat the vulva.

Urinary tract infection

Urinary tract infection (UTI) is a common complication during pregnancy. Asymptomatic bacteriuria is prevalent in 5–10% of pregnant women, and almost a third of these women will develop symptomatic infection if left untreated. Acute pyelonephritis is associated with fetal morbidity and mortality (Chaliha & Stanton 2002). It is recommended that an uncontaminated mid-stream urine (MSU) be obtained from pregnant women around 12–16 weeks gestation to ascertain whether there is asymptomatic bacteriuria (Nicolle 2002). Women who have had previous UTIs often recognise the symptoms associated with a UTI and present early to their caregiver. Midwives should only prescribe for lower tract infections and refer to an obstetrician if there are any symptoms of pyelonephritis (pyrexia, loin pain) or if there are recurrent urinary infections during the pregnancy. If there are recurrent urinary infections (more than two) during the pregnancy, an obstetrician might recommend prophylactic antibiotics for the continuation of the pregnancy and/or renal investigations.

Recommended prescribing

- Diagnosis of UTI should only be made by careful assessment of symptoms and an uncontaminated MSU obtained *prior* to the commencement of any antibiotics.
- Antibiotics might need to be prescribed before laboratory results are available (if a woman is symptomatic). Microscopy of urine can occur quickly (in 1–2 hours if indicated as urgent); however, culture

of bacteria currently takes about 36 hours. If laboratory service is unavailable, urine dipstick can be done for white cells and nitrate.

- Microscopy associated with UTI generally shows a raised white count (epithelial cells should be nil or very low numbers in an uncontaminated specimen). Culture shows a high bacterial count and usually a single organism as opposed to mixed bacterial species. Consult with the local laboratory for parameters used and always consult with a microbiologist or an obstetrician if unsure how to interpret the laboratory findings (e.g. sterile pyuria).
- If a prescription for antibiotics is indicated, reassess the woman for any allergies or adverse reactions prior to prescribing.
- Consider local resistance to antibiotics and also consider microbiologist and/or obstetrician recommendations regarding first line drug of choice during pregnancy.
- Refer the woman if there are any symptoms associated with pyelonephritis or if the woman has had more than two UTIs in this pregnancy.
- Follow-up culture and sensitivity of original MSU, and alter antibiotics where indicated according to the bacteria isolated and sensitivity.
- Ensure the woman does a clean MSU 7–14 days after completing antibiotics to make certain that the infection has cleared.
- Treat women with asymptomatic bacteriuria with three-day regimen and screen monthly for UTI (Lang 2001).
- Antibiotics that can be used for UTI (not in order of preference):
  - nitrofurantoin 100 mg BD for three to five days for an uncomplicated UTI. Do not use urine alkalinisers during treatment with nitrofurantoin, as this drug requires an acidic urinary pH to work effectively. Do not use in women with G6PD deficiency or when labour is imminent. Side-effects: GI.
  - amoxycillin/clavulanic acid 625 mg TDS for three days. Side-effects: possible candidiasis.
  - cefaclor 250–500 mg q 6 hr for three days. Oral cephalosporins should not be first choice for community-acquired UTIs (Lang 2001; Nicolle 2002).

Sexually transmitted infections

New Zealand midwives are legally able to prescribe for women during the antenatal, intrapartum and postnatal period. The legislation does not allow prescribing for any partners. Hence decisions need to be made with the woman concerning screening for sexually transmitted infections (STIs) and the rationale for eradication of any infections. If a woman returns a positive *Chlamydia* or gonorrhoea swab, a discussion needs to occur regarding the importance of treatment to avoid risk of pelvic inflammatory disease, preterm labour and stillbirth (Gencay et al 2000; Say 2004). In cases of STIs, all sexual partners require simultaneous treatment. Some sexually acquired infections can be asymptomatic and might be present but undetected for a number of years. *Chlamydia* screening during pregnancy generally includes a urethral swab and a cervical swab (Say 2004). Urine screening for *Chlamydia* and self-administered swabs are still being evaluated for efficacy.

Recommended prescribing

- *Chlamydia* (partners require treatment simultaneously for all STIs):
  - Erythromycin ethylsuccinate 800 mg BD for 7–10 days.
  - Specialist doctors are currently using azithromycin 1 g orally stat. At the time of print, azithromycin is listed as Category B by the FDA.
- *Trichomoniasis*:
  - Metronidazole 200 mg TDS for seven days.
  - A longer course is more effective in pregnancy than stat doses.
- *Gonorrhoea*: current recommendations are to refer all women with gonorrhoea in pregnancy to an STI specialist in view of bacterial resistant patterns associated with treating gonorrhoea. Say (2004) recommends that all patients with gonorrhoea be treated for incubating *Chlamydia* infections at the same time.
- *Human immune-deficiency virus (HIV)*: there is currently debate as to whether HIV serology screening should be optional or routine screening during pregnancy.[1] Formal counselling prior to HIV screening is available in some areas. Treatment regimens continue to develop and antenatal therapy clearly reduces the maternal–fetal transfer of HIV. This information should be shared with women when screening is discussed.

Mastitis

The importance of good assessment skills is paramount in detecting and managing mastitis. Continuity of care and regular postnatal visits will assist the woman and the midwife to problem solve most situations related to mastitis. Complementary remedies are used by a number of women; however, these remedies lack formal evidence and are therefore at the woman's discretion. Symptoms of mastitis include 'flu-like' symptoms, sore breast with reluctance to breastfeed from that breast and possibly a firm red wedge area on the breast. Redness of the breast might not be visible until 12 or more hours after the 'flu-like' symptoms in a deep tissue breast infection. Mastitis frequently originates from a previous sore or cracked nipple. If rapid response to conservative management does not occur, treatment with antibiotics is warranted.

Recommended prescribing

- Undertake a full physical assessment of the woman, including temperature and pulse to exclude other pathology.
- Check for penicillin-related allergy.

- Flucoxacillin 500 mg QID either one-hour prior to food or two hours after food for 10–14 days (10 days is usual treatment, but 14 days might be required if recurrent mastitis).
- Rationale for flucloxacillin is to use the narrowest-spectrum antimicrobial for the pathogen. *Staphylococcus aureus* is the most common cause of mastitis, entering through a cracked or damaged nipple, and > 98% of *S. aureus* are currently susceptible to flucloxacillin. Risk factors for flucloxacillin-induced liver injury include treatment greater than 14 days, high doses, and female gender (Begg 2001).
- Dicloxacillin is an alternative to flucloxacillin (if funded) and has less risk of hepatic reaction than flucloxacillin. However, it appears to have a greater risk of interstitial nephritis.
- Amoxicillin-clavulanate and cefaclor are broader-spectrum antimicrobials and therefore have more side-effects such as diarrhoea and candidiasis. The use of these might encourage resistant organisms. First-generation cephalosporins could be used depending on restrictions such as hospital-only medicines and funding restrictions. Cefaclor is not recommended, as noted previously, because of its broader spectrum of activity and concerns about serum sickness (Begg 2001).
- If the woman is penicillin-allergic and has safely taken erythromycin previously, prescribe 400 mg erythromycin QID or 800 mg BD for 10–14 days.
- Follow up to ensure that the woman breastfeeds from the affected breast (to prevent a breast abscess). There should be notable improvement within 24 hours; if not, refer to a colleague (midwife or doctor) experienced in the management of mastitis. The woman might require intravenous antibiotics to combat severe infection, or require an incision or aspiration to remove large amounts of pus within blocked ducts.

Endometritis

Endometritis occurs more commonly after caesarean births than vaginal births. The infection may be early (two to three days post partum) or late (three to six weeks post partum) (Chaim et al 2003). This can be caused by a number of pathogens, including odourless bacteria such as Group B Streptococcus. The midwife needs to have a low threshold for consultation regarding any woman suspected of having endometritis, in view of possible systemic infection. Reporting of elevated temperature is essential and the New Zealand referral guidelines indicate consultation with an obstetrician when the woman's temperature is > 37.6°C with tachycardia.

Prescribing should be in consultation with an obstetric specialist. If fever is present, an obstetrician might prescribe intravenous antimicrobials. A cervical swab should be cultured to isolate the causative organism(s). Oral amoxicillin/clavulanic acid 625 mg TDS for five to seven days could be prescribed for women who are not pyrexic with abdominal tenderness and/or foul-smelling lochia (Chaim et al 2003). If the woman is penicillin-allergic, consider erythromycin in consultation with an obstetrician.

BOX 29.4 Prescription guidelines

To ensure accurate prescription of a pharmaceutical medicine:

- Use accurate physical examination and diagnostic skills.
- Consider whether a pharmaceutical is appropriate for the condition.
- Have comprehensive knowledge of 'commonly' used drugs, including action/effect, and communicate this information to the woman.
- Ensure that the treatment is regarded as safe during pregnancy or during lactation.
- Consider the evidence in relation to the clinical scenario.
- Prescribe the appropriate drug, dose, frequency and duration of treatment.
- Monitor for any adverse reactions and refer accordingly.
- Do follow-up culture and sensitivity and alter drug if necessary.
- Be able to research information about drugs used less commonly.
- Have a low threshold for consultation with an obstetrician or general medical practitioner.

(Source: adapted from Banning 2004 and Lethard 2001)

Lower-segment caesarean section wound infection

In view of rising caesarean rates and shorter postnatal stays, midwives are increasingly monitoring women in the community for wound infections. Prescribing for wound infections should be discussed with an obstetrician, as it is outside the scope of midwifery practice. Clean the wound site prior to collecting a swab. Be vigilant at following up culture and sensitivity of the wound swab.

Postpartum contraception

Lactational amenorrhoea provides reasonable contraceptive efficacy in the first six months, provided the criteria of amenorrhoea (after 56 days post partum) and exclusive breastfeeding are met. However, many women want to add a pharmaceutical method such as the progestogen-only pill for extra protection. Lactational amenorrhoea is generally not a reliable method of family planning in Western countries (Stables & Rankin 2005).

Progestogen-only pill

The progestogen-only pill (POP) has 96–97% efficacy, depending on compliance, and is frequently chosen as an

oestrogen-free contraceptive method post partum. POPs do not reduce the milk volume for lactating women (Perheentupa et al 2003) and minute amounts of the POP pass through the breast milk to the baby, according to studies done on norethisterone- and levonorgestrel-containing POPs (Guillebaud 2004). The POP, as with most other medicines, is metabolised by the liver. The most important mode of action is increased viscosity of cervical mucus, making sperm transport less favourable. Anovulation occurs in approximately 60% of women, but varies in each woman's cycle and between women, with older women more likely to experience anovulation. The variations in menstrual bleeding, from amenorrhoea to women experiencing regular menstrual cycles, are related to ovarian activity. The POP also decreases the receptivity of the endometrium and alters tubal motility (Guillebaud 2004). Perheentupa et al (2003) concluded that the POP contraceptive effect is due to local action of the POP on the endometrium and cervix, and that it is breastfeeding itself that suppresses the ovarian function.

As with any medicine, midwives should not prescribe the POP to any women with altered liver function. The POP is affected by enzyme-inducing drugs such as some anticonvulsants and rifampicin. Women taking medication should have a consultation with a medical practitioner in order to assess drug interactions and to ensure safe prescribing. Other contraindications include arterial disease (including hypertension BP > 140/90), abnormal lipids, any cancers, trophoblastic disease, pathological changes in nervous or muscle tissue, previous ectopic pregnancy, functional ovarian cysts (as these appear increasingly with use of the POP) and undiagnosed irregular menstrual bleeding (Guillebaud 2004). The World Health Organization has deemed the POP an acceptable contraceptive method for use in women with a history of venous thrombosis, pulmonary embolus, diabetes and obesity (Apgar & Greenberg 2000); however, all these conditions warrant a decision by a medical practitioner as opposed to a midwife prescriber.

Prescribing recommendations

- It is prudent to reassess the woman carefully concerning her history, and to document this discussion.
- Record the woman's blood pressure and document.
- There is increased likelihood of irregular bleeding if the POP is started before day 21 post partum. If the woman chooses, she could start the POP at six weeks post partum to lessen any exposure of the newborn to the POP (Guillebaud 2004).
- Provide sound education on the POP. A pill needs to be taken every day of the month within three hours of the same time each day (there are no inactive/sugar pills in POP packages, unlike some combined oral contraceptives).
- If a POP is 'missed'—considered as > 12 hours late if the woman is breastfeeding and has amenorrhoea (Szarewski & Guillebaud 2000), otherwise > 3 hours late—then the woman should either abstain from sexual intercourse or use a barrier method of contraception for 48 hours until viscous cervical mucus re-establishes (Apgar & Greenberg 2000).
- Antimicrobials do not affect the POP unless they are enzyme-inducing drugs (oestrogen is recycled in the entero-hepatic cycle, not progestogen) such as rifampicin for tuberculosis and griseofulvin used for fungal infections of the skin and nails (Szarewski & Guillebaud 2000).
- Counselling should be given regarding symptoms of ectopic pregnancy and functional ovarian cysts. The woman should be informed of the possibility of irregular bleeding.
- Do not write 'mini pill' on the prescription form, as the pharmacist might interpret this as a low-dose combined oral contraceptive pill.
- Brand names are acceptable on the prescription form. Check which brands are fully subsidised, to minimise cost to the woman.
- Some brands of POP include: ethynodial acetate (Femulen®); norethisterone (Noriday 28®), levonorgestrel (Microval/Microlut®).

Combined oral contraceptive

Some non-lactating women elect to use the combined oral contraceptive (COC) as their choice of contraception in the immediate postpartum period. Bryant and colleagues (2003) detail the actions of the COC containing oestrogen and progestogen. It appears that oestrogen decreases FSH release, thus impairing follicle development and reducing the likelihood of ovulation. Progestogen reduces the LH release necessary for 'triggering' ovulation, along with effects on the cervix and tubal motility. In contrast to the POP, the main action of the COC is suppression of ovulation.

COCs have been associated with venous thromboembolism (VTE) and fatal pulmonary embolism. O'Brien (1999) commented that four well-designed studies that reported an increased risk of VTE with 'third-generation' pills had been subjected to relentless criticism. O'Brien concluded that in a $3 billion world contraceptive market the stakes are high, yet on evidence the second-generation COCs should be the first choice of pill when prescribing. Factor V Leiden mutation might also contribute to VTE and is reported as the most common genetic risk factor. Vandenbrouchke and colleagues (1996) have suggested screening women who use COCs for this characteristic (referral to a doctor would be necessary).

Parkin and colleagues (2000) reviewed fatal pulmonary embolism in all New Zealand women of childbearing age from 1990 to 1998. Third-generation oral contraceptive pills containing the newer type progestogen, desogestrel and gestodene (purported to have less androgenic effects), were the most commonly used COC by the women who died. Skegg (2000) concluded that women taking third-generation (desogestrel or gestodene) COCs have about twice the risk of

Clinical point

The dose of oestrogen in the COC is kept as low as is compatible with clinical effectiveness in order to reduce the possibility of adverse effects. However, because of the high hepatic first pass, a significant percentage of molecules travel around the entero-hepatic cycle before reaching the general circulation. If a woman takes antibiotics while on the COC, the resulting lack of intestinal bacteria can reduce the amount of oestrogen that is de-conjugated in the intestine and thus available for reabsorption into the circulation. The resulting lowered blood levels can fall into the sub-therapeutic range, exposing the woman to the possibility of conceiving (Galbraith et al 2001).

VTE of women using preparations containing levonorgestrel (second-generation COC).

Prescribing recommendations

- Check thoroughly for history that would preclude midwifery prescribing of COC (e.g. past or present circulatory disease in the woman or in her family history, disease of the liver, conditions affected by sex steroids, possible pregnancy, undiagnosed genital tract bleeding, any cancers, hypertension, smokers over 35 years of age, immobilisation, use of other medication, breastfeeding, etc) (Guillebaud 2004).
- Document the investigation of risk factors and record the woman's blood pressure.
- Do not prescribe the COC prior to 21 days post partum. After 21 days post partum there is a lower risk of thrombosis, as blood-clotting factors have returned to normal levels. The earliest fertile ovulation after a full-term pregnancy was shown biochemically to be 28 days post partum in non-lactating women (Guillebaud 2004). Hence a start on day 21 post partum allows seven days to suppress follicular activity.
- Document whether or not the woman has used the COC previously and any effects related to previous use.
- Prescribe a second-generation COC with ethinyloestradiol of 30–35 μg or less, combined with levonorgestrel or norethisterone.
- It is acceptable to use a 'brand' name on the prescription. Ensure that the 'brand' selected is subsidised.
- Provide the woman with advice for taking the COC and information if a pill is 'missed' (> 12 hours late) (family planning brochures are useful).

Injectable progestogen contraceptive

The primary action of the progestogen dose given by injection is to suppress ovulation. There is a much higher dose level initially, which then declines. It is essential that the injection site is intramuscular and is *not* massaged, as this shortens the duration of action. Guillebaud (2004) recommends that postpartum women preferably receive a first injection at 5–6 weeks post partum, as earlier administration increases the likelihood of heavy and prolonged bleeding. Lactation is not inhibited by the use of injectable progestogen. There have been isolated cases of anaphylactic reactions after injection of progestogens. It is prudent practice to administer the injection in a setting where adult adrenaline and resuscitation facilities are available.

Critical thinking exercise

1. How will you decide whether a woman requires antibiotics to treat mastitis or whether to consider conservative management initially?
2. Explore the research findings on the contraceptive efficacy of lactational amenorrhoea. Why do you think lactational amenorrhoea is 'under-used' by Western postpartum women?
3. Discuss how you would explain to a woman the pathophysiology of VTE in association with particular types of combined contraceptive pills.
4. Differentiate the signs and symptoms associated with each of the following vaginal infections: candidiasis, trichomoniasis, chlamydia and gonorrhoea.
5. Discuss the 'pros and cons' of injectable progestogens and the information that you would share with women who might be considering this method of contraception post partum.

Rules for writing prescriptions

There is no formulary list for New Zealand midwives. Midwives are expected to prescribe within their scope of practice. Prescriptions must conform to the requirements of Regulation 41, Medicines Regulations 1984 (Amendment No. 3 1990):

> 41 – Form of prescription – Every prescription shall (a) be legibly and indelibly printed: and (b) be signed personally by the prescriber with his [her] usual signature (not being a facsimile or other stamp) and dated; and (c) set out the address of the prescriber.

Prescriptions can be made on individual client prescription form, hospital medication order charts, and women's notes for midwife administration of drugs at a home birth.

Specific rules

Individual prescription forms must include:

- *prescriber information*—name, address and contactable

telephone number, designation (i.e. registered midwife), Midwifery Council Annual Practising Certificate number, signature, date of writing prescription
- *client information*—client's title, full name (include middle name or initial), residential address (PO box number is not sufficient), date of birth (if under 13 years)
- *medication information* (use one box on the prescription form per medication)
- name of drug, strength of preparation (e.g. 250 mg), dose, frequency of dose, route of administration, instructions for administration (e.g. before food), quantity dispensed or period prescribed for. Strike out any unused medication boxes.
- *prescription codes*—codes serve an administrative function to enable batching of prescriptions and payment to pharmacists. They are altered periodically. Midwives should ensure that they use the current codes.

Only use established abbreviations that have clear meaning to pharmacists. Writing instructions in full might prevent any miscommunication.

Conclusion

In this chapter an overview of pharmacology has been provided in order to assist student midwives with revision of pharmacology and the physiological changes during pregnancy. Antimicrobials that are commonly used for conditions experienced during pregnancy and childbirth have been reviewed. Specific pregnancy-related conditions have been discussed in association with evidence-based practice in relation to assessment, diagnosis and treatment. The authors stress the need for midwives to maintain a current knowledge base of pharmacology and pharmaceuticals. Midwives need to have a low threshold for referral and to only prescribe medicines within the scope of midwifery practice and legislation. Midwives need to have particular concern for the wellbeing of the woman and baby, and consider the effects of pharmaceuticals upon the maternal–infant dyad. Midwives also have a responsibility to encourage women and families to maintain optimal lifestyles and to minimise the use of antibiotics. Finally, if midwives do undertake prescription of medicines, accuracy of the prescription and follow-up of the client are essential for best midwifery practice.

Review questions

1. How does the Australian Categorisation of Drugs and Safety during pregnancy assist midwives in safe prescribing practices?
2. What conditions (occurring during pregnancy or pre-existing conditions) might affect liver function and therefore preclude the prescription of medicines by midwives?
3. Explain the physiological changes that take place during normal pregnancy and how these might affect pharmacokinetics.
4. Explain bacterial resistance in relation to urinary tract infection and the implications this has for prescribing practice.
5. List five principles that prescribers can employ to help minimise bacterial resistance.
6. How would you decide whether to treat a pregnant woman with a suspected urinary tract infection or to wait for the availability of laboratory findings?
7. What factors would you consider in deciding (in partnership with the woman) whether or not to commence iron supplementation during pregnancy?
8. How would you respond if a pregnant woman's partner asked you to write a prescription for his/her own personal needs?
9. Review all the assessments that you would undertake prior to prescribing a postpartum woman the progestogen-only pill.
10. What sources will you need to use/access in order to maintain your current knowledge to enable safe prescribing practice as a midwife?

Note

1 In March 2006 the New Zealand Ministry of Health introduced routine antenatal screening of pregnant women for HIV. Midwives need to be aware of their responsibilities in relation to routine screening.

cervical screening, closure, cultural health, debrief, documentation, Edinburgh Postnatal Depression Scale, emotional health, family planning/contraception, informed choice, physical health, professional friendship, referral, sexual health, six-week development, social health, spiritual health, Standards Review, support services, vaccination, well baby, well woman

Chapter overview

This chapter outlines a model final assessment by the midwife, of the woman and her baby. This assessment ordinarily includes: modified physical assessments of both mother and baby; a final review of the mother's mental wellbeing; contraception needs/choices; cervical screening; referral to well child and well woman providers; and a final debriefing of the maternity experience and reflection on care. The chapter concludes with final documentation requirements and an indication of the role of subsequent midwifery Standards Review process.

Learning outcomes

Learning outcomes for this chapter are:

1. To explain the importance of a thorough physical, mental and social assessment of the woman and baby before transfer from the maternity carer to well woman / well child carers
2. To establish what constitutes normal six-week or four-week developments for the woman/family and for the baby
3. To identify what should be conveyed in referral notes to these carers and what may require earlier referral
4. To discuss the methods of family planning appropriate for the woman and her partner, and the provision of information and advice, and ordering/prescribing for a method within the norms and legislation of New Zealand and/or Australia, according to the woman's informed choice
5. To explain the requirements for documentation of the completion of care and safe, comfortable closure of the professional friendship with the woman and her family
6. To highlight the important aim of care in the puerperium to affirm the woman's self-esteem and confidence in independent parenting

The woman's health

The midwife's approach to the final assessment should be a holistic one, seeking information on the woman's current health status and following up on issues that have arisen in the previous six weeks (e.g. with regard to the woman's physical health). Recent literature draws attention to the following physical symptoms at six weeks that are typically played down by postpartum women: backache; perineal pain (whether or not there is a healing wound); urinary incontinence; sexual problems; haemorrhoids; constipation; faecal incontinence; headaches; fatigue; recovery from infection (of, for example, a caesarean wound or episiotomy wound) (Glazener et al 1995, cited in Symon et al 2003; MacArthur 1999).

It is most important to attend to outstanding social issues, such as: mobility, financial restraints, access to support services and new mothers' groups (e.g. La Leche League, Australian Breastfeeding Association, Ukaiko, locally organised new mothers' groups/playgroups for older siblings). Also consider issues such as whether the woman plans to return to work, and if so, how she will continue breastfeeding.

Those who plan to return to work or study prior to their baby reaching six months may well need advice and support to continue exclusively or fully breastfeeding. Hopefully, this issue will have arisen in discussion much earlier in your care than at the discharge check. Among the information the woman will require is an explanation of why it is important to continue breastfeeding until six months, and how to inform and gain the support of her employer—for example, the advantages of a family-friendly workplace include happier workers who take less time off due to baby illness. Figure 30.1 shows some options to discuss with women who intend to work and breastfeed. It is recommended that you discuss and leave clear written instructions regarding expressing milk, storage and hygiene. The women will also require local information on organisations specialising in breastfeeding support.

Emotional health

What does the woman notice about her mood? What does her partner/family/any significant other notice? What efforts does she make to leave the house and actively seek social contact?

The Edinburgh Postnatal Depression Scale (EPNDS) questionnaire has not been universally applauded as effective (Forman et al 2000; Shakespeare et al 2003). However, Barclay

Clinical scenario 1

You arrive at S's basement flat. She greets you with a warm smile and welcomes you in her mid-European accent. S is a recent immigrant, resident in your country through marriage, whose husband left her during the pregnancy. She is bringing up their daughter alone with the support of her husband's family, a wide circle of friends and intermittent contact from him. She has a thriving baby girl whom she is exclusively breastfeeding. Her labour and birth were spontaneous. Her perineum sustained a second-degree tear and was sutured. A summary of her postpartum recovery includes referral to a lactation consultant for training of her daughter to breastfeed, not nipple suck, as she left hospital doing. Also her perineum continued to cause discomfort without developing an infection requiring treatment. She has, however, reported improvement over the last two weekly visits at four and five weeks.

As S's midwife, summarise your discharge visit priorities.

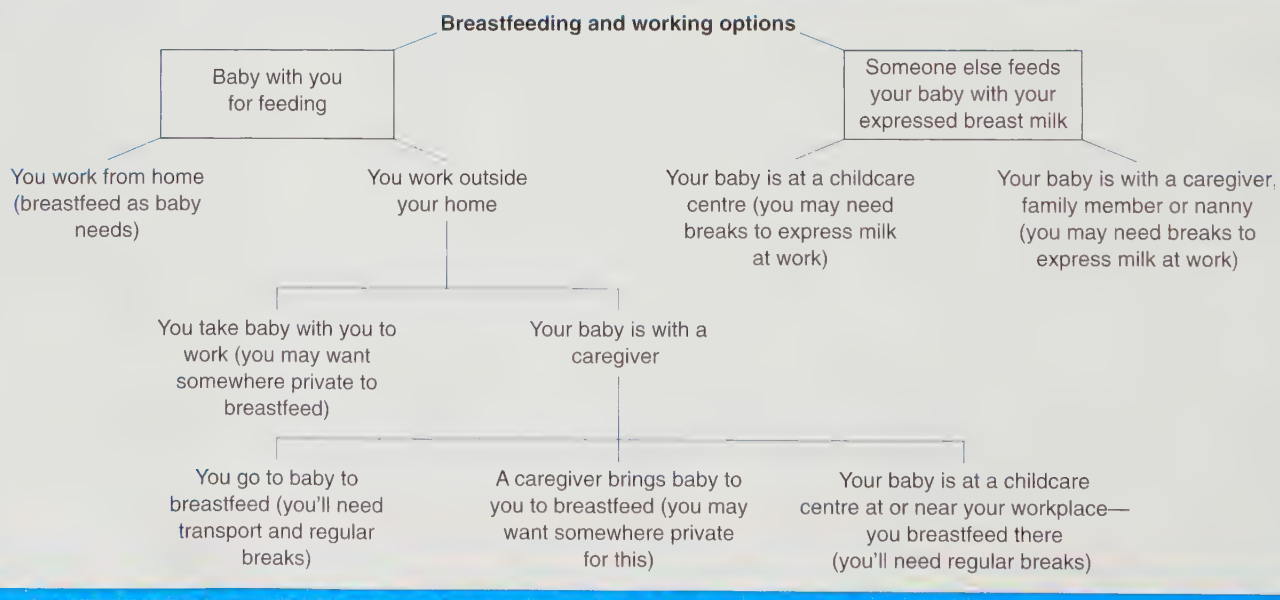

Figure 30.1 Options for working and breastfeeding (based on Ministry of Health 2001)

BOX 30.1 Support groups

Does the woman know what resources are available for support for postnatal distress? For example, the following website provides contact details of consumer mental health support groups in New Zealand: http://www.nzgg.org.nz/guidelines/0039/Appendix_8.pdf

and Lie (2004), after a chart review conducted by investigators from the University of Rochester School of Medicine in New York, reported that 'the EPNDS should be considered for use in screening for post partum depression (PPD) in the first year well-child visit setting. However, adequate quality control measures need to be in place for consistent implementation'. They also stated that 'the EPNDS results in higher rates of detection of maternal depression during the postpartum year' (Barclay & Lie 2004). This screening device is used by some New Zealand lead maternity carers to assess the need to refer with possible pathological postnatal distress/depression.

Spiritual health

Supporting the woman's spiritual needs requires a carefully accrued knowledge of the woman and her pregnancy, childbirth and early parenting journey (possible with LMC continuity of care), and actively listening to her reflections. Some women can articulate these clearly; others require gentle, persistent delving if the midwife detects spiritual pain. You might not feel qualified to support the woman in spiritual difficulty. Rather, your role might be to involve the woman's own spiritual guides through her family.

Sexual health

Many women may be reluctant to discuss sexual ill health fully with their midwife, even at six weeks. A midwife is expected to raise the topic: enquire about dyspareunia and impart the clear message (whether or not intercourse has resumed) that the woman does not need to tolerate any ongoing discomfort, and should seek help if she needs it. Sensitive questioning may help elicit other sexual health related concerns and lead to a discussion about lack of desire. Several factors such as a difficult birth, lochial discharge, tender, secreting breasts, sore nipples, altered physical appearance (some women may never have considered that their genitals would be permanently changed), or fear of becoming pregnant again, can combine to depress the woman's interest in intercourse. Breastfeeding also has an effect: 'Although there are some physiological similarities between sexual arousal and breastfeeding, erotic stimulation and/or orgasm do not usually accompany breastfeeding. The hormonal basis of breastfeeding usually causes the woman to "fall in love" with her baby, thereby ensuring that she will respond to its needs' (Auckland Homebirth Association 1993, p 139). Exhaustion, changes in libido, deterioration in general understanding and communication between the couple can all develop, whether or not there is discomfort. It is beginning to be understood that such difficulties are common (Dixon et al 2000; Force 2000).

Clinical scenario 2

C is a woman who, with her second pregnancy, approached you to be her labour and birth midwife on advice from her rural midwife LMC. She chose to birth at a secondary care birth facility. Her first labour was complicated by fetal distress and she vividly remembers travelling in second stage in an ambulance from a birthing unit to a secondary care maternity facility because of concern for the baby. The resulting tension and extreme discomfort guided her choice this time, to labour and birth some 90 minutes away from home, to avoid a possible repeat of the transfer in late first stage. Her (second) labour was spontaneous and she birthed normally without fetal distress—a second daughter. However, her perineal laceration, you determined, was beyond your skills to repair, and you sought advice and assistance from a senior registrar. He speedily repaired her wound, and she returned to her local primary facility for postpartum care and six-week assessment.

Five months later, she has phoned you, seeking your help in reviewing her perineal condition. She is experiencing severe dyspareunia, to the extent that sexual intercourse is impossible, and her marriage is under strain. She very much wants a third child.

1. What steps can you take within the system of referral in your area?
2. How does any lesson learned from such a scenario guide you in your approach to sexual function assessment in future six-week discharge visits?

Cultural health

Like spiritual health, cultural health is largely 'glanced off' in both societies. In New Zealand the tangata whenua (people of the land) have only recently asserted the clear principle of cultural safety among the healthcare spheres of New Zealand society (Ramsden 1993). The capacity of the LMC midwife to acknowledge a culture that may be different from the dominant culture yet clearly potentially influential on the health status of her client, is to be carefully nurtured. Both countries claim multicultural communities. However, in both, the dominant ethnic group has been Anglo-Saxon. This power imbalance between the groups requires constant vigilance in order not to abuse it.

At six weeks it is late in the day to begin assessment. Ideally the midwife will already have incorporated, within her holistic approach, attention to the language, customs, culturally sensitive aspects and safety measures relevant to her client and the family. These efforts will enable her now to seek valid

feedback from her client. A midwifery 'wisdom' developing in New Zealand, at least, is the appropriateness, or standard, of regarding each pregnant woman as having her own unique culture. It should be seen as one you will respect throughout the childbearing year (nine and a half to ten months) that you are alongside her.

Infant feeding

By six weeks most women have settled into the method and implementation of the feeding choice they have made for their baby. However, a small number of women may continue to have difficulty with breastfeeding and may require ongoing support. Consumer support groups such as the La Leche League can provide useful support to all breastfeeding women, whether they have experienced problems or not. It is helpful to put women in touch with such community support services. Family can also play an important role with ongoing support.

Some women will gain valuable support and advice from their well-child provider (such as a Plunket nurse or general practitioner) and it is important that your referral to this service provides appropriate information about the progress of infant feeding and any issues that may have arisen.

At the final examination it is important to find out how the woman feels the feeding is going and her reflections on the experience so far. The honest admiration you express of the thriving, smiling, healthy baby is invaluable and will leave a lasting, empowering impression on a first-time breastfeeding mother.

BOX 30.2 Breastfeeding resources

Is the woman aware of all the community-based breastfeeding resources available to her, such as:

- La Leche League (NZ)—provide information on breastfeeding, telephone counselling, and run breastfeeding support groups.
- Plunket Society (NZ)
- hospital and community lactation consultants
- Australian Breastfeeding Association.

Physical assessment

The six-week check is so-timed as it is known that the endometrium is fully healed by six weeks (Sweet 2000; Fraser & Cooper 2001). Ideally your timing management of this physical check for the mother will ensure that this is attended to some time prior to the baby waking/being woken. Much can be discussed during this one-to-one opportunity with the woman. Wider personal and public health information can be passed on (diet, exercise, smoking, cervical screening), and final questions asked, such as:

- Does she have any concerns regarding her breasts and nipples?
- If there is a caesarean scar and if she chooses midwife discharge assessment (as opposed to returning for an obstetrician clinic appointment), how well healed is this scar?

You should find the uterus completely involuted and not palpable abdominally.

- Has her bleeding stopped? In New Zealand, funding for a scan of the uterus to detect retained products is part of the LMC budget only until six weeks. Ongoing lochial discharge, suggestive of non-involuted uterus and some retention of membrane or other placental fragment, could be assessed at five weeks and an appropriate scan ordered with consent, to avoid the woman/couple sustaining the cost. However, recent studies suggest that ongoing loss up to 42 days is not unusual (Marchant et al 2002) and a decision regarding a scan may best be held over until 8 or 10 weeks and require general practitioner (GP) referral. Obviously the budget issue does not affect Australian midwives and

Clinical scenario 3

H and T conceived their twins by in vitro fertilisation. They live in a small town half an hour's drive out of the city. The twins were born by caesarean section at 38 weeks, as it appeared that the second twin, their son, was in distress on a routine growth scan. Both babies had good Apgars; the girl weighed 2740 g, the boy 2500 g. The girl's cord remnant swelled and oozed post partum and the boy developed mild physiological jaundice. H began by exclusively breastfeeding but the girl's failure to gain weight and show good urine output, together with H's exhaustion, meant that eventually she partially breastfed and partially bottle fed, until the twins were stronger. At home, the girl was mainly bottle fed, the boy mainly breastfed.

What are your discharge priorities and preparations for this family?

Clinical point

Continuity and perineal care

Among the continuity-of-care midwife's rarely noted but distinctive advantages in maintaining and improving good practice is the unique opportunity she has to gain insight in the way in which she looks after the woman's perineum. Such a midwife has the opportunity to follow up on the outcome of her care, and often more than once. In her recent review of midwives' approaches to care of the perineum, Wickham noted (while commenting on Lewis's study) that: 'midwives were able to reflect upon their practice in relation to the woman's experience, something which midwives working in systems without continuity of partnership are not often given the opportunity to do' (Wickham 2001, p S26). Those midwives were then able to alter their practice significantly.

Critical thinking exercise

Research and plan approaches to the following topics as part of your discharge visits:

- ongoing substance (including tobacco) abuse issues
- obesity
- exercise/relaxation needs.

advice by them to see the GP at the more reasonable time of eight weeks with ongoing, non-period bleeding would suffice.

- If there is bleeding, is it lochial or menstrual?

If there has been any perineal, vaginal wall or labial damage (sutured or not) the area should be assessed for degree of healing. Use a good light, and gloved hands. If she has not done so already, the woman should be encouraged to look in a mirror herself to know how differently her genital area now appears.

The question of dyspareunia is a natural one to arise now. The appropriateness of pelvic examination, cervical smear and vaginal swabbing to take place during this examination is dealt with elsewhere in this book. Do not overlook the state of the anus and the presence of haemorrhoids. Ask directly about faecal incontinence (O'Connell 1997).

Family violence screening

Family or domestic violence is a complex issue that spans all socio-economic strata. A recent study recommends that 'questions regarding abuse should be included in all clinical practices' (Hedin 2000, cited in MIDIRS 2000, p 366). New Zealand LMCs and Australian midwives who are trained to screen for family violence, screen women at booking and discharge.

Indicators of possible family violence are:

- repeated contact with health care practitioners (besides yourself) and hospitals for minor injuries or nonexistent complaints
- constant presence of partner at all your visits, who intervenes to answer your queries for the woman
- making light of bruising
- repeated non-compliance with advice or prescribed treatment.

The baby's health

As you assess baby, note her or his social development and how the mother/parents relate to the baby—that is, continue your assessment of the holistic health of the mother as you interact with the baby. You should also seek and flag any ongoing information needs, including what developments would cause the mother to seek medical attention.

BOX 30.3 Family violence

- Do you know the process of documenting your concerns and conveying them to the appropriate agency?
- Does your College of Midwives have Best Practice Guidelines for your response in these situations?
- NZ midwives can view the NZCOM Consensus Statement on family violence screening at: www.midwife.org.nz/content/documents/93/family%20violence.2002.doc

BOX 30.4 Child sickness danger signals

Is the mother aware of the list of child sickness danger signals detailed on the back cover of the *Well Child Tamariki Ora Health Book* (in New Zealand) and similar publications in Australia? (See the online resources list.)

Feeding and behaviour patterns

Breastfeeding

Questions to ask:

- Is breastfeeding going as well as the woman expects?
- Is the baby having yellow, paste-consistency stools?
- How many wet napkins are there in 24 hours?
- How long is the baby's longest sleep?

There might be no discernible pattern yet to the baby's sleeping and feeding behaviour. This may or may not be a concern for the mother/parents. Stress how normal it is for there to be no pattern despite popular expectations of babies quickly establishing a routine of sleeping and feeding (Gainsford 1999). Fatigue will generally be the outstanding physical symptom for the mother, and it is not too late to discuss ways in which she can manage her sleep/rest needs.

Combined breast and bottle feeding

Enquire about the balance between the two and whether the mother is satisfied. Is she aiming to achieve exclusive breastfeeding? Or is there evidence that her supply is reducing—artificial milk being used increasingly—and if so, is this of concern to her? Your goal is to enable satisfaction with her chosen method of feeding her baby; the secure emotional bond between mother and baby is a priority over the ideal of exclusive breastfeeding. Check that she has some understanding of the quantity of milk needed in 24 hours as the baby matures.

Artificial feeding

If the woman began by this method, it is important to review the amounts and the implications. If she began by breastfeeding, this is a time to touch on that experience and debrief, with her consent and readiness.

Behaviour

At six weeks many babies are typically midway through a gut maturation, which they generally achieve by 12 weeks

(anecdotal evidence conforms with the author's 15-year experience; see also Viccars 1998). This manifests as distress, described by the parents as a combination of pain and tiredness, to a greater or lesser degree, usually late afternoon/evening. The parents typically report 'difficulty' with winding the baby, and a perceived reluctance by the baby to settle. This does not affect all babies. There is little a midwife can add to the resolution of this phase (ibid) but an ability to listen to the impact this has on their enjoyment of parenthood, and conveying a confidence-boosting prediction that it will normally resolve around the three-month mark. In New Zealand, a group of remedies has been suggested, but none of these, apart from removing dairy products from the maternal diet, has been researched adequately. The challenge is to distinguish, clinically, between the popular diagnoses of 'colic' and 'reflux', and the actual development of true colic and reflux. These conditions do, of course, happen, but to a far lesser extent than is reported or investigated. There is some suggestion of an ethnic basis—such 'colicky' episodes are reported less frequently by Polynesian and Aboriginal mothers/parents.

The baby's sleeping patterns may require a review of feeding or may provide some insight into the degree of the mother's postnatal distress (Greig & Sahar 1999).

Developmental assessment

The outstanding milestone at six weeks is the social smile. The majority of babies developing normally, by this age, have learned to smile directly in response to the other person smiling at them.

Full physical examination

New Zealand midwife LMCs are qualified to carry out the first three well baby checks of the eight laid down by the Department of Health, to track the child's wellbeing up until the age of five years (that is, the physical examination carried out in the baby's first 24 hours, at five to seven days of age, and at the six-week discharge visit).

Before carrying out the examination, take some care to optimise the environment. You will need to set aside an hour to 90 minutes to complete this visit unhurriedly. Ideally it will be timed as closely as possible to a loosely predictable awake time for the baby. The location should be warm and well lit. Take care to anticipate that the baby may spill, void or defecate. Assemble your equipment out of range of audience siblings, unless it has been your approach to share your less expensive, more robust items of gear with curious other children, who respond to being involved and experimenting with the instruments (and subsequently can usually be relied upon to lose interest!)—much better than when these are forbidden. Within your personal safety boundaries, at all times reinforce the discipline approach of the parents.

Engage with the baby, who ideally has had part or all of a feed, and is not unsettled or preoccupied. Note any findings if you doubt they are normal. You will develop your own style of examining; some find it useful to work methodically from 'top to toe'.

- Measure head circumference—assess contour of scalp, palpate suture lines, anterior fontanelle. Discuss this 'soft spot', how to accommodate it, and when it will close over (18 months).
- Examine the eyes with an auriscope for red reflex (both retinas).
- Observe whether the baby follows with her or his eyes as you move in front of the face. Ordinarily you will be chatting with the mother throughout the examination. Her observation of the baby 'following'—indeed, her observation of all the developments you are there to confirm—is naturally reaffirming of her unique expertise regarding her baby.
- Any pseudostrabismus? Explain, reassure, inform of regular monitoring/review.
- Examine the baby's mouth—there may be something you have overlooked in previous examinations, and you need to assess for thrush infection. Do not neglect the gums.
- Ears—ask the woman what she notices about the baby's reaction to loud noise. Any doubts about the baby's ability to hear have probably already been raised, and appropriate referral made. At this point you can remove baby's clothing down to singlet and nappy.
- Skin—as you work your way down the body of the baby, you are assessing health, integrity, colour, temperature and tone of skin and muscle. Openly inspect skin grooves and creases in the baby's body (behind the ears, neck, axillae and groin) for unavoidable moisture traps, which eventually may cause excoriations of the skin and possibly cellulitis.
- Examine the fingernails—are they healthy or is there some parenchyma?
- Auscultate the apex of the heart, preferably through a singlet. You are listening to confirm ongoing absence of murmur. Ideally any suspicion of irregularity has long ago been investigated by a paediatrician. You should also record the rate.
- Auscultate both lungs—listen just below collar bone on left and right, turn baby and listen just below the scapula bilaterally. Record respiratory rate. Remove singlet.
- Palpate the abdomen, remark on continuing breast swelling, check for obvious masses, enlarged liver, discuss benign and also reportable 'lumps' (herniations).
- Assess healing of the umbilicus—is it dry, clean, erythematous? Is there any granuloma? Polyp? Explain ongoing hygiene of the area. Remove napkin. Be aware of the contents of the napkin—comment, give assessment.
- Palpate the femoral pulses—whether or not these have been felt or believed to be felt in earlier well baby checks.
- Baby boy—assess for bilateral descent of testes. Refer to GP if feel undescended on either/both side(s). Comment on normal colour changes of scrotum. Re-check normality of location of urethral opening/meatus. Discuss current approach to hands-off cleaning beneath meatus (Johnston 1994).
- Baby girl—reaffirm, re-educate regarding hygiene and

trust of natural self-cleaning mechanism of mucous membrane, which protects vagina and interior labial walls from infection.
- If baby sufficiently relaxed, check stability of hips.
- Turn baby onto stomach and follow the backbone to the sacrum—confirm no sinus, no dimple, assess symmetry of creases of legs held extended.
- Check for reflexes—Moro or startle (elicited if you hold the baby seated and allow to fall momentarily backward, and catch), stepping reflex etc.
- Any medications due (e.g. third oral dose vitamin K)?

Appendix A shows the six-week well baby check summary documentation as used in the *Well Child Tamariki Ora* book.

Vaccinations

'The purpose of vaccination is to induce protection (immunity) from subsequent disease, similar to that of natural infection, with minimal or no systemic symptoms' (MOH 2002a, pp 1–2). Immunisation is the state of successful vaccination (passive immunity), or of having been exposed to the illness (active immunity), so that the individual is no longer susceptible to the disease.

Health department policy

Free vaccinations are provided in New Zealand and Australia for all children under 16 years of age against: diphtheria, tetanus, pertussis, hepatitis B, *Haemophilus influenzae* type b, measles, mumps, rubella, polio, tuberculosis (for high-risk individuals and groups), and group B meningococcal disease.

Tables 30.1 and 30.2 show immunisation schedules in New Zealand and Australia.

Informed choice/consent issues

An independent midwife whose philosophy includes informed choice is presented with many difficulties when discussing vaccines and informed choice. She must set aside her personal bias, in guiding new parents who may never have considered the issues. Her choices are: to educate herself intensively on all the complex arguments; or to summarise and provide couples (who are serious about choice) with avenues of research for themselves to become informed independently.

Legal provisions that the New Zealand midwife needs to be aware of include: the *Health and Disabilities Commissioner's Act 1994*, the Code of Health and Disability Services Consumers' Rights 1996; and the *Privacy Act 1991*.

TABLE 30.1 Immunisation schedule, New Zealand

	Diphtheria tetanus acellular pertussis-inactivated polio vaccine	Hib (*Haemophilus influenzae* type b) hepatitis B[1] vaccine	Hepatitis B[1] vaccine	Inactivated polio vaccine	Measles mumps rubella vaccine	DTaP/Hib vaccine	Adult type tetanus diphtheria vaccine
	DTaP-IPV	Hib-HepB	HepB	IPV	MMR[2]	DTaP/Hib	Td[3]
Route	IM	IM	IM	SC	SC	IM	IM
6 weeks	DTaP-IPV	Hib-HepB					
3 months	DTaP-IPV	Hib-HepB					
5 months	DTaP-IPV		HepB				
15 months					MMR	DTaP/Hib	
4 years	DTaP-IPV				MMR		
11 years				IPV*			Td

*For children who have not received a fourth dose of polio vaccine

IM: intramuscular. SC: subcutaneous

BCG should be offered to babies who will be living in a household or family/whanau with a person with either current TB or a past history of TB; or have one or both parents who identify as being Pacific people; or have parents or household members who have within the last five years lived for a period of six months or longer in countries where there is a high incidence of TB; or will during their first five years be living for three months or longer in a high incidence country.

1 Babies of HBsAg positive mothers need HBIG and hepatitis B vaccine (5 µg) at birth; then continue with the usual schedule at six weeks, three months and five months,. Household and sexual contacts of hepatitis B cases and carriers should be offered hepatitis B immunisation.

2 Women of childbearing age who are susceptible to rubella should be offered MMR or rubella vaccine.

3 Boosters of Td should be offered at 45 and 65 years of age, and after some injuries.

TABLE 30.2 NHMRC standard childhood vaccination schedule for Australian babies, 2005

Age	Disease	Vaccine
2 months	diphtheria, tetanus & pertussis poliomyelitis *Haemophilus influenzae* b	DTPw triple antigen OPV Sabin vaccine HibTITER
4 months	diphtheria, tetanus & pertussis poliomyelitis *Haemophilus influenzae* b	DTPw triple antigen OPV Sabin vaccine HibTITER
6 months	diphtheria, tetanus & pertussis poliomyelitis *Haemophilus influenzae* b	DTPw triple antigen OPV Sabin vaccine HibTITER
12 months	measles, mumps & rubella	MMR Measles/mumps/rubella
18 months	diphtheria, tetanus & pertussis *Haemophilus influenzae* b	DTPa Infanrix HibTITER
4–5 years	diphtheria, tetanus & pertussis poliomyelitis	DTPa Infanrix OPV Sabin vaccine
10–16 years (Year 6)	measles, mumps & rubella hepatitis B	MMR Measles/mumps/rubella Hepatitis B vaccine (3 doses)
15 years or prior to leaving school (Year 10)	diphtheria & tetanus poliomyelitis	ADT adult diphtheria & tetanus OPV Sabin vaccine

Hepatitis B vaccine should be given in a schedule of birth, one and six months for:

- infants and children up to 10 years of age where the mother is a hepatitis B carrier.
- infants and children up to 10 years of age who belong to ethnic groups in which the hepatitis B carrier rate exceeds 2%. These groups are: individuals from all countries in Asia, Africa, Oceania, central and south America, eastern Europe and the Mediterranean region, and Aboriginal and Torres Strait Islander children. Children of Aboriginal or Torres Strait Islander background should receive PedvaxHIB at two, four and 12 months rather than HibTITER.

Advice for LMCs can also be found in such governmental publications as *Principles and Guidelines for Informed Choice and Consent for all Health Care Providers and Planners* (Department of Health, Wellington, May 1991) and *Consent in Children and Youth Health: Information for Practitioners* (Ministry of Health, Wellington, December 1998). One non-governmental source is the Australian Vaccination Network (http://www.avn.org.au), which provides advice for New Zealand and Australia.

Midwife's role

The midwife's role is confined to providing balanced information and response to parents' questions regarding vaccination and immunisation schedules, diseases, reactions (and how to manage these), varying the recommended schedules, ideal timing and support of babies undergoing first immunisations, evidence-based options and alternative approaches. There are advantages in restricting the administration of vaccines to a clinic or medical centre environment: such clinics are set up to deal with reactions, including anaphylaxis; and medical centre administrations are better placed to record batch numbers and run a recall system to ensure the regimen/schedule chosen by the parent(s) is completed.

Critical thinking exercise

Research the following questions, which are typically put by parents-to-be. Try to provide a balanced response to each.

1. What is vaccination?
2. Is there a difference between vaccination and immunisation?
3. Do vaccinations work?
4. Are vaccines safe?
5. What is in a vaccine?
6. Can I alter the routine schedule?
7. What does it cost?
8. What precautions should I take if I choose vaccinations?
9. What precautions should I take if I do not choose vaccinations?
10. My baby is premature—should I delay the vaccination schedule?
11. What if my baby has a reaction?

During the woman's pregnancy you will have had occasion to discuss immunisation/vaccination information. This aspect of child health is the subject of widespread MOH advertising, and usually new parents-to-be are conscious of the government recommendations. Often a query will arise from the woman during pregnancy.

In New Zealand, Section 88 makes specific reference to the expectation that government has of LMCs. Service specification and quality requirements 4.5 (Services following birth) includes: '4.5.2 provision of Ministry of Health information on immunisation' (MOH 2002b, p 14). For the current Australian schedule of immunisation, midwives are advised to go to the NHMRC website and search for immunisation.

Contraception and sexual function

The issue of resumption of intercourse, and the need for contraception, may have arisen prior to your discharge meeting. The resumption of intercourse following childbirth has no well-defined, socially acceptable, ideal timing. The prohibition on sex until six weeks post partum is mythical but may nevertheless be a useful boundary marker for some women. Two people's needs are involved, within a wide spectrum of maturing relationships and communication skills. It could be among the first things on the woman's mind, or the very last.

It has not been established that postpartum education about contraception is effective in the long term (Hiller et al 2004). However, a midwife is uniquely placed to assess contraception needs and offer advice, towards the latter part of the postnatal care period.

You may have raised the issue; or the woman may remark that she wonders what she should do about contraception. Or she may have already asked you to provide information on a specific form of contraception. Sometimes during pregnancy the woman discusses, and enquires about, the form of future contraception she intends to try.

A caseloading midwife offering total midwifery care, or full postnatal care, will encounter the full range of contraceptive needs. These can extend from caring for a teenager pregnant from her first experience of intercourse, who has never used contraception, to a woman who has tried all known methods, knows precisely her preferred method, or has never found any to be effective. The effective outcome of your family planning counselling time will depend upon the establishment over the weeks of pregnancy of a good partnership with clear and well-established communication channels. Your intuition, professionalism and comprehensive knowledge, and her trust, will promote her assertive control over her fertility to optimise her health, both physical and sexual.

The woman may be undecided about whether she wishes to have more children. Your partnership will help you decide on the right time to offer advice and stimulate some thinking to planning beyond this baby and the sometimes all-encompassing preoccupation with this baby. It is important to spend time making the right choice for her situation. The following quote nicely summarises your message and your part in the choice: 'Choosing contraception that is right for you requires accurate information as well as negotiation and communication skills. Issues like effectiveness, safety and freedom from adverse effects need to be weighed up against convenience, cost and issues of trust and control' (Better Health Channel 2005).

In New Zealand, midwives are licensed to prescribe progesterone-only medication and condoms.

Your role as midwife encompasses the following questions and responsibilities:

- Is your information on contraceptive methods up-to-date?
- Presumably you will be aware of her sexual orientation—but this issue is mentioned to alert you to the dangers of assuming incorrectly, and the importance of thorough data collection during the establishment of the partnership.
- Do you understand and can you convey the effect that exclusively breastfeeding/partially breastfeeding/artificially feeding has on the woman's fertility?
- What impact on contraceptive choice does her birth outcome—caesarean, normal, instrumental, major perineal damage, major postpartum haemorrhage—have?
- What sensitivities are posed by her religious and/or cultural beliefs? And what by her intellectual abilities and social support deficiencies?
- Was the baby conceived by in vitro fertilisation? If so, what constitutes sensitive advice in this situation?
- Does her medical history affect her contraceptive choice?
- If she is not in a relationship, should you make any assumption about her contraceptive needs?
- Are you counselling—discharging—this woman following a miscarriage?
- How does introduction of a hormone-based contraceptive interfere with vaginal discharge—the tapering off of lochial flow as the endometrium heals and the incidental bleeding provoked by the introduction of the pill/injection and the recognition of the first real period, so a cycle can begin to be charted?

When should contraception begin again?

If the woman is not, or is partially, breastfeeding, contraception needs to begin prior to the first ovulation following birth. Menses can begin as early as day 35 to day 40 post partum. Ovulation would have happened 12–16 days prior to this. Therefore the contraception method for women who have resumed intercourse must begin by day 21. If the method is hormone-based, a 14-day period of adjustment is required before that method can be deemed reliable. Alternative methods of contraception are needed in the interim.

A detailed description of contraceptive methods is given in Chapter 31.

Well child referral

The rationale for well child referral is to provide monitoring and assessment of normality and the earliest possible documentation and follow-up care for any deviation, from birth to school age.

Well child care in New Zealand began in 1907 with the Plunket Society (originally named the Society for Promoting the Health of Women and Children). Plunket nurses were specially trained to care for babies and children (Coney 1993). But access to the Society was restricted to white middle-class mothers. The health reforms of the 1980s and the setting up of a whare Hauora concept increased access to well child care for Polynesian women. The *Plunket Book* is now called the *Well Child Tamariki Ora Health Book*. The well child system—Plunket and whare Hauora—provides:

- a free well child/Tamariki Ora service
- home or clinic visits
- key public health concepts of supportive environments, disease prevention and health promotion
- clinical assessment, core screening, surveillance, education and support entitlements.

Both organisations are staffed by registered general and obstetric nurses, or registered comprehensive nurses who have met the competencies for child health as approved by New Zealand Nursing Council. In areas not supplied by family support workers (see below), the Plunket Society also provides a home-visiting service entitled 'Plunket Additional Care Contract'. Family support is a government-funded network of organisations specifically established to address the needs of disadvantaged families. These organisations operate in conjunction with Plunket and local iwi-run, well child services.

General practitioners, sometimes through their practice nurses, simply provide the eight free well child checks or clinical assessments. This constitutes the fourth option for well child referral by LMCs.

In Australia, the equivalent well child health system varies slightly from state to state. Child health nurses are government-paid, well child care providers. Women also use their GPs. The following websites provide useful information from each state and territory regarding the child services available in each area:

Midwife's role

The midwife's role is to explain the local choices of well child care provider. Ordinarily this should happen during third trimester. Ideally, discussion will have begun at the fourth decision point (i.e. at the 36-week assessment) (NZCOM 2005).

Regarding the timing of referral, within your assessment of the social, emotional and education needs of woman/family/whanau, which is ongoing and dynamic, you will have assessed the level of need for well child care. Additional care needs, if present, will guide you in referral, even antenatally, to a more intensive well child support system to cultivate a relationship and understanding between woman/whanau and well child carer during the pregnancy. Otherwise, for routine well child referral, the convention in New Zealand is at four weeks. An example of a well child referral form is shown in Appendix B.

Well woman referral

Integral to a midwife's understanding of her scope is a clear recognition of normal maternity-related issues for the woman/family and how these are to be distinguished from medical issues, unrelated or only indirectly related to the pregnancy and puerperium, which are appropriately referred, with the woman's consent, to medical practitioners. The midwife recognises her limits with regard to the health of her client and her responsibility to inform the woman's usual caregiver, ordinarily the GP, with as complete, but succinct, a picture of the woman's pregnancy and birth and postpartum experience as possible.

In New Zealand the woman may have chosen not to involve her GP at any stage of her pregnancy. She may have approached her midwife from the outset to confirm her pregnancy and initiate midwifery care. Her GP may have no knowledge of this pregnancy. Alternatively, the GP may have cared for the woman until she was eligible to register with an LMC (i.e. at 14 weeks), but have had no contact since then.

Each midwife can devise her own preferred referral process. An example of a well woman referral letter template is shown in Appendix C.

Documentation: health record

The New Zealand definition of a health record is 'a record describing every aspect of the healthcare provided to an identifiable consumer/patient and may be in a single file, multiple file, hard copy (paper based) or electronic (digital, audio, video, etc.) format, and held by the consumer/patient themselves' (Standards New Zealand 2002, p 6).

Health records take a variety of forms. Institutions ordinarily devise and provide stationery that facilitates the documentation it requires to record care, communicate among caregivers, comply with legal requirements, and hold result forms. With respect to maternity information, it is likely that in the lifetime of this textbook it will become widespread practice to have minimal documentation within the institution, and that the person to whom the information belongs—the woman—will carry the bulk of the information. Care is recorded by the healthcare professional at whichever point the woman encounters this person.

Standard Four of the NZCOM Standards for Practice states that: 'The midwife maintains purposeful, on-going, updated records and makes them available to the woman and other relevant persons' (NZCOM 2005, p 11).

The main compliance requirements for documentation and structure of health records are described by Hendry in the June 2004 *Midwifery News*:

- The content must be accurate, legible, jargon-free, in chronological order and non-erasable.
- All alterations, corrections and additions must be signed and dated.
- The record must have a unique identifier that enables a correct match with a consumer.
- Alert stickers should be used to identify potential adverse reactions.
- Verbal orders and consumer information obtained from others must be dated, signed and the source identified within the health record (Hendry 2004).

Whatever format you use to document your care, you must consider its comprehensibility to the woman and provide a glossary of the abbreviations used. Any medical term must be neatly translated into lay description the first time it is used. Your language should be non-judgemental, and positively phrased where possible, and you must summarise her care as succinctly as possible without repetition. A self-evident guide to the effectiveness of your documentation is to ask yourself: 'If I was relieving this midwife, would I easily grasp the progress or current concerns of this woman/whanau and/or baby?'

The discharge visit: assessment

In New Zealand, when the midwife is concluding the discharge visit, in addition to documenting the woman's physical, mental and social state, the midwife should also ask the following questions:

- Would you like your copy of the notes sent to you/left with you?
- May I write to your GP/well woman care provider with a summary of your pregnancy experience?
- Are you aware that my practice is reviewed annually? This is an opportunity to further explain the Midwifery Standards Review and the role of the consumer feedback.

  Midwifery Standards Review has been developed to provide a systematic process that enables the midwife, whatever her practice setting, to reflect on her midwifery practice with two midwifery colleagues and two consumers of midwifery services, who have been specifically educated to do this work for the New Zealand College of Midwives. The design of the process reflects the midwifery profession's partnership with women as well as the requirement for the midwife to be professionally accountable to herself, the women for whom she cares, and the profession (NZCOM 2004, p 11).
- As part of the review, may I send you the consumer feedback questionnaire?
- Would you consent to the use of your notes should yours be chosen at random by the Review Panel, just prior to Review, to check the standard of documentation?

Care of documentation

From the day you discharge the woman, you are required by law, currently (2005), to keep her records safe. 'Safe' includes protected from unauthorised access, locked securely, held in fireproof and waterproof containers. If the woman was not sent a copy then she must always know where to find her records during your guardianship of them. If you cease to practise, those records in your care must be transferred to a nominated organisation or service provider. It is even required that you nominate in your Will the appropriate transfer or disposal of these documents in the event of your demise.

An example of a summary of care assessment at discharge is shown in Appendix D. It is a useful checklist for the LMC midwife discharging a client/family at six weeks post partum.

Cervical screening

Cervical screening is a program of regular diagnostic investigation of cervical cytology among a population of women. A number of cervical cells are removed to detect cervical intraepithelial neoplasia (CIN) at the earliest possible time. These cells are taken from the squamo-columnar junction between the endocervix (columnar epithelium) and the ectocervix (squamous epithelium) in the transformation zone—the squamo-columnar junction, just at the outside end of the canal (area between internal and external os) where the canal opens into the vagina. This zone moves, depending on the stage of life and whether the woman is

Critical thinking exercise

1. If a result is not normal, what does this mean?
2. What are 'dysplasias' and CIN 1, 2 and 3?
3. How are abnormal or pre-cancerous cells treated?
4. What causes cervical cancer?
5. What are the risk factors that predispose to cervical cancer?

Clinical scenario 4

Julie is a first-time pakeha mother whose labour was augmented, as her membranes had ruptured and there was no spontaneous onset of labour within the negotiated time. Despite every effort to achieve vaginal birth, with obstetrician and midwife collaboration and planning, Julie developed a high fever and there was no acceptable progress in her labour. Her birth outcome was emergency caesarean section after 16 hours of established labour. Julie and her partner had done all they could during the pregnancy to have as natural and as 'low intervention' labour and birth experience as possible. This also is your philosophy. You choose to support women to birth relying predominantly on their own resources and the best possible information, evidence-based where possible, and emotional encouragement. You also cover the occasional discrepancy between planning for the normal and being aware of abnormal developments and intervention, based on sound obstetric rationale.

Following the birth, you debrief about the abnormal labour and outcome at as sensitive an interval as your experience clues you to do. Julie downplays the shift from dearly held expectations to the actual reality of her experience. She reports feeling well informed and able to understand the events that unfolded. She indicates that she has resolved her feelings of disappointment. She is delighted with her healthy boy. Her focus shifts to the feeding. She has some ups and downs while learning to feed but eventually achieves exclusive breastfeeding. However, the true breastfeeding commitment of such a good-sized, frequently feeding boy, and his evident need to be close, all the family and societal expectations of firmly 'disciplining' a baby from birth, as well as recovery from surgery are overwhelming and she cries most days of her postpartum time with you. You make yourself available to listen and you reinforce at every opportunity the good decisions she is making, seeking to bolster her confidence. Together you explore the source of her postnatal distress. This, you feel, is not too excessive considering what she is undergoing. She articulates many times the gap between what she expects from her partner, and what he offers. Much is attributed to fatigue and inadequate communication between the couple. During her discharge visit she admits again to crying most days.

1. How would you terminate this partnership and fulfill your role?
2. How do you yourself reflect upon and debrief this challenge so as to approach similar future cases differently?

Clinical scenario 5

Another first-time mother, Maori woman Rebekka has had a normal pregnancy, spontaneous labour and planned home birth, third-degree laceration, transferred to secondary care facility for repair, healthy baby girl, has taught herself to breastfeed, had no need to refer to any reading material you suggested. The baby is now thriving. A smear was last done three years prior, and the woman received notification that the next was due during her pregnancy. She lives with her mother. List your priorities and documentation for the six-week discharge visit for Rebekka.

breastfeeding. This is the part most likely to undergo cancerous changes.

Some midwives use the final discharge visit to offer the woman a cervical smear if it is due. Regardless of whether you plan to become a registered smear-taker and include this choice for women, the discharge visit is an appropriate time to raise the issue of screening, provide information, and address any questions the woman may have.

The rationale for routine screening is that cervical cancer is largely preventable. In 2005 the statistics showed that each year without screening, 1 in 90 women develop cervical cancer, and 1 out of 200 women will die from cervical cancer in New Zealand. Proportionally more Maori women figure in these statistics than non-Maori (cultural associations keep them away from having smears) (*Screening Matters*, Special Issue, February 2005). With screening, only 1 in 570 develop the cancer and only 1 in 1280 die from the cancer. Before symptoms develop there are changes in cervical cells that predict pathology. The success rate for adequate treatment of pre-cancers revealed by these changes is 98–100%. Any woman who has ever had sexual intercourse is at risk and would benefit from routine screening. The information you provide may ensure that the woman makes an informed decision about undergoing, or not undergoing, the screening. Explain why it is in her best interests but also how she can feel comfortable about taking the test. In your locale you should be fluent with the answers to such questions as:

- How long will the test take?
- How much will it cost?
- Who is most likely to take the smear?
- Can I have a third person present? This could be a friend, husband, partner, member of her family, practice nurse as chaperone or interpreter (if English is her second language and the smear-taker does not speak her first language).
- Any other query the woman has, until you believe that she is clear about the test.

Encourage women going for the first time to make this clear to the smear-taker. If she has never had a smear it will be necessary to explain how a smear is taken. She will be asked

Clinical scenario 6

First-time mother, Soo Lei, of Asian ethnicity, birthed by emergency caesarean section six weeks previously. You are confident that there are no ongoing issues related to that labour and birth, but Soo Lei's baby Anna had severe tongue tie. Your referral, in the postnatal ward, to a sympathetic paediatrician resulted in his recommendation to continue without frenulotomy. The baby, Anna, appeared to latch adequately and, with initial good supply, did well. Postnatal staff members were reassuring. On discharge you continued to assess the baby, however, as 'nipple' feeding. You arrange a frenulotomy with a sympathetic GP and appointment for retraining of tongue with the community lactation consultant (LC). Some improvement results (some strengthening of her untethered tongue muscle), but Anna vacillates between strong sucking and weak, tired sucking. Weight gain is just adequate and there are more visits to the LC. Any day now you expect Anna to strengthen and train herself. You continually reinforce the solid commitment and good-humoured tolerance and enthusiasm of the couple to explore every avenue to achieve exclusive breastfeeding. You arrive for the six-week visit with the feeling of a 'job not done'.

How would you vary your closure of this relationship from that of scenario 5?

Clinical scenario 7

Barbara is a 38-year-old pakeha, multiparous woman who was exposed to rubella in her mother's womb. This left her with a 40% hearing disability, and an inability to store fat reserves. She has borderline adequate nutritional status due to chronic hyperemesis throughout her 38 weeks of pregnancy; she also has cardiac and thyroid complications. She now has four children. Each of her pregnancies has resulted in labours where her hypertensive state escalated alarmingly. She has a steady relationship with this baby's father.

1 How would you advise and counsel her on her contraceptive needs?
2 What information would you accumulate before your six-week discharge visit with her?

Reflective exercise

1 What are your supervision and/or debriefing needs following on from the experiences related in these scenarios?
2 What are the major questions you need to have answered by the visit, to complete the partnership?
If you have provided lead care or continuity of care, your 'knowing' of the woman, and every step of her maternity care experience, is an advantage to you at this visit. You can help the woman/couple/family pull the whole experience together and confront unresolved feelings that this naturally intense episode in their lives may have generated.
3 In what other ways can you evaluate satisfaction with care?

to take off her lower garments, and to lie down on her back or side. Then a warmed metal or plastic instrument called a speculum is placed in the vagina so that the cervix—she may well be familiar with this term through antenatal classes or your care of her in labour, but do not assume this—can be seen. Ordinarily the vaginal wall is collapsed like a closed umbrella, and the speculum is used to hold the walls apart, thus allowing a light source to illuminate the cervix. Once the smear-taker has positively identified the cervix, a sample of cells is gently taken with either a spatula or small brush or specially shaped 'cervi-broom', smeared onto a laboratory slide, and sprayed with cell fixative. This slide is then sent to the laboratory and the cells examined under a microscope.

If a woman is having her very first smear, and if this result is normal she is recommended to have her second test one year later. If this also is normal, then the frequency of smear tests is recommended to be three-yearly in New Zealand (www.healthywomen.org.nz) and two-yearly in Australia (DHA 2001).

Smear-taking at the six-week discharge visit

If you contemplate taking smears at the six-week discharge visit, you need to consider the following issues:

- As an LMC with an annual caseload of 40–60 women, would you do a sufficient number of smears to maintain an acceptable standard of smear-taking?
- Breastfeeding women are known to have cervical differences due to altered hormonal state when they are lactating. The crucial endocervical cells (transformation zone) retreat up the canal, are difficult to reach and, therefore, a satisfactory sample is less likely.
- If the woman is due for a smear and you do not do it within your postnatal budget module, she must then attend a clinic, or GP, at her own expense. This reduces the likelihood of compliance.
- Do you wish to return the woman to her undressed, exposed self again after she has slowly assumed her sense of privacy and dignity since the intimacies of the birth? Can you manage this return to intimate, and

possibly painful, exposure, and still end your care on the respectful, positive, uplifting note you would choose? This naturally requires good communication skills and a sensitive, professional approach.

On the other hand, the midwife is often coincidentally required to examine and assess the healing of a wound, the involution of the fundus, the appearance, or not, of a rash or a suspect discharge. Also, it can be a relief to the woman to have smear and pelvic exam complete, be reassured and then able to relax about such an exposure not being required for another three years. Often she will feel that she has done the responsible thing and attended to this aspect of her present and future health. Needless to say, you will have prepared her for the physical side of her discharge assessment and discussed with her the appropriateness of a smear being taken.

Concluding the partnership

A significant function of the discharge visit is the closure or ending of the relationship. Standard Nine of the NZCOM Standards for Practice states that: 'The midwife negotiates the completion of the midwifery partnership with the woman' (NZCOM 2005, p 21). The parting between midwife and woman/whanau is signalled at the very first introductory visit. When the woman is choosing her midwife, you explain how the partnership begins, and when it conventionally ends. Then you will have reminded the woman at least one more time, perhaps at the beginning of the postpartum period, and you signal this again as you set up the six-week assessment at four or five weeks post partum. You are explicit with each other, at that visit, regarding her readiness (or not) for discharge.

Review questions

1. Outline a holistic health assessment of the woman at six weeks post partum.
2. What key points are necessary to convey when transferring your care of baby to a well child care provider?
3. Which social and physical milestones has a baby usually achieved by six weeks of age?
4. What are a woman's choices for well child referral in your country?
5. Write a summary of the side-effects of all methods of contraception.
6. What are the legal requirements for midwifery documentation in your country?
7. Discuss the strengths and weaknesses of the support networks and resources for postpartum women in your community.
8. What is the role of Standards Review with respect to LMC midwives?
9. How would you describe the benefits of breastfeeding to a teenage mother?
10. How would you deal with the knowledge that a young unmarried woman in your care is suffering from domestic violence? Can you list the resources available to you and to her locally?

CHAPTER 31

Contraception

Helen Calabretto

Key terms

basal body temperature, body mass index, combined oral contraceptive, emergency contraception, fertility awareness-based methods, progestogen implant, human immunodeficiency virus, intrauterine device, intrauterine system, lactational amenorrhoea method, progestogen-only injection, progestogen-only pill

Chapter overview

This chapter gives an overview of the methods of contraception used in Australia and New Zealand and will provide midwifery students with a beginning knowledge in this area. It is not within the scope of this chapter to provide complete information about each method of contraception. Rather, it should be viewed as an introduction to the methods with key points of information. Completion of a course offered at local family planning organisations and undertaking wider reading will provide additional invaluable information for midwives working with women in the antenatal and postnatal periods in particular.

Learning outcomes

Learning outcomes for this chapter are:

1. To identify contraceptive services available
2. To describe the role of the midwife in providing contraception counselling
3. To identify the factors that influence the selection of a suitable method of contraception for a woman or couple
4. To discuss the impact of culture, disability and pre-existing health problems on the choice of contraception
5. To explain the efficacy of various methods of contraception with typical and perfect use
6. To differentiate the changed patterns of contraceptive use at different times of a woman's reproductive life
7. To describe the way in which the following methods of contraception act, the reasons they may be selected as a method, and their suitability for use during lactation and the postpartum period: lactational amenorrhoea method; fertility awareness-based methods; barrier methods; intrauterine devices/systems; hormonal contraception; spermicides; vaginal douche; coitus interruptus; and sterilisation.

Introduction

Attempts to control fertility have been documented throughout history and have included methods such as the insertion of objects (e.g. stones) into the vagina or uterus, douches made of carbonated beverages, and plastic wrap to simulate the function of condoms (Varney 1997). Fortunately there are many more efficacious methods of contraception available to women. In the twentieth century, Margaret Sanger, a nurse, made an important contribution to women's quest for planning their families and the right of children to be born when they are wanted. She recognised the correlation between poverty and high birth rates, and in 1952 founded the Planned Parenthood Federation of America, which is now the International Planned Parenthood Federation (IPPF) and links national autonomous Family Planning Associations (FPAs) in over 180 countries worldwide.

In Australia and New Zealand, contraceptive services are provided in a variety of settings. These may include family planning clinics, general practice, women's health centres, community health centres, youth health centres, sexual health services and services provided within acute care hospitals. The leading organisations for contraceptive services are the Family Planning Association of Australia (with separate organisations in each state and territory), and the Family Planning Association of New Zealand. Their services encompass a broader focus than clinical services, including professional and community education, training, consultation and research. A list of the head offices is provided at the end of this chapter, as well as web addresses for other relevant organisations that provide reproductive health information (see Online resources).

Contraception counselling: the role of the midwife

Although many women plan their pregnancies, this is not the case for all women (Forrest 1994). Midwives must be cognisant of the fact that the woman's current pregnancy may not be wanted, or may be mistimed and may have resulted from contraceptive failure, error with the method or non-use of contraception. After the current pregnancy, women may wish to continue with their previous method of contraception, or may lack confidence in their previous method and want to consider a different method. Some women will want to start using contraception, and for other women a permanent method of contraception will be preferred. Midwives are therefore in a unique position to assist women during pregnancy, childbirth and the puerperium with their future contraception and safer sex needs.

Unfortunately, provision of contraceptive information is often a hasty activity included in a checklist of other topics as part of discharge education in the postnatal ward (Glasier et al 1996). A recent Cochrane Review (Hiller et al 2004) concluded that there is not enough evidence to establish that current postpartum contraception education is effective, and that research is required to examine the best timing and approaches. Until such time as this is undertaken, it would be reasonable to assume that discussion about contraception should be initiated in the antenatal period and revisited in the postnatal period. It is important that the issue is adequately discussed, and in addition to provision of verbal and written information about contraceptive methods, there needs to be referral to a primary health care provider for ongoing contraceptive needs. An up-to-date list of providers is a useful adjunct for counselling.

Critical thinking exercise

Go to the website of your local family planning organisation (see the addresses at the end of the chapter) and familiarise yourself with the services offered and location of the clinics. Compile a resource list for use in your own clinical practice.

Advice about contraception is critical because in the absence of breastfeeding, it is possible that ovulation may occur from day 28 postnatally (Guillebaud 2004). A number of factors will influence the method of contraception selected by a woman or couple. These include:

- whether the individual or couple is seeking a permanent or temporary method of contraception
- their understanding of the effectiveness of the method (see Table 31.1)
- the perceived or actual side-effects of the method
- any previous positive or negative experience(s) of a method(s)
- the cost and convenience of the method
- the ease of use of particular methods
- the number of sexual partners
- current popularity of a particular method
- influence of the media, friends and family
- religious and/or cultural factors (WHO 2004; Varney 1997).

Choices of contraceptive method change at various times in the childbearing years, as exemplified in Tables 31.2 and 31.3. Information should be provided about the effectiveness of various methods, none of which are 100% effective (see Table 31.1), their action, potential side-effects and the benefits and risks of the method as they relate to the individual woman. The time it takes for fertility to return after cessation of the method is also important when couples want to have more children, and whether the method also affords protection from sexually transmitted infections will be important for some women. Midwives should be aware of when particular methods can be commenced in the postpartum period, and their suitability during lactation. Some women have existing health problems that affect the suitability of some methods. These are summarised in Appendix A. In the past, most women

TABLE 31.1 Percentage of women experiencing an unintended pregnancy during the first year of use and the percentage continuing use at the end of the first year, USA*

Emergency contraceptive pills: Treatment initiated within 120 hours after unprotected intercourse reduces the risk of pregnancy by at least 75%.[9]			
Lactational amenorrhoea method (LAM) is a highly effective, *temporary* method of contraception.[10]			

* Equivalent data are not available from Australia and New Zealand

1 Among *typical* couples who initiate a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

2 Among couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the % who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

TABLE 31.1—cont'd.

3 Among couples attempting to avoid pregnancy, the % who continue to use a method for one year.

4 % becoming pregnant in columns (2) and (3) are based on data from populations where contraception is not used and from women who cease using contraception in order to become pregnant. Among such populations, about 89% become pregnant within one year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within one year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

5 Foams, creams, gels, vaginal suppositories and vaginal film. Note: vaginal suppositories and film are not available in Australia and New Zealand.

6 Cervical mucus method supplemented by calendar in the pre-ovulatory and basal body temperature in the post-ovulatory phases.

7 With spermicidal cream or jelly.

8 Without spermicides.

9 This doesn't mean a 25% pregnancy rate. If 100 women have intercourse in the middle of their cycle, approximately eight pregnancies will occur and use of the EC will reduce that number to two—a reduction of 75% (American College of Obstetricians and Gynecologists 1997)

10 However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breastfeeds is reduced, bottle feeds are introduced or the baby reaches six months of age.

(Source: adapted from Trussell 2004)

with intellectual disabilities, particularly those who were institutionalised, had induced amenorrhoea using continuous progestogens or by surgical approaches (Grover 2002). Now, their choices are the same as for non-disabled women, with infrequent use of surgical intervention.

Different cultural views about the use of contraception must also be respected by midwives when discussing ongoing contraceptive needs with women. It is not possible here to discuss each cultural group represented in Australia and New Zealand; however, it is important for midwives to be familiar with the cultural mores of the common groups of culturally and linguistically diverse (CALD) women in their care. These women (like other women in the dominant culture) may have poor knowledge of contraceptive methods from their schooling or teaching within the family, particularly where virginity is highly prized and expected until marriage. Information about contraception may be withheld as being more appropriate to be discussed at the time of marriage. Some groups of women may have had particular methods of contraception used without their informed consent and may be distrustful of all methods. Other women may be refugees or have migrated from countries where access to contraceptive services was limited or unavailable. Some women may have come from countries with pronatalist policies, and other may have come from countries where limitations are placed on family size. When discussing contraception with CALD women, traditional values must be respected and dealt with sensitively. There must also be acknowledgement that women may want to move away from traditional approaches to

contraception that may at times differ from the views of their partner and/or community.

The advice and information provided must be framed within the woman's values and beliefs. It is important that the midwives or other health professionals provide non-judgemental contraceptive advice and do not allow their own values to influence the advice they give to women. The midwife's counselling role also needs to extend beyond advice about contraception. Although the birth of a baby can strengthen a relationship and perhaps enhance sexual intimacy, resumption of sexual intercourse may take several months. Hormonal changes can result in a low libido; there can be physical discomfort from an episiotomy, perineal tear or caesarean section, and physical and emotional exhaustion from sleepless nights and the demanding role of parenting (Guillebaud 2004). Other issues include decreased lubrication from reduced oestrogen secretion; bloody lochia, which may interfere with sexual feelings; changed feelings about the erotic significance of the breasts; and adjustment of the relationship to include a new family member (Kennedy & Trussell 2004).

Reversible methods of contraception

Lactational amenorrhoea method (LAM)

Breastfeeding can provide a natural contraceptive effect and is a method that can be used when a woman is exclusively or near-exclusively breastfeeding for the first six months following a birth. Infant suckling at the breast inhibits ovulation, and although this is often attributed to high levels of prolactin, it is due to the disruption of the pulsatile release of gonadotrophic hormone (GnRH) by the hypothalamus, which in turns affects the pulsility of LH needed for follicle stimulation of the ovary. The small amounts of secreted oestrogen are insufficient to trigger the LH surge necessary to induce ovulation (Kennedy & Trussell 2004). LAM provides 98% protection against pregnancy if all of the following three criteria are met:

- The woman must breastfeed both day and night, providing a minimum of 90% of the infant's nutritional requirements.
- She must be amenorrhoeic.
- The infant must be under six months old (WHO 2004).

2 Totals may not add to 100% due to rounding.

3 Among Maori women, this category is mainly injection.

(Source: Pool et al 1995)

If supplements are given, they can only be non-milk (e.g. water and juice), given infrequently (no more than and preferably less than 5–15%), and not via a bottle (Kennedy & Trussell 2004). This ensures maximum suckling stimulation of the breast. Interestingly, in one study, higher rates of pregnancy (5.2%) were seen in working women using LAM, which indicates that even in the presence of good milk production and full breastfeeding, it is frequent suckling that is necessary to gain the maximum effect of LAM (Kennedy & Trussell 2004). In Australia, 64% of infants less than three months of age (ABS 2001) and in New Zealand, 55% of infants less than three months of age (NZ Plunket Society 2004) are fully breastfed. If women were better informed about this method, it could gain popularity and improve breastfeeding rates, although this would require good support for breastfeeding by the healthcare system, employers, and family and friends.

LAM suits women who do not want to use a hormonal method while they are exclusively breastfeeding their babies, but it is not suitable for women who plan to use supplemental feeding. However, it could be used for the time during which the woman meets the conditions described above, even if it is less than six months. Once the baby is six months old, or before that time if any of the criteria are not met, the mother should plan to use an additional method of contraception to avoid pregnancy. LAM is unsuitable for women with HIV because there is a 14–29% chance of the virus being passed through breast milk. In Australia and New Zealand, the current recommendation is to not breastfeed if the mother has HIV infection. LAM is also unsuitable if a woman has an infection or is taking particular medications that are passed in the breast milk and are harmful to the infant, or when the infant is unable to suck at the breast due to congenital abnormalities, prematurity or being small-for-dates and full breastfeeding is difficult.

Fertility awareness-based methods (FAB)

These methods, sometimes called 'natural methods' or 'natural family planning', use recognition of the changes in the woman's body at various times of the menstrual cycle. They acknowledge that the estimation of the period of fertility needs to take into account the sperm viability in the female genital tract—an average of three to four days with a theoretical possibility of up to seven days—and the fertile period of the ovum, which is estimated to be 24 hours (Guillebaud 2004).

FAB methods require cooperation and commitment within a relationship to maximise its effectiveness through agreement

by the couple to abstain from intercourse or have protected intercourse using barrier methods in the potentially fertile period of the woman's menstrual cycle. The methods are suitable when religious or cultural beliefs exclude the use of contraception, and there is a preference for a method that is free of physical side-effects and one that is inexpensive once the instruction is completed. Couples are advised to learn these methods correctly from expert practitioners to maximise efficacy. Local family planning organisations (see the list at the end of this chapter) can provide information about the specialist organisations providing this education. It should also be noted that these methods may also be used to assist conception. Couples may choose one or a combination of approaches described below.

Calendar (rhythm) method

The calendar method is the least reliable of these methods (see Table 31.1). It is based on the premise that ovulation occurs in the middle of the cycle, and the fertile period lasts for six days—the five days before ovulation and the day of ovulation (Jennings et al 2004). Calendar methods are not particularly effective, and there are relatively few days in a cycle during which some women are not fertile, including the day of the cycle when they expect their next menstrual period (Wilcox et al 2000). These researchers found that only 30% of women were fertile in the currently accepted clinical guidelines as being between days 10 and 17 of the cycle. Even for women who closely study their cycles to identify shortest and longest cycle length, life events may disrupt predictions and alter the fertile period unexpectedly. Some women have less regular cycles, which makes the method even less predictable. Refer to Guillebaud (2004, p 29), who outlines the way in which the fertile period is calculated, to maximise the effectiveness of this method.

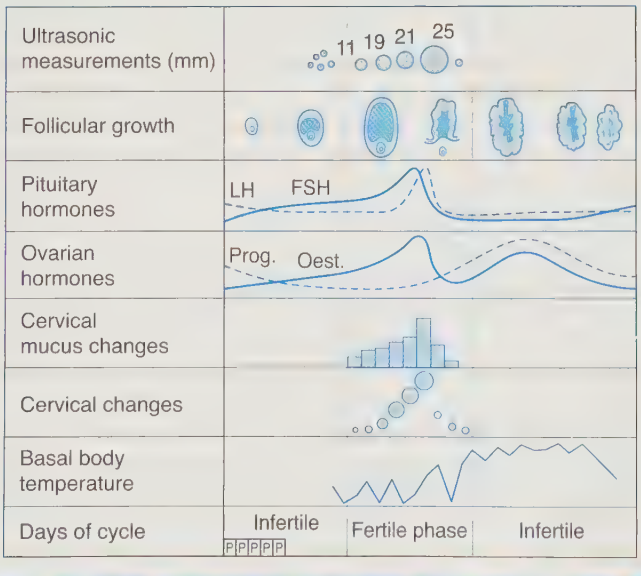

Figure 31.1 Fertility chart (based on Guillebaud 2004)

Basal body temperature (BBT)

The BBT method is based on the fact that there is a drop in the woman's body temperature 12–24 hours prior to ovulation, with a sustained rise for several days. Knowledge of temperature change is only useful in establishing when ovulation has already occurred over several cycles and thus the infertile period in which safe intercourse can occur. The temperature needs to be taken accurately each morning before the woman does *any* activity, using the same (oral, vaginal or rectal) route and charted on a temperature chart. The problem with relying on this method is that there is great individual variation in BBT, which can be affected by life events such as illness, emotional stress, irregular sleep, sedatives, use of electric blankets, alcohol intake, time of day, climate and immunisations (Varney 1997, p 77). In addition, some women have no identifiable BBT pattern (Hatcher et al 1994).

Cervical mucus charting (ovulation or Billings method)

This method originated in Australia in the 1950s (Varney 1997). In this approach, the woman is taught to recognise her fertile days by both the appearance and sensation of mucus at the vulva. She learns to recognise the difference between feelings of wetness and dryness. The fertile mucus (Spinnbarkeit mucus) assists the sperm to enter the cervix and is produced under the influence of unopposed oestrogen in the follicular phase of the cycle (Guillebaud 2004). It is likely that ovulation occurs within a day before, during or one day after the last day of abundant slippery discharge (Jennings et al 2004). The method is most effective if the fertile period is considered to begin when there is any type of mucus noted before ovulation. Following ovulation, the mucus changes under the influence of progesterone in the luteal phase, becoming impenetrable and hostile to sperm, and sticky (Guillebaud 2004). A disadvantage of this method is that some women may not secrete adequate amounts of mucus to notice cyclic changes.

Sympto-thermal method

This method incorporates cervical mucus observation and BBT as described previously and additional indicators of ovulation. These include symptoms such as the recognition of the softening and lowering of the external cervical os at the time of ovulation by the woman palpating her cervix (Guillebaud 2004). Cervical palpation each day towards the end of lactation can be a useful adjunct to assist the woman to recognise the return of fertility when using the LAM method. Additional symptoms include: mittelschmerz pain caused by follicular rupture resulting in symptoms such as dragging pain in the lower abdominal area; and rectal pain, which may occur before, during or after ovulation. Other symptoms may include increased libido, mood changes, breast tenderness and tenseness (Varney 1997).

Breastfeeding considerations

The current WHO (2004, p 3) guidelines outline the following information in relation to FAB, which may be less effective when breastfeeding.

Before six weeks post partum, women who are primarily breastfeeding and are amenorrhoeic are unlikely to have sufficient ovarian function to produce fertility signs and hormonal changes during the first six months post partum. During LAM, the likelihood of resumption of fertility increases with time over the postpartum period and with substitution of breast milk by other foods.

After menses commences, when the woman notices fertility signs (particularly cervical secretions), she can use a symptoms-based method. Prior to that time, a barrier method should be offered if the woman plans to use a FAB method later.

Postpartum considerations

The current WHO (2004, p 3) guidelines outline the following information in relation to postpartum use of FAB.

Non-breastfeeding women are unlikely to have sufficient ovarian function to either require a FAB method or have detectable fertility signs or hormonal changes prior to four weeks post partum. Although the risk of pregnancy is low, a method appropriate for the postpartum period should be offered.

After four weeks, non-breastfeeding women are unlikely to have sufficient ovarian function to produce detectable fertility signs and/or hormonal changes at this time; and the likelihood increases rapidly with time post partum. Women can use a calendar-based method as soon as they have completed three postpartum menses. Methods appropriate for the postpartum period should be offered prior to that time.

Barrier methods

Barrier methods include male and female condoms, diaphragms and cervical caps. They are generally used in conjunction with spermicides and prevent spermatozoa coming in contact with the ovum. Barrier methods are used only as they are required, and in addition to their contraceptive value, prevent the transmission of some STIs.

Male condom

This is a widely available and popular male method of contraception (see Tables 31.2 and 31.3) that is readily reversible. Male condoms are one-use-only sheaths most commonly made of latex (rubber). Polyurethane (plastic) condoms are also available but are more expensive than latex condoms. They are thinner and have a higher breakage rate than latex condoms, although they provide a good alternative for individuals with allergies, sensitivities or personal preferences that might prevent the use of latex condoms (Gallo et al 2004). In some countries, 'lambskin' condoms are available, and although they are effective as contraceptives, they are not effective in preventing the transmission of infections. They are not available in Australia or New Zealand.

Condoms rarely break or slip off, and provide high contraceptive efficacy if used correctly and consistently (Walsh et al 2004). Refer to Table 31.1 for efficacy of the method. Male condoms can be used alone or with a spermicide, and can also be used as an adjunct to other methods of contraception when there is a risk of STI transmission.

Prior to use, the integrity of condoms must be confirmed by checking the expiry date, checking for the presence of a bubble when the unopened packet is squeezed gently between the thumb and forefinger, and for holes or other damage to the packet. Condoms must be stored in a cool, dry place, and therefore wallets kept in clothing pockets, and car glove boxes, are unsuitable places for storage. A new condom must be used for each act of sexual intercourse and should be put on to the erect penis before any contact is made with the female genitalia, anus or mouth. The condom is placed over the glans penis, and the air expelled from the end of the condom so that room is left for the semen after ejaculation. Failure to do this may result in the condom breaking. The condom is then rolled down to the base of the erect penis. Following ejaculation, the condom must be removed from the vagina before the penis loses its erection. The condom is held at the base of the penis during withdrawal so that it does not accidentally come off and cause spillage of semen. It is important that the used condom is removed from the woman's genital area and that the penis makes no contact with that area until the penis is cleansed.

Oils and creams can break down the latex and should not be used as lubricants with condoms. These include vaginal products used to treat *Candida albicans*, such as Nilstat™, Fungillin™, Nystatin™ and Monistat™ (Australia), and Nilstat™, Clocreme™, Clotrimaderm™, Clomazol™, Gyno-Pevaryl™ and Micreme™ (New Zealand). Oil-based lubricants like Vaseline™, baby oil, massage oils and hand and body lotions are also unsuitable. Only water-based lubricants should be used with latex condoms. Oil-based lubricants can, however, be used with polyurethane condoms. Care must be taken in the handling of all condoms to ensure that tearing does not occur at any time during their use.

Condoms come in different colours and flavours, but some of these are not safe to use. It is also important that users check that the condoms are Australian or New Zealand standards approved where pregnancy and/or STI prevention are wanted. Condoms are available from many sources including supermarkets, pharmacies, vending machines, health services and entertainment venues, and are reasonably cheap, particularly when bought in bulk. New Zealand midwives are licensed to prescribe condoms. Some manufacturers make wider and longer condoms, which suit men who find standard condoms uncomfortable. It should be noted that condoms do not afford protection against all STIs, but are effective in reducing the risk of transmission of HIV (Weller & Davis 2004), and also of herpes simplex virus 2, gonorrhoea, chlamydia and syphilis, and in protecting women against trichomoniasis (Holmes et al 2004).

Breastfeeding considerations

Male condoms do not interfere with lactation.

Postpartum considerations

Male condoms can be used when the couple are ready to resume sexual intercourse. When vaginal dryness or perineal

soreness is a problem, additional water-based lubricant will make intercourse more comfortable.

EC alert

Women should be provided with information ahead of time about emergency contraception (see Emergency contraception section later in this chapter), so they can prevent pregnancy if: the condom breaks, slips off or is damaged in any way; there is any semen leakage from the condom; there is contact of the penis with the female genital area before the condom is applied, or before it is removed and the penis cleansed.

Female condom (Femidom™)

The female condom is a loose polyurethane sheath (see Fig 31.2) that is inserted into the vagina. It has a 60 mm ring at one end that fits into the vaginal fornices in contact with the cervix (in much the same way as a diaphragm) and an outer ring 70 mm in diameter that is in contact with the vulva, preventing it from retracting into the vagina. Although female condoms are not a particularly popular method of contraception, they will suit women who want to control the use of a condom, because they can insert the female condom ahead of time (up to eight hours). Female condoms are pre-lubricated; however, additional lubricant can be used to assist in reducing the noise that generally accompanies their use during thrusting of the penis. As with male condoms, female condoms afford protection against several STIs (Guillebaud 2004). Because they are made of polyurethane rather than latex, they can be used with oil-based lubricants. Although it is generally recommended that female condoms are one-use only, if used for contraceptive purposes alone, they can be washed in bleach for one minute, then in soap and water and then rinsed and hung up and dried. They can be re-used up to five times (WHO 2004).

Female condoms are four times the cost of male condoms. In 2004, a decision was made to not import Femidoms™ into Australia in the future. If women want to use female condoms, they should be referred to the local family planning organisation (see contact details at the end of this chapter) for information about mail or internet ordering from another country. In New Zealand, Femidom™ is imported by the Family Planning Association and sold through clinics and by mail order.

Breastfeeding considerations

Female condoms do not interfere with lactation.

Postpartum considerations

Female condoms can be used when the couple are ready to resume sexual intercourse.

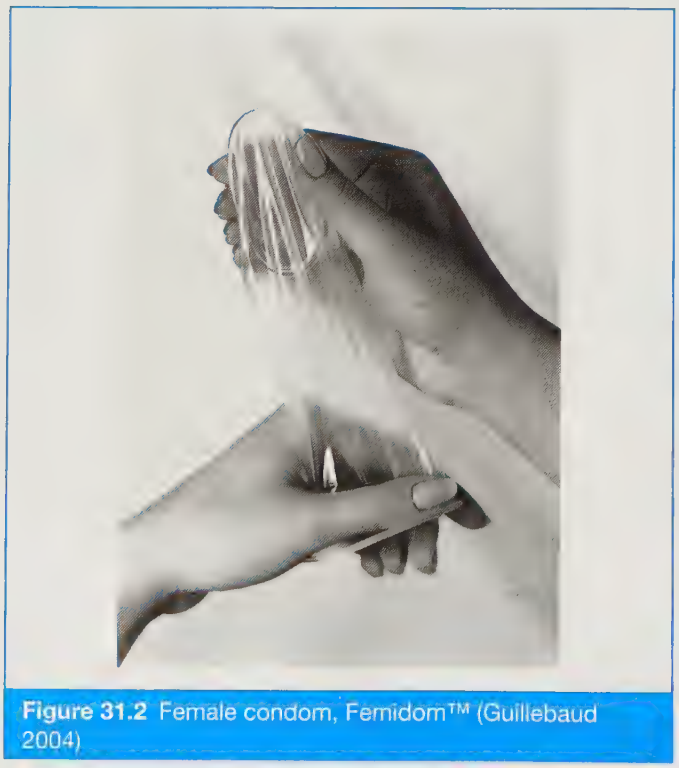

Figure 31.2 Female condom, Femidom™ (Guillebaud 2004)

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy if: the penis is wrongly positioned (between the female condom and the vaginal wall); the female condom is damaged in any way; there is any semen leakage from the female condom; there is contact by the penis with the female genital area before the female condom is inserted, or before it is removed and the penis cleansed.

Diaphragm

A diaphragm is a soft, latex dome with a flexible metal spring encased in the rim (see Fig 31.3). It is inserted into the vagina to cover the cervix and is used in conjunction with a teaspoon of spermicide in the dome, which is in contact with the cervix

Figure 31.3 Diaphragm (Guillebaud 2004)

(Cook et al 2004a). Diaphragms come in circumferences ranging from 70 mm to 90 mm. They also come in different varieties named for the type of spring that holds the diaphragm in position: flat spring (flat band of lightweight stainless steel), coil spring (flexible circular coil), and all-flex (combination of flat and coil spring). Flat-spring diaphragms are not currently available in Australia or New Zealand. The spring in the circumference of the dome springs back into shape when the diaphragm is in place and holds in it position. There are no randomised controlled trials providing evidence that diaphragms provide protection against infection; however, it is likely that they provide protection of the cervix from infection (Cates & Stewart 2004).

Diaphragms needed to be correctly fitted by a qualified practitioner, and should be replaced after two years, after childbirth and if a woman gains or loses four or more kilograms in body weight. Failure of diaphragms is caused by poor fitting of the diaphragm, improper positioning, and inconsistent use (Guillebaud 2004). Diaphragms are not suitable for all women, in particular those with a shallow pubic ledge and women with poor vaginal and/or perineal muscle tone or with latex allergy. Women who choose this method must feel comfortable with their bodies and confident in inserting and removing the diaphragm from their vagina. They must be taught how to insert their diaphragm, check that it is in place and covering the cervix, the technique to remove the diaphragm and how to recognise when the diaphragm is no longer fitting correctly. Diaphragms can be inserted up to eight hours before intercourse and require the insertion of additional spermicide before subsequent intercourse. They need to be left in for six hours after intercourse because that is how long the spermicidal preparation takes to immobilise and kill the sperm. If intercourse takes place more than once within a six-hour period, the diaphragm should be left in place and more spermicide added using a plastic applicator. Diaphragms can be left in all the time, but must be removed every 24 hours and cleaned before replacing.

The cautions about oil-based lubricants and other products outlined earlier in the section on male condoms are the same for diaphragms. Only water-based lubricants should be used with diaphragms. Care also needs to be taken with diaphragms to prevent the latex from deteriorating. They need to be washed carefully with a mild soap, rinsed and dried well, and stored in the plastic box provided, away from light and heat. Diaphragms can be dusted with cornflour or *unscented* talcum powder before putting them in the storage box. They must also be checked regularly for holes, and the latex checked for tackiness, which indicates the need for replacement because the latex is starting to perish.

Breastfeeding considerations

Diaphragms and spermicides do not interfere with lactation.

Postpartum considerations

Diaphragms can be fitted six weeks after delivery. LAM or condoms and spermicide are suitable alternative methods that can be used in the interim.

EC alert

Women should be provided with information ahead of time about emergency contraception, so they can prevent pregnancy if they become aware that the diaphragm did not feel as though it fitted correctly, if it became dislodged, or if it was not used.

Cervical cap

The Dumas or vault cap (suitable for a woman who has a short, wide cervix) and the Prentif cavity rim cervical cap (suitable for women with a long, straight-sided cervix) are available in both Australia and New Zealand. Caps are made of latex rubber, are smaller than diaphragms and have a thick rim (see Fig 31.4). They cover the cervix and are held in place by suction. Spermicides are placed in the dome, but it is important that no spermicide gets on the rim of the cap, otherwise the suction action may be diminished (Guillebaud 2004). Fitting and care of cervical caps is the same as for diaphragms.

Breastfeeding considerations

Cervical caps and spermicides do not interfere with lactation.

Postpartum considerations

Cervical caps can be fitted six weeks after delivery. LAM or condoms and spermicide are suitable alternative methods that can be used in the interim.

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy if the woman becomes aware that the cap did not feel as though it fitted correctly, if it became dislodged, or if it was not used.

Intrauterine devices

The intrauterine contraceptive device (IUD or IUCD, see Fig 31.5) is a highly effective (see Table 31.1) and economical method of contraception. It is inserted into the uterus and left in situ, and when removed will provide prompt return of fertility. Because of the problems associated with the Dalkon Shield™ and subsequent litigation, the IUD has decreased

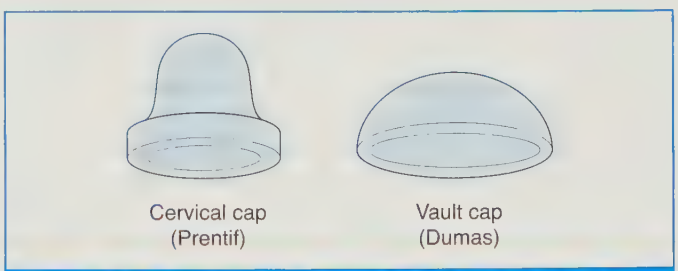

Figure 31.4 Cervical caps (based on Guillebaud 2004)

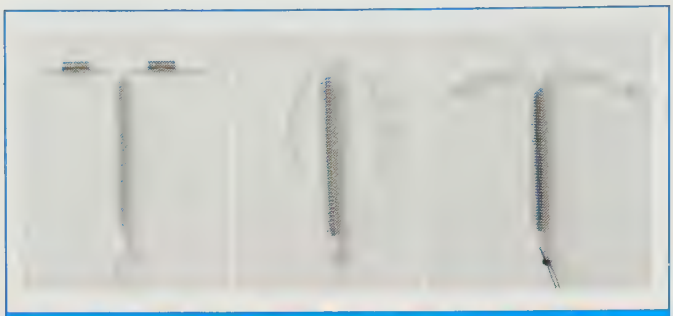

Figure 31.5 Intrauterine contraceptive devices (a) Copper-T 380™ (b) Multiload Cu 375® (c) Nova-T 380™ (Guillebaud 2004)

in popularity, although it is potentially a suitable method for many women. In Australia, the Copper-T 380a™ and Multiload Cu 375® are currently available and both of these are copper-bearing. The Copper-T™ can be left in place for eight years, and the Multiload for five years. In New Zealand, both the Nova T™ and Multiload Cu®375 (also copper-bearing) are available and can be left in place for three years and five years respectively. The Mirena® intra-uterine system (IUS), a levonorgestrel (LNG) releasing system, is available in both countries and has a five-year lifespan.

The IUD acts as a foreign body to change the endometrium, and also the uterine and tubal fluid. The device itself and the copper on the device act to block fertilisation and impede the transport of sperm (Guillebaud 2004). The copper on the devices is also toxic to ova and sperm. Copper IUDs can also be used for emergency contraception (see Emergency contraception section). The main disadvantage of IUDs is that they may cause a heavier menstrual flow for some women. On rare occasions they may perforate the uterine wall and occasionally migrate to the peritoneal cavity.

The end of menses through to mid-cycle is probably the best time for insertion of an IUD, because the likelihood of expulsion is minimal at that time. It is preferable for intercourse to not take place for three to four days following insertion, to minimise the risk of infection. If intercourse does take place during that time, a male or female condom should be used to counteract unexpected or unnoticed expulsion. Each month, the woman needs to check for the IUD strings, which are palpable at the cervical os.

The Mirena® IUS releases 20 µg of levonorgestrel per day. Its action is to block oestrogen and progesterone receptors, and also reduce sperm penetrability of the uterine fluid and cervical mucus. It also has an anti-implantation effect that takes time to develop (and is therefore unsuitable for emergency contraception, unlike other IUDs). IUSs are more expensive than IUDs and are better targeted to women who are concerned about menstrual bleeding and pain with an IUD. Since amenorrhoea is associated with the use of an IUS and was found to be the main reason for discontinuing the method, information about this aspect should be provided to assist women in making an informed decision about whether to use an IUS (van Vilet et al 2004).

Pelvic inflammatory disease (PID) is a complication of IUDs but is not caused by them, as was thought previously. It is possible, however, that asymptomatic cervical infection may be introduced into the uterus during the insertion process. Selective screening may be performed to exclude the presence of infection prior to insertion. A low rate of infection has been found with or without use of prophylactic antibiotics (Grimes et al 2004). IUDs do not provide protection against STIs, and so condoms should be used if there is any risk of infection.

Breastfeeding considerations

IUDs do not interfere with lactation. WHO (2004) guidelines suggest that the risk to the neonate due to exposure to steroid hormones with use of LNG-IUSs during the first six weeks post partum is the same as for other progestogen-only contraceptives.

Postpartum considerations

Although they can be inserted earlier (FFPRHC 2004), current practice is to postpone insertion of IUDs and IUSs until after six weeks post partum after a vaginal birth, and 12 weeks after a caesarean delivery. This is because the reason for postpartum bleeding will be unclear—for example, whether it is due to retained products or the IUD. LAM or condoms and spermicide are suitable alternative methods that can be used in the interim.

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy should the woman become aware that the IUD/IUS was not in situ and sexual intercourse had occurred.

Hormonal methods

Combined oral contraceptive (COC) pills

Combined oral contraception, commonly known as 'the pill', is both an effective (see Table 31.1) and popular (see Tables 31.2 and 31.3) method of contraception. COCs are a combination of synthetic oestrogen and progestogen in different amounts depending on the brand. COCs are either monophasic (all the same active pills in the packet with the same strength of oestrogen and progestogen), biphasic (two types of active pills in the packet where the oestrogen dosage and type remain constant and the type of progestin changes between the two last weeks of the active pills), or triphasic (three types of active pills in the packet where the oestrogen level may remain constant or change with the progestin component, and progestin has three different levels in the three weeks of active pills).

The action of COCs is to suppress ovulation by suppressing FSH and LH production 90–95% of the time, and also to thicken the cervical mucus, thus blocking sperm penetration. Additionally, a thinned endometrium inhibits implantation,

and tubal and endometrial motility is slowed (Hatcher et al 2004a). COCs do not protect against STIs and should be used in conjunction with condoms and spermicides if the woman is at risk for STIs.

Table 31.4 shows the currently available pill brands with the combination of hormones in each formulation. Given the large number of COCs available, it is usually possible to find a formulation that suits each woman in whom this method is not contraindicated. Some pill packets have a total of 21 pills, which are all active (hormone) pills; other pill packets have a total of 28 pills—21 active pills and 7 placebo pills. Pills are taken each day at around the same time for the 21 active pills in the packet. For the remaining seven days, which is also called the 'pill-free interval' or PFI, either no pills are taken, or the placebo pills are taken. A withdrawal bleed (WTB) occurs during that time. Many women equate the WTB with a normal menstrual period. However, the normal menstrual cycle does not occur because ovulation has been suppressed; the bleeding is the result of the withdrawal of hormones resulting in endometrial shedding (Guillebaud 2004). It is important that the PFI is not extended by missing one of the active pill(s) the day before or the day after the PFI. An extension of the PFI week risks ovulation and thus the possibility of pregnancy should intercourse occur at that time. This means that every pill in the packet should be taken, and the woman needs to plan ahead so that she has a new packet ready to take at the end of the PFI.

In addition to their contraceptive effects, COCs offer other advantages. These include regular, light and less painful periods, possible reduction in premenstrual symptoms, protection from PID, and a decreased incidence of ectopic pregnancy (Fraser & Cooper 2003). Additionally, the time and frequency of menstruation can be manipulated; there is a reduction in ovarian and endometrial cancer rates, and decreased risk of death from colorectal cancer (Hatcher et al 2004a).

Complications

Some of the potential side-effects of COCs include venous thromboembolism, which is associated with the oestrogenic component. The risk is greater with 50 μg pills than with 20–35 μg pills. The risk is also higher for women with a BMI of greater than 30, those who have had a previous venous thromboembolism, and women who are immobile. In addition, women with focal migraine headaches or new onset of headaches are at greater risk of haemorrhagic stroke and should not take COCs (FFPRHC 2003; Hatcher & Nelson 2004). There is also an increased risk of acute myocardial infarction (AMI) for women over 35 years who smoke, and women with hypertension, diabetes, hyperlipidaemia or obesity. One per cent of women develop hypertension, which is reversible within 14 months of ceasing COCs. There is also a slightly increased risk for breast cancer, which declines in the first 10 years after discontinuing the Pill (Hatcher et al 2004a). Smoking potentiates most of the risks associated with COC use, such as ischaemia, and haemorrhagic stroke and AMI (Hatcher & Nelson 2004). Additional unwanted effects include headaches, breast tenderness, nausea, weight increase, depression and loss of libido. These effects often diminish over time or may improve with a change of pill.

Precautions

Some prescription medications can decrease the efficacy of COC and make it an unsuitable method for women taking these medications. Examples include rifampicin, phenytoin, primidone, carbamazepine, phenobarbitol and griseofulvin (Varney 1997). Other medications may potentiate the effect of COCs, and the efficacy of others may be reduced. Information about medication interaction is provided in the package insert, and should be highlighted to women to maximise the efficacy of COCs. St John's wort, a complementary medicine, may have a wide range of potency, and is therefore also not suitable for COC and progestogen-only pill takers. It is important that a careful prescription and non-prescription medication history is taken from women who want to commence COCs. Clearly written information about managing problems such as missed pills, vomiting, intractable diarrhoea and taking medications should be provided to women who are taking COCs. COCs should be ceased for four weeks before major surgery where the woman will be immobilised and a progestogen-only method used—otherwise thromboprophylaxis and compression stockings should be used (Guillebaud 2004; RCOG 2004). For minor surgery, COCs do not need to be discontinued.

Breastfeeding considerations

There is no consensus about when COCs should be commenced, when a woman is breastfeeding. There is a theoretical concern that the neonate may be at risk due to exposure to steroid hormones via breast milk during the first six weeks post partum, and that the duration of lactation may be decreased and therefore the growth of the infant may be affected (WHO 2004). This is, however, not supported in a recent Cochrane Review that concluded that existing randomised controlled trials were unable to establish an effect of hormonal contraception on milk quality and quantity, and the evidence inadequate to make recommendations regarding hormonal contraception for lactating women. Additionally, no adverse effects on infant growth have been documented (Truitt et al 2004). It would seem prudent, however, to advise women to postpone the commencement of COCs until lactation is well established (FFPHRC 2004). Given that there are other choices such as a combination of progestogen-only pills and LAM that provide almost 100% efficacy (Guillebaud 2004), excellent alternatives are available.

Postpartum considerations

In non-lactating women it is preferable to wait for three weeks to commence COCs. At this time, the risk of thrombosis is minimised due to the decrease of the high oestrogen levels of pregnancy. Blood coagulation and fibrinolysis are essentially normalised by this time. Additionally, ovulation will not have occurred by this time (Guillebaud 2004; WHO 2004). COCs may be used when blood pressure is back to normal levels in women who have had pregnancy-induced hypertension.

(Sources: AMH 2004; MIMS 2004)

Women who have had severe pregnancy-induced hypertension with persistent biochemical abnormalities are at greater risk of thrombosis, and if no alternative method is acceptable should wait until eight weeks to commence COCs (Fraser & Cooper 2003).

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy in the event that pills have been omitted (particularly those that extend the PFI), or when vomiting or intractable diarrhoea has occurred.

Progestogen-only pill

The progestogen-only pill (POP), also known as the 'mini-pill', provides the same amount of one of three progestogens (levonorgestrel, norethisterone or ethynodiol)—see Table 31.4. It is suitable for women in whom oestrogen and thus COC is contraindicated. Efficacy is listed in Table 31.1, but it should be noted that in lactating women, its efficacy is nearly 100% (Guillebaud 2004). The POP is taken every day with no PFI. Unlike the COC, which has a 12-hour leeway for the dose of active pills, POPs have to be taken within three hours of the same time each day. The action of POPs is the same as other progestogen-only contraception: blocking passage of sperm by thickening the cervical mucus, inhibiting ovulation in most women for most cycles, and decreasing endometrial receptivity. As with the other progestins, bleeding patterns may be altered during POP use, although amenorrhoea is likely during lactation (Guillebaud 2004).

Precautions

As POPs are low-dose contraceptives there is a very narrow margin of error for missed pills. If the pills are taken late, a back-up method of contraception should be used for 48 hours until the woman is back on schedule. In the event of vomiting, the usual pills should be taken and a back-up method such as condoms and spermicide should be used for 48 hours. When commencing POPs at any time other than during lactation or post partum, additional precautions are not required if it is commenced on day 1 of the cycle. Rifampicin and griseofulvin are both enzyme-inducing antibiotics, so extra precautions need to be taken during and after their use because their effect will be reduced by POPs. This does not apply to other antibiotics. As with COCs, St John's Wort is not suitable for POP users. POPs do not protect against STIs and should be used in conjunction with condoms and spermicides if the woman is at risk for STIs.

Breastfeeding considerations

The current WHO (2004) guidelines state that breastfeeding studies have shown that progestogen-only contraception did not affect breastfeeding performance and infant health and growth. However, there are no current data evaluating the effects of progestogen exposure via breast milk on brain and liver development.

Postpartum considerations

Although Fraser and Cooper (2003) state that postnatal use is associated with breakthrough bleeding, current WHO guidelines state that POPs can be started at any time during the postpartum period (WHO 2004). Some women may find the narrow timeframe in which to take POPs difficult to adhere to when they are experiencing erratic sleeping and waking patterns, so some women may prefer to commence COC instead, once breastfeeding is established.

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy should a dose of POP be omitted or vomited.

Injectable contraception

Depo-medroxyprogesterone acetate (DMPA), known as Depo-Provera® 150 μg, is an intramuscular contraceptive injection that is effective for three months (see Table 31.1 for efficacy). It suits women who prefer a non-coitus-dependent method of contraception, but should be used in conjunction with condoms for women who are at risk for STIs. It is suitable for women who need a method that does not include oestrogen (e.g. smoker, where there is a history of thrombosis), women who have oestrogen-related side-effects from the COCs, or who are taking medications that are contraindicated with COCs.

DMPA is administered by deep intramuscular injection into the deltoid or gluteus maximus. The woman is given the date (calculated by 12 calendar weeks) from that date for the next injection, although there is a leeway of up to 14 weeks in which it can be administered. Its action is to suppress ovulation by inhibiting the LH and FSH surge, thickening cervical mucus, thus blocking sperm entry into the upper reproductive tract, slowing tubal and endometrial motility, and causing thinning of the endometrium (Hatcher et al 2004a).

When commencing this method, the first injection should generally be administered before day 7 of the cycle, and no further precautions are required, although some clinicians advise extra precautions for a week if it is later than day 2 (Guillebaud 2004). Women currently on POP or COC and definitely not pregnant can be given the first injection at any time during the cycle with no added precautions. Some women experience irregular menstrual bleeding and spotting, particularly in the first few months of use, and with time, amenorrhoea occurs for many women (50% by one year). Importantly, fertility may take up to a year to return after ceasing DMPA, and so it is not suitable for women who want reasonably prompt reversibility of contraception. Some women experience a progressive weight gain due to increased

appetite (Hatcher 2004). Headaches, dizziness, abdominal pain, or discomfort and weakness and fatigue, have been reported as other side-effects (Guillebaud 2004).

The other important issue is the greatly reduced bone mineral density in the lumbar spine and femoral neck in women who have used DMPA for at least five years, particularly after 15 years and when started before the age of 20 years (Hatcher et al 2004a). All users of DMPA should therefore be encouraged to undertake regular weight-bearing exercise. Their diet should include adequate dietary calcium, and if it does not, the need to take calcium supplements should be advised.

Breastfeeding considerations

The current WHO guidelines are that DMPA should be delayed until six weeks post partum because although breastfeeding studies have shown that progesterone-only contraception does not affect breastfeeding performance and infant health and growth, there are no data evaluating the effects of progestogen exposure via breast milk on brain and liver development (WHO 2004).

Postpartum considerations

Current guidelines are to wait until six weeks post partum, because heavy and prolonged bleeding may occur prior to that time. An alternative method must be used during that time and for seven days after the first injection. Guillebaud (2004) states that in theory, DMPA can be administered one week post partum, if the woman is not breastfeeding and might not return for the first dose.

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy in the event that the next DMPA injection is not given within the time limit and sexual intercourse has taken place.

Implant

Implanon® is a matchstick-sized progesterone-releasing rod, implanted under local anaesthetic, parallel to the skin on the inside upper arm (see Fig 31.6). It has a three-year lifespan and high efficacy rate (see Table 31.1) and suits women who want a non-coitus-dependent method that is 'set and forget'. The action, side-effects and precautions related to the use of Implanon® are the same as for DMPA. Implanon® contains 68 µg of etonorgestrel and releases 60 µg of progestin per day. It acts by blocking passage of sperm by thickening the cervical mucus, inhibiting ovulation, and making the endometrium atrophic (Hatcher et al 2004a). Implanon® may cause initial irregular and unexpected bleeding, which may be unacceptable to women, although supplemental hormones can be used to manage this. If at any time the method needs to be discontinued, the implant can be removed. Some women will become amenorrhoeic using this method. As with DMPA, weight gain can be a problem for some women.

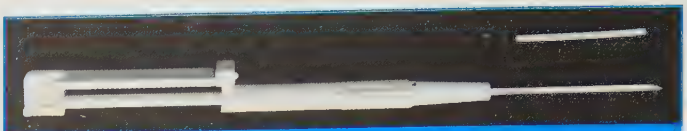

Figure 31.6 Contraceptive implant, Implanon®

Implanon® can be inserted from day 1 to 5 of the woman's cycle; however, if it is later than day 2, additional precautions should be used for seven days. If the woman is changing from COC or any other progestogen-only or uterine method, Implanon® can be inserted on any day, and the preceding method or condoms can be used for a further few days (Guillebaud 2004).

Breastfeeding considerations

The current WHO guidelines state that Implanon® should be delayed until six weeks post partum because although breastfeeding studies have shown that progesterone-only contraception does not affect breastfeeding performance and infant health and growth, there are no data evaluating the effects of progestogen exposure via breast-milk on brain and liver development (WHO 2004).

Postpartum considerations

Day 21 is recommended as the day of insertion of the implant because of the additional risk of irregular bleeding prior to that time, and to circumvent the need for additional contraceptive precautions. Another contraceptive method should be used for seven days, if the insertion takes place after day 21 (Guillebaud 2004).

Emergency contraception

Emergency contraception has been highlighted as a back-up method throughout this chapter. It is an important and under-used method of contraception that can be used for contraceptive failure (ruptured or slipped condom, dislodged diaphragm, missed pill(s) and so on), non-use of contraception, and for sexual assault. It is a method of contraception that should be included as part of counselling for most contraceptive methods as well as made more widely known about in the community (Calabretto 2004).

Hormonal emergency contraception

Hormonal emergency contraception is the main approach for emergency contraception. In the past, combined oral ethinyloestradiol and progestogen was used. In Australia this was off-label use of a COC brand, Nordiol (no longer available), and in New Zealand a dedicated product called PC4. An important multi-centre trial led to the current levonorgestrel-only method of EC (Task Force on Postovulatory Methods of Fertility Regulation: WHO 1998).

EC is sometimes erroneously thought to be an abortifacient. However, it is important to understand that EC does not interrupt an already implanted pregnancy (Calabretto & Galloway 2004). It is most likely that the main mechanism of action is to interfere with ovulation and prevent fertilisation,

and there is no reliable evidence that EC interferes with implantation (Croxatto 2002). LNG is a synthetic progestin and is able to produce similar changes to the endometrium normally needed for implantation and continuation of pregnancy. This adds further support to the argument that the effect of EC is likely to be pre-ovulatory (Faundes et al 2003). Additional actions may be an effect on sperm transport, and alteration in cervical mucus (AMH 2004).

In Australia, Postinor-2® is the current levonorgestrel EC, and is available without prescription from pharmacies but requires counselling by a pharmacist prior to dispensing. It is no longer available on prescription. In New Zealand, Levonelle® is the levonorgestrel EC and can be sold with counselling, by accredited pharmacists and nurses. Postinor-2™ is a subsidised medicine available on prescription in New Zealand. EC may also available from other sources such as family planning clinics, women's health clinics, community health clinics, sexual health clinics, and youth health clinics, where it may be provided free or at a lower cost than in a pharmacy or on prescription.

The package insert states that EC must be taken as soon as possible within 72 hours of unprotected sexual intercourse, as two single doses of 750 µg, and taken 12 hours apart. In keeping with the study by Rodrigues et al (2001), current practice is now for EC to be commenced as soon as possible within 120 hours of unprotected sexual intercourse with the pills taken together as a single dose of 1500 µg. Importantly, although the extended timeframe does provide more leeway for women, the efficacy does decrease over time. In the future, it is likely that there will be a 1500 µg pill rather than the two-pill dose, and the package insert will reflect the extended timeframe.

The IUD as emergency contraception

A copper-bearing IUD (non LNG-IUS) can also be used as EC. It is inserted not more than five days after the most probable calculated date of ovulation, even if there have been multiple acts of unprotected intercourse, or five days after any single (earliest) exposure (Guillebaud 2004). Use of the IUD for the purpose of EC is most appropriate for women who want to use it as an ongoing method of contraception.

Breastfeeding considerations

EC may be safely taken during lactation (WHO 2004).

Postpartum considerations

EC may be safely taken during the postpartum period (WHO 2004).

Other contraceptive methods

Spermicides

Spermicides are chemical agents that destroy or immobilise sperm, making them incapable of fertilising an ovum. They are not recommended as a contraceptive alone (see Table 31.1 for efficacy), but are useful in increasing the efficacy of barrier methods such as diaphragms and condoms. Nonoxynol-9 is the active agent in most spermicides, and some condoms come pre-lubricated with this spermicide. Spermicides are effective against several STIs. However, repeated and frequent use of this spermicide has been associated with increased risk of genital lesions, and may actually increase the risk of HIV (Wilkinson et al 2002). Spermicides, in the form of gels, cream or jelly, are inserted near the cervix using the applicator that comes with the product. It is important that the information provided on the package insert that comes with the particular spermicide is followed. Spermicide must be inserted prior to intercourse, and reapplied prior to subsequent episodes of intercourse.

Breastfeeding considerations

Spermicide use does not interfere with lactation.

Postpartum considerations

Spermicides can be used when the couple are ready to resume sexual intercourse.

Vaginal douche

There is an erroneous belief that vaginal douching is contraceptive by flushing sperm out of the vagina (Varney 1997). Most sperm are contained in the first few drops of ejaculate, and within 90 seconds of the deposit of semen at the cervical os, sperm have entered the cervical canal. It is simply impossible to douche in time to prevent pregnancy, and douching may also cause an increased risk of pelvic infections. It is therefore not advisable to recommend this practice (Cates & Raymond 2004).

Coitus interruptus (withdrawal)

This is a method that requires the man to withdraw his penis from the vagina before he ejaculates. The method may variously be described as 'withdrawal', 'being safe' or 'being careful' or by other euphemisms (Varney 1997). It is important to be aware of the meaning behind such descriptions when a woman discusses her contraceptive method. It has a low rate of contraceptive efficacy (see Table 31.1), although when used consistently and correctly it has the same efficacy as barrier methods and therefore should not be dismissed. It must also be appreciated that some cultural groups use coitus interruptus as their main method of contraception when spacing families and, for some people, is the only contraceptive method they will use throughout their reproductive lives. See Tables 31.2 and 31.3 for use in each age group.

Of importance to this method is the fact that sperm from a previous ejaculation may be present in the pre-ejaculate and therefore pose a pregnancy risk if intercourse occurs again within a short time. Although it has yet to be researched, it is probably advisable for the male to urinate after ejaculation to remove any sperm from his urethra, and he should also cleanse the external surface of the penis before contact with the woman's internal and external genitalia occurs (Kowal 2004). The method will fail if the man ejaculates on, or in the vicinity of, the female's external genitalia. Use of a spermicide will increase the efficacy should there be a small number of sperm in the pre-ejaculate from a previous ejaculation (Guillebaud 2004). Its advantage as a method is that it is free and always

available as a method or back-up method, although it requires good communication and cooperation between the couple and excellent control by the male.

Breastfeeding considerations

Coitus interruptus does not interfere with lactation.

Postpartum considerations

Coitus interruptus can be used when the couple are ready to resume sexual intercourse.

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy should ejaculation occur in the vagina or vulva.

Permanent methods of contraception

These highly effective (see Table 31.1) surgical methods block the passage of ova in women and sperm in men. Although reversibility may be possible for some procedures, sterilisation should be considered as permanent, and it is therefore important that appropriate counselling is provided so that expectations are accurate. None of the procedures affect the hormonal levels in the body, and will not diminish and may in fact enhance sexual response because the fear of pregnancy is removed. These techniques do not provide protection against STIs, and so use of condoms and spermicides is needed for women who are at risk for STIs.

Tubal sterilisation

Female sterilisation, or tubal occlusion, is performed by a gynaecologist under conscious sedation, or general or local anaesthetic. The surgical approaches that may be used are laparoscopy, mini-laparotomy (performed after childbirth) or laparotomy. Once the fallopian tubes have been accessed, they are sealed off with clips, rings or bands applied to the tubes, or diathermy may be used to heat and seal the tubes. The method is effective immediately, and sexual intercourse may be resumed when the woman is ready to do so.

The newest method of female sterilisation—the Essure® technique—is performed using a cervical block and leaves no abdominal scars. Nickel titanium coils are inserted hysteroscopically into the ampullae of the fallopian tubes to cause scarring, and thus blockage of the tubes. At three months, a hysterosalpingogram or ultrasound is performed to confirm the presence and position of the coils (Teoh et al 2003). Until the blockage is confirmed, another method of contraception must be used. At present in Australia, the Essure® method is performed in some public hospitals under Medicare arrangements or for a cost of $A2000 in private hospitals. In New Zealand the procedure can only be undertaken privately. Although it is the least-invasive method of female sterilisation, it is the least commonly performed procedure at present.

Breastfeeding considerations

This method does not interfere with lactation.

Postpartum considerations

The current WHO guidelines state that female sterilisation can be safely performed from immediately post partum up to seven days; however, there is an increased risk of complications from days 7–42 when the uterus has not fully involuted (WHO 2004).

A tubal ligation may be performed after a caesarean delivery. The WHO (2004) guidelines also note that women who have had pre-eclampsia or eclampsia have increased anaesthetic-related risks; and where there has been prolonged rupture of the membranes for 24 hours or more, when the woman has had puerperal sepsis, intrapartum or puerperal fever, there is an increased risk of postoperative infection. Women who have had a severe antepartum or postpartum haemorrhage may be anaemic and unable to tolerate further blood loss. If there has been severe trauma to the genital tract—cervical or vaginal tract tear at time of delivery—there may have been significant blood loss and anaemia, and the procedure may be more painful.

Prior to the procedure being done during the postnatal period, counselling needs to take place to ensure that this is a well-considered decision. It may be preferable to delay the procedure until 12 weeks post partum so that the woman will not regret a decision made at an early, more emotional time (Guillebaud 2004), unless the decision has been carefully considered in the antenatal period.

EC alert

Women should be provided with information ahead of time about emergency contraception so they can prevent pregnancy should intercourse take place in the first three months after the Essure® procedure.

Hysterectomy

Removal of the uterus for obstetric emergencies or gynaecological problems also confers permanent contraception.

Vasectomy

This is a male method of contraception where the vas deferens is cut and the end sutured to block the vas deferens and passage of sperm from the testes. There is local swelling and discomfort for a few days after the procedure. After vasectomy, sperm are reabsorbed. The procedure is usually performed under local anaesthesia, by a urologist, surgeon or GP. Higher rates

of vasectomy success are associated with greater experience in vasectomy technique (Cook et al 2004a). Following the procedure, between 15 and 20 ejaculations are needed for the remaining sperm to be expelled from the body, so additional precautions need to be taken until a semen analysis is done to confirm the absence of sperm in the seminal fluid. After a vasectomy, the seminal fluid will not be noticeably different because only 2–5% of semen is sperm; most of the seminal fluid is composed of secretions from the seminal vesicles and prostate gland.

EC alert

Information about emergency contraception should be provided ahead of time so that pregnancy can be prevented should intercourse take place before a semen analysis has confirmed the absence of sperm.

Critical thinking exercise

Complete a table using the model below, including commencement time and compatibility with breastfeeding.

Method of contraception	When can the method be commenced during the postpartum period?	Is the method compatible with breastfeeding?
LAM		
COCs		
Condoms (female)		
Condoms (male)		
Diaphragm, cap		
EC		
Fertility awareness methods		
Implant		
Injectable		
IUD		
POPs		
Spermicides		
Tubal ligation		
Vasectomy		

Review questions

1. Are midwives adequately prepared to provide information about fertility control?
2. When is the best time to discuss fertility control with women?
3. Do you know where to refer women for contraceptive counselling and services?
4. What resources should be available in clinics or units to assist midwives to discuss contraception with women?
5. How do midwives ensure that their own negative views about a particular method(s) of contraception are not imparted to women?
6. Do you always discuss emergency contraception when you talk to women about contraceptive methods? Think about strategies to ensure that this aspect is not omitted.
7. Think about why some women or couples may be ambivalent towards the use of contraception. How might you assist them?
8. Think about the reasons that a woman might stop using a method of contraception, and how you would counsel her in this situation.

Review questions—cont'd

9 Decreased bone mineral density can be a problem for women who are long-term users of DMPA, and so these women should be taking adequate dietary calcium. How many µg of dietary calcium is adequate for a non-pregnant woman? Provide examples of common foods that would add up to this amount in a 24-hour period.

10 A woman in your care says that her partner does not want her to use any contraceptive method because of his cultural beliefs, although she would prefer to use a hormonal method, to space her family. Discuss the strategies you would use to assist your client to resolve this situation with her partner.

APPENDIX A: Contraceptive methods for women with existing health problems

Condition	Unsuitable methods	Suitable methods
Cardiovascular diseases		
Venous thromboembolism	COCs contraindicated. No sterilisation until condition treated and resolved.	Progestogen-only methods, IUDs.
Ischaemic heart disease or stroke	COCs contraindicated.	Progestogen-only methods when other methods are not available or acceptable.
Valvular heart disease		Progestogen-only methods. COCs if there are no complications such as pulmonary hypertension, atrial fibrillation, or history of subacute bacterial endocarditis.
Hypertension	Moderate and severe hypertension complicated with vascular disease are contraindications for COCs. Sterilisation for women increases GA risk, therefore vasectomy could be considered instead.	Low dose COC for mild hypertension and no additional risk factors (ie smoking, diabetes, obesity, or age > 35 years) when other methods unsuitable or unavailable POPs, IUDs, implants good choices, DMPA good second choice.
Diabetes	Hormonal contraception unsuitable when there are vascular complications. Female and male sterilisation can be performed but with additional precautions to anticipate hypoglycaemia or ketoacidosis and increased risk of infection. Copper IUD with screening and treatment of pre-existing infection prior to insertion, strict asepsis. Prophylactic antibiotics considered.	COCs normally contraindicated except where there is no vascular disease. POI (injectables) but only if other methods are not available or acceptable to the client. Hormonal contraception may be used if there are no vascular complications (nephropathy, neuropathy, or retinopathy). POP or Implanon can be used when there are vascular complications.
Convulsive disorders	DMPA and Copper or LNG IUD. EC—in the absence of scientific data on how drug interaction affects efficacy, the standard regimen should be used.	All methods are suitable but use of anticonvulsants—phenytoin, carbamazepine, ethosuximide, phenobarbitone & primidone—may reduce the efficacy of COCs, POPs, Implanon.
Migraine	COCs contraindicated in focal migraine. Onset or exacerbation of migraine with a new pattern which is recurrent, persistent or severe requires discontinuation of the COC and evaluation of the cause. POPS, DMPA or Implanon are usually discontinued in the presence of headache.	For focal migraine, POPs, Implanon or non-hormonal methods. POIs is last choice in the absence of hypertension. Low-dose COC for women who have simple migraine without aura.
Liver disease	COCs contraindicated in active liver disease, severe cirrhosis, or liver tumour.	Non-hormonal method should be first choice. Progestogen-only contraceptives may be used if other methods not acceptable or not available. Women who carry hepatitis viruses can use any method of contraception. Mild cirrhosis can generally use progestogen-only contraception, with COCs only as last choice.
Malignant diseases		
Breast cancer or liver neoplasms		Pregnancy should be avoided in women with a genital tract premalignant or malignant disease. With most genital tract malignancies, the treatment is such that there will be no further pregnancies. Pre-malignant conditions of the cervix—any method is suitable.

(Continued)

APPENDIX A: Contraceptive methods for women with existing health problems—cont'd

Condition	Unsuitable methods	Suitable methods
Breast cancer	Breast cancer: CU IUD is a good choice.	BC: COCs, POI contraindicated. POPs and LNG IUSs should not be initiated.
Endometrial, ovarian, cervical cancer		Copper IUDs should not be initiated but may be continued if cancer develops during use. Treatment usually causes sterility. If treatment is not available and contraception is needed, COCs, POPs, POI and Implanon® can be used.
Haematological disorders		
Anaemia	Copper IUCDs not suitable as they can increase blood flow.	COCs. Progestogen-releasing IUD, POI can reduce blood loss through menstruation.
Sickle cell disease		Pregnancy can be life-threatening for women with sickle-cell anaemia, therefore effective method is needed. Long-acting progestogen-only contraceptives should be first choice. COC and copper IUD are good second choices.
Thalassaemia	No methods are contraindicated.	
Infectious diseases		
Tuberculosis		Efficacy of COCs, POPs and Implanon is reduced, therefore the woman should be advised to employ a back-up method while taking Rifampicin and for two weeks after cessation of therapy.
Malaria		No contraindications to any method. No known drug interaction between antimalaria medications.
HIV infection	Spermicide used alone is not adequate.	Whatever the contraceptive choice, male condoms should also be used. The female condom is less well studied but should also reduce the risk of HIV infection when used consistently and correctly.
Psychiatric disorders	Sterilisation is not recommended for women or men with a psychiatric illness such as depression that may impair informed decision-making.	Methods that do not require strict compliance are more suitable for women with an acute or severe psychiatric disorder for whom making contraceptive choices may be difficult.
Mental disability	Careful consideration needs to be made to ensure that there is no coercion to use a particular method of contraception. Most methods are suitable and are dictated by the woman's ability to manage a particular method.	Sterilisation in the absence of informed consent by the client must involve the legal guardian and team of professionals. The decision must be guided by legislation.

SECTION THREE

COLLABORATIVE PRACTIVCE

CHAPTER 32

Screening and assessment

Sally K Tracy

Key terms

anaemia, asymptomatic bacterial vaginosis, asymptomatic bacteriuria, blood grouping, *Chlamydia trachomatis*, cytomegalovirus, Down syndrome, fetal anomalies, gestational diabetes mellitus, haematological conditions, hepatitis B virus, hepatitis C virus, HIV, infections, muscular dystrophies, placenta praevia, pre-eclampsia, preterm birth, red cell alloantibodies, rubella, sickle cell disorders, streptococcus group B, structural anomalies, syphilis, thalassaemia, toxoplasmosis

Chapter overview

Screening is a way of detecting a predisposition for a condition or a disease in people who are considered otherwise healthy and without any signs of the condition that is screened for. It can involve specific tests, or simple questions. It is important to note that a screening test is *not* a diagnosis or a diagnostic test. It merely brings to our attention someone or a group of women who may be at higher risk of having a disorder or disease. The next step, once a screening test has shown positive results, is for the woman to undertake further tests, which may be more expensive, invasive and time consuming. Screening usually begins early in pregnancy to check whether a woman has any conditions or infections that could affect her or her baby's health. It is important to always explain the purpose of any test that is offered, and it is of utmost importance to ascertain whether or not a woman wishes to have any particular test. The information that tests provide may help you and the woman to consider certain pathways or treatments during the antenatal period. The test results will also invariably affect the way women make choices during their pregnancy.

This chapter builds on the information in Chapter 20. It follows on from the assessments that will have been made during the antenatal visits and discusses in depth the screening and assessment techniques currently undertaken in New Zealand and Australia. The chapter is not intended as a 'cookbook' guide on when and how to advise women about screening. You will be aware of the different screening policies at the national and area health service levels. This chapter is intended to introduce the student midwife to current debates and information appropriate to practice.

Learning outcomes

Learning outcomes for this chapter are:

1. To explain the concept of screening during pregnancy
2. To describe the test, examinations and other procedures available to women
3. To discuss the known benefits and disadvantages of screening procedures
4. To discuss the ethical, legal and social dilemmas accompanying the use of innovative medical technologies in antenatal screening.

Introduction: screening guidelines

In Australia and New Zealand there are various sets of evidence-based guidelines prepared and published to guide midwives (and others) through the maze of screening options available for women having uncomplicated pregnancies. Some of these are listed here, with brief overviews of their contents.

Three Centres Consensus Guidelines

The *Three Centres Consensus Guidelines on Antenatal Care* are available online at http://www.health.vic.gov.au/maternitycare/anteguide.pdf.

Information on the content of visits should include the rationale and timing of routine tests and investigations. Wherever possible, any reduction in the total number of visits should be accompanied by an increase in time allocated.

The evidence accumulated for the Three Centres Project suggests a baseline eight-visit antenatal schedule as follows:

- **Visits 1 and 2** are in the first trimester. From the carer's perspective, first trimester visits are primarily to assess maternal and fetal wellbeing, particularly the risk of complication, to date the pregnancy, take a comprehensive history, discuss smoking behaviour and establish care options. The visits are scheduled in order to offer screening tests recommended for asymptomatic bacteriuria, syphilis, HBV, HCV, HIV and Down syndrome.
- **Visits 3 and 4** are in the second trimester. Second trimester visits are primarily scheduled to monitor fetal growth, maternal wellbeing and signs of pre-eclampsia. If ultrasound is routinely offered, it should be included as part of a visit at 18–20 weeks. If women have glucose screening this should be part of a visit at 24–28 weeks.
- **Visits 5–8** are in the third trimester. Third trimester visits are primarily to monitor fetal growth, maternal wellbeing, signs of pre-eclampsia, and to assess and prepare women for admission, labour and going home. These visits may include bacteriological screening for GBS (at 35–37 weeks), and preparations for admission, labour and 'going home', consistent with other guidelines.

It is important to establish each person's expectations and understanding, as women may have a different perspective on the purpose and timing of antenatal visits. The option and timing of additional visits should be discussed with all women.

NICE Guidelines

The NICE (National Institute for Clinical Excellence) Guidelines are available on the RCOG website. See 'Antenatal care: routine care for the healthy pregnant woman' (http://www.rcog.org.uk/index.asp?PageID=693).

Midwives Handbook

The NZCOM's *Midwives Handbook for Practice* (NZCOM 2005) says that the first decision point in pregnancy (within the first 16 weeks of pregnancy) is timed to allow for a comprehensive assessment to be made according to the best available evidence. It is an ideal time to discuss the role that both the midwife and women will undertake in the following pregnancy and birth. It will also ensure that there is time to make appropriate decisions regarding treatment and decisions to intervene in the pregnancy if this is what eventuates following the screening procedures that may be undertaken. It is important that the midwife adequately explains to a pregnant woman what screening tests are meant to detect, how they are conducted, possible risks to her and her fetus, the type of results that will be reported (e.g. probability, risk), the likelihood of false-positive or false-negative results, and the choices she will face once results are obtained (NICE 2003).

Information shared

The first step in screening is to review the woman's history to identify any factors that may need follow-up. Midwifery factors include a discussion of what the woman and midwife understand to be the role they will play during the pregnancy. It may involve discussion of previous experiences of labour and birth; or it may include an in-depth discussion of the scope of practice of the midwife and the appropriateness of referral and consultation. In this first screening visit it is important to ascertain the support networks available and the priorities for medical consultation, if this is recommended.

Chapter 20 covered in detail how to do a booking and the regular observations that midwives attend to in the antenatal period. This chapter discusses the contemporary screening options offered to women, and discusses the appropriateness of screening for each condition.

Review of current and past maternity history

At this time you will ascertain the number of pregnancies a woman reports (gravida) and the number of births (parity). (Note: The definitions of mortality differ between Australia and New Zealand. In both Australia and New Zealand, a live birth is recorded if the fetus is 20 weeks gestation or over, and weighs 400 g or more at the time of birth (AIHW 2004). The perinatal death rate in Australia includes stillbirth (or fetal death) and death up to 28 days after birth; in New Zealand, a perinatal death is a stillbirth (fetal death) or a death up to 7 days after birth. The denominator for perinatal death rate is per 1000 births: both live and stillborn over these time periods.)

At this time it is important to ascertain whether a woman has had any spontaneous or elective abortions or whether she has experienced preterm labour and birth, or had a stillbirth or a neonatal death. This information helps to build a better

picture about whether a woman might benefit from more intensive screening than the usual methods offered to most women regardless of any risk markers.

Definition of terms:

- Parity refers to the total number of pregnancies continued beyond 20 weeks gestation, regardless of the outcome (i.e. live birth or stillbirth) or the number of fetuses in the uterus (i.e. parity is not influenced by multiple births—plural pregnancies are counted as one). A nulliparous woman has never given birth to a viable infant, or, in other words has never completed a pregnancy beyond 20 weeks gestation.
- The term primiparous refers to a pregnant woman who has given birth and has had no previous pregnancy before this birth resulting in a live birth or stillbirth.
- Multipara refers to a pregnant woman who has had at least one previous pregnancy resulting in a live birth or stillbirth before this one, or, in other words, having completed at least one pregnancy beyond 20 weeks.
- Grand multipara refers to a pregnant woman who has had four or more previous pregnancies resulting in a live birth or stillbirth (i.e. this is her fifth (or more) pregnancy).

Screening tests

A good screening test should be able to discriminate clearly between those who are at high risk, and those who are not. It should be safe, have a reasonably defined cut-off level and be both valid and reliable. Although the latter two terms are often used interchangeably, they are distinct. Validity is the ability of a test to measure what it sets out to measure, usually differentiating between those with and without the disease. By contrast, reliability indicates repeatability (Grimes & Shultz 2005, p 882). It refers to a method of measurement that consistently gives the same results (NICE 2003).

However, being labelled as at 'high risk' is only useful if something can be done to alter or decrease the risk. In addition, risk factors are not things that cause an outcome —they are only markers of a particular situation, and serve to alert the midwife to the fact that diagnostic tests might be required to ascertain whether or not the woman has a certain condition. This leads us to our first ethical dilemma.

Screening differs from the traditional clinical use of tests in several important ways. When we believe there is something wrong with us, it prompts us to consult an expert (perhaps a doctor) about the complaint or problem, and this in turn prompts testing to confirm or exclude a diagnosis. By contrast, screening engages apparently healthy women who are not seeking medical help (and might prefer to be left alone). In addition, the occurrence of false-positive results and true-positive results may lead to (dangerous) interventions. Although the anxiety induced by a correct diagnosis may be overwhelming, those incorrectly thought to have a problem suffer as well. For example, although failing to diagnose sexually transmitted diseases can have important health implications, incorrectly labelling people as infected can wreck marriages and damage lives (Grimes & Schulz 2002).

Assessing the effectiveness of a test

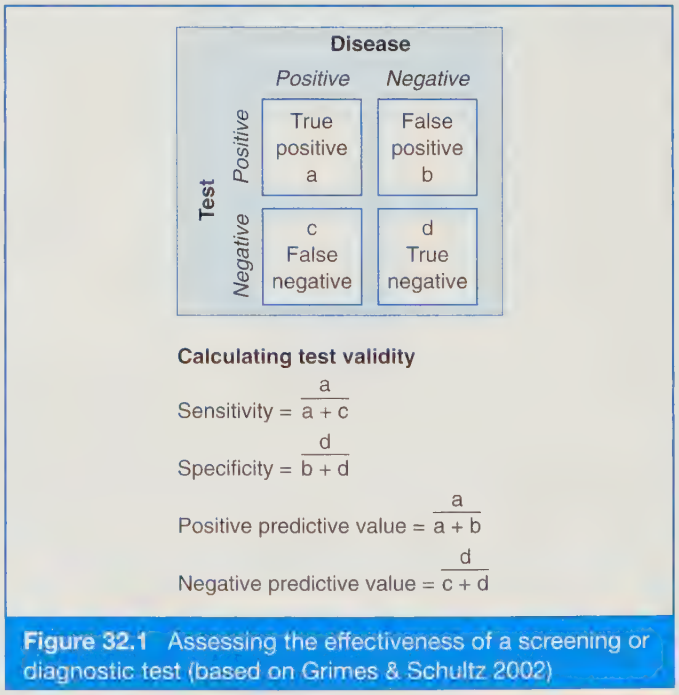
There are four indices of the validity of a test: sensitivity, specificity, and predictive values of positive and negative (see Fig 32.1).

Sensitivity

Sensitivity is sometimes termed the 'detection rate'. It describes the ability of a test to find those with the disease (Grimes & Schulz 2002). In diagnostic testing, sensitivity refers to the chance of having a positive test result, given that you have the disease. One hundred per cent sensitivity means that all those with the disease will test positive, but this is not the same the other way around. A woman could have a positive test result but not have the disease—this is called a 'false positive'. The sensitivity of a test is also related to its 'negative predictive value' (true negatives): a test with a sensitivity of 100% means that all those who get a negative test result do not have the disease. To fully judge the accuracy of a test, its specificity must also be considered (NICE 2003, glossary).

Specificity

Specificity denotes the ability of a test to identify those without the condition (Grimes & Schulz 2002). In diagnostic testing, this refers to the chance of having a negative test result, given that you do not have the disease. One hundred per cent specificity means that all those without the disease will test negative, but this is not the same the other way around. A woman could have a negative test result, yet still have the disease—this is called a 'false negative'. The specificity of a test is also related to its 'positive predictive value' (true positives):



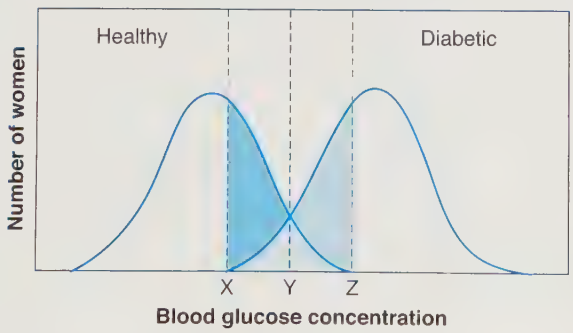


Figure 32.1 Assessing the effectiveness of a screening or diagnostic test (based on Grimes & Schultz 2002)

a test with a specificity of 100% means that all those who get a positive test result definitely have the disease. To fully judge the accuracy of a test, its sensitivity must also be considered (NICE 2003, glossary).

For the purposes of this chapter, it is important to understand these concepts broadly, so that you understand how screening works in real life. For example, the trade-off between sensitivity and specificity (see Fig 32.2) is demonstrated by the following. For any continuous outcome measurement (e.g. blood glucose), the sensitivity and specificity of a test will be inversely related. If we place the cut-off for abnormal blood glucose at a very low point, thereby producing perfect sensitivity (i.e. we manage to identify all those women with diabetes), the low cut-off identifies all those with diabetes. However, the trade-off is poor specificity—that is, those women who also have blood glucose at the level specified but are part of the 'healthy distribution' (i.e. at one end of 'normal') and are incorrectly identified as having abnormal values. Placing the cut-off higher yields the opposite result: all those who are healthy are correctly identified (perfect specificity), but the cost here is missing a proportion of women who are diabetic. Selecting a cut-off point is a compromise, mislabelling some healthy people and some people with diabetes. Where the cut-off should be depends on the implications of the test.

As in other areas of maternity care, there is healthy debate about what constitutes evidence-based screening and what does not. This has been instrumental in driving a serious attempt to outline the most reasonable path to follow with screening in pregnancy. For the purposes of this chapter, the road map for screening will be that developed by the National Institute for Clinical Excellence (NICE). The NICE Guidelines were developed in the United Kingdom and drew on the first attempt in Australia to gather evidence-based guidelines to help practitioners and women navigate their way through the maze of screening technology available. The Guidelines developed by this group in the United Kingdom represent:

Setting cut-off for abnormal at X yields perfect *sensitivity* at the expense of specificity. Setting cut-off at Z results in perfect specificity at the cost of lower sensitivity. Cut-off Y is a compromise.

Figure 32.2 Hypothetical trade-off between sensitivity and specificity (based on Grimes & Schulz 2002)

Reflective exercise

Look closely at the references cited in the NICE Guidelines, the Three Centres Consensus Guidelines from Australia, and the New Zealand Guidelines for antenatal screening, and determine how many interventions are based on Level 1 evidence.

the view of the Institute, which was arrived at after careful consideration of the evidence available. Health professionals are expected to take it fully into account when exercising their clinical judgment. The guidance does not, however, override the individual responsibility of health professionals to make decisions appropriate to the circumstances of the individual patient, in consultation with the patient and/or guardian or carer (NICE 2003).

Appointment times for screening

The following summary of screening visits and what to do are based on the NICE Guidelines (2003, pp 10–12). Remember that these are only a guide to practice: screening is an individual thing, and many women will not necessarily find this level of surveillance a comfort or a necessity. It is therefore most important to respect women's views in these matters.

First appointment

At the first appointment:

- give information to enable informed decision-making about screening tests
- identify women who may need additional care
- check blood group and Rhesus D (RhD) status
- offer screening for anaemia, red-cell alloantibodies, hepatitis B virus, HIV, rubella susceptibility and syphilis
- offer screening for asymptomatic bacteriuria (ASB)
- offer screening for Down syndrome
- offer early ultrasound scan for gestational age assessment
- offer ultrasound screening for structural anomalies (20 weeks).

After the first (and possibly second) appointment, for women who choose to have screening, the following tests should be arranged before 16 weeks of gestation (except serum screening for Down syndrome, which may occur up to 20 weeks of gestation):

- ultrasound scan to determine gestational age using:
  - crown–rump measurement if performed at 10 to 13 weeks
  - biparietal diameter or head circumference at or beyond 14 weeks
- Down syndrome screening using:
  - nuchal translucency at 11 to 14 weeks
  - serum screening at 14 to 20 weeks.

16 weeks

The next appointment should be scheduled at 16 weeks to:

- review, discuss and record the results of all screening tests undertaken.

18 to 20 weeks

At 18 to 20 weeks, if the woman chooses, an ultrasound scan should be performed for the detection of structural anomalies. For a woman whose placenta is found to extend across the internal cervical os at this time, another scan at 36 weeks should be offered and the results of this scan reviewed at the 36-week appointment.

28 weeks

At this appointment:

- offer a second screening for anaemia and atypical red-cell alloantibodies
- investigate a haemoglobin level of less than 10.5 g/dL and consider iron supplementation, if indicated
- offer anti-D to Rhesus-negative women.

31 weeks

Review, discuss and record the results of screening tests undertaken at 28 weeks.

34 weeks

At 34 weeks, all pregnant women should be seen in order to:

- offer a second dose of anti-D to Rhesus-negative women.

36 weeks

At 36 weeks:

- for women whose babies are in the breech presentation, offer external cephalic version (ECV)
- review ultrasound scan report if placenta extended over the internal cervical os at previous scan.

Gestational age assessment

The information in this section is from the NICE Guidelines (2003, pp 7–8).

Pregnant women should be offered an early ultrasound scan to determine gestational age (in lieu of last menstrual period (LMP) for all cases) and to detect multiple pregnancies. This will ensure consistency of gestational age assessments, improve the performance of mid-trimester serum screening for Down syndrome, and reduce the need for induction of labour after 41 weeks. (The guidelines underpin this advice with a level of evidence obtained from randomised controlled trials and systematic reviews.)

Ideally, scans should be performed between 10 and 13 weeks and crown–rump length measurement used to determine gestational age. Pregnant women who present at or beyond 14 weeks gestation should be offered an ultrasound scan to estimate gestational age using head circumference or biparietal diameter. (This recommendation is based on a 'good practice point'.)

Ultrasound scans

Early in pregnancy (usually around 10 to 13 weeks), the first ultrasound scan may be offered. It is used to estimate when the baby is due and to check whether there is more than one fetus. If you don't see women this early, it is appropriate to offer the scan at the earliest time. Between 18 and 20 weeks appears to be the optimum time to offer a second scan to check for physical abnormalities in the fetus. Beyond these it is not recommended that women have any further routinely offered scans, as they have not been shown to be useful (NICE 2003).

Individual clinicians, maternity units and geographic regions have adopted widely varying strategies for combining LMP and early ultrasound (EUS) estimates of gestational age (GA). Some still use LMP, others rely exclusively on EUS, while many base GA on EUS only when the discrepancy with LMP exceeds a given limit, such as ±7, 10 or 14 days (Blondel et al 2002).

Table 32.1 shows the effect of estimating the GA in a fetus using the various methods of estimation in a study in 44,632 pregnancies in France. Note the discrepancies between postdates babies using the LMP method and the EUS method. Some authors recommend ultrasound estimation as the first choice for dating all pregnancies; others have voiced reservations about exclusive use of EUS estimates. Because of these different approaches to resolving discrepancies in LMP and EUS estimates, both among and within countries, geographic and temporal trends in preterm and post-term birth remain difficult to interpret (Blondel et al 2002).

Estimates of gestational duration based on the timing of the last normal menstrual period (LMP) are dependent on a woman's ability to recall the dates accurately, the regularity or irregularity of her menstrual cycles and variations in the interval between bleeding and anovulation. Crowther and colleagues (1999) estimate that between 11% and 42% of GA estimates from LMP are reported as inaccurate. Ultrasound measurements are based on standard growth curves, but fetal growth may deviate from the standard, even early in gestation. Fetuses that grow faster than the standard curve will be given a biased, longer gestational length, and therefore an increased probability of being classified as post-term, even when they are not (Olesen et al 2004). The opposite will be seen for slow-growing fetuses. Lower early ultrasound-based GA estimates therefore seem attributable in some cases to slower fetal growth (Olesen et al 2004). This observation was also reported by Smith et al (1998).

In a study that examined the determinants and consequences of fetal growth restriction as a function of differences in GA estimates, Morin et al (2005) found that several maternal and fetal characteristics influenced the magnitude of the discrepancy between the GA estimates. These included socio-economic differences and potential determinants of early fetal growth restriction (Morin et al 2005). Mothers with severe pre-eclampsia and short stature were more likely to have

TABLE 32.1 Rates of preterm and post-term birth, estimated from LMP or EUS, according to six algorithms for combining the two estimates (n = 44,623)

	Algorithm*					
GA	1 LMP alone	2 LMP or EUS (14-day rule)	3 LMP or EUS (10-day rule)	4 LMP or EUS (7-day rule)	5 LMP or EUS (3-day rule)	6 EUS alone
Preterm birth (%)						
< 32 weeks	1.3	1.3	1.3	1.3	1.3	1.3
< 34 weeks	2.2	2.1	2.2	2.2	2.3	2.3
< 37 weeks	7.6	7.8	8.1	8.5	9.0	9.1
Post-term birth (%)						
≥ 41 weeks	20.9	16.9	15.1	13.4	11.7	11.2
≥ 42 weeks	6.4	3.5	2.8	2.4	2.0	1.9

*EUS source if discrepancy between the two sources > 14 days (Algorithm 2), > 10 days (Algorithm 3), > 7 days (Algorithm 4), > 3 days (Algorithm 5)
(Source: Blondel et al 2002)

positive differences (higher menstrual than early ultrasound-based GA estimates), suggesting that these widely recognised determinants of fetal growth might begin to exert their effects by the early second trimester. Small differences in growth may also depend on fetal sex, maternal age, parity and smoking (Olesen et al 2004). The NICE guideline group conclude, however, that there is thought to be little variation in fetal growth rate up to mid-pregnancy and, therefore, estimates of fetal size by ultrasound scan provide estimates of GA that are not subject to the same human error as LMP (NICE 2003).

Ultrasound assessment of GA at 10–13 weeks is usually calculated by measurement of the crown–rump length. For pregnant women who present in the second trimester, GA can be assessed with ultrasound measurement of biparietal diameter or head circumference (NICE 2003). Ultrasound measurement of biparietal diameter is reported to provide a better estimate of date of delivery for term births than first day of the LMP (NICE 2003, p 51). Routine ultrasound before 24 weeks is also associated with a reduction in rates of intervention for post-term pregnancies. A 1998 Cochrane Review (Neilson 1998) found that, compared with selective ultrasonography, routine prenatal ultrasonography before 24 weeks gestation provided better GA assessment and earlier detection of multiple pregnancies and fetal malformations. This review reported, in the long-term follow-up of Norwegian and Swedish children, no adverse influence on school performance or neurobehavioral function as a consequence of antenatal exposure to ultrasound; however, fewer of the ultrasound-exposed children are right-handed (Neilson 1998). The 'Alesund' trial, which was reported in 2000 (Eik-Nes et al 2000), claimed the possible benefits of the routine use of ultrasound screening in pregnancy as a lower incidence of induced labour due to apparent post-term pregnancies—approximately 70% lower in the ultrasound-screened group. Inductions from all causes were also less frequent among ultrasound-screened women. Among the controls, three pairs of twins remained undiagnosed until the mothers were admitted to the hospital in labour at between 36 and 38 weeks gestation. The authors concluded that for women who were screened with ultrasound, obstetricians were less likely to induce labour due to apparent post-term pregnancy, than for women who were not screened (Eik-Nes et al 2000).

Accurately assessing the GA also permits optimal timing of antenatal screening for Down syndrome and fetal structural anomalies. Reliable dating is important when interpreting Down syndrome serum results, as it may reduce the number of false-positives for a given detection rate (NICE 2003).

Side-effects of ultrasound

The use of ultrasonography for evaluating the developing embryo/fetus continues to rise, although the potential risks from exposure are uncertain (Barnett et al 2000; Marinac-Dabic et al 2002; Miller et al 1998). An effect of ultrasound on intellectual performance cannot, at present, be ruled out. Researchers from Sweden who published their work in the journal *Epidemiology* in 2005 concluded that further action to evaluate possible neurotoxic effects of ultrasound should be taken, particularly because ultrasound exposure in the published studies looking at long-term effects of exposure was low compared with present levels of exposure (Kieler et al 2005).

Prenatal exposure to ionising irradiation in the second trimester has been found to affect the developing brain, resulting in intellectual impairment (Schull & Otake 1999). Whether other forms of radiation such as ultrasound have similar neurotoxic effects is not yet known (Ziskin & Barnett 2000). Ultrasound has the potential to damage tissue by

BOX 32.1 What is ultrasound?

The term 'ultrasound' refers to the ultra-high-frequency sound waves used for diagnostic scanning. Ultrasound waves are emitted by a transducer (the part of the machine that is put onto the body), and a picture of the underlying tissues is built up from the pattern of 'echo' waves that return. Hard surfaces such as bone will return a stronger echo than soft tissue or fluids, giving the bony skeleton a white appearance on the screen.

Ordinary scans use pulses of ultrasound that last only a fraction of a second. In contrast, Doppler techniques, which are used in specialised scans, fetal monitors and hand-held fetal stethoscopes, feature continuous waves, giving much higher levels of exposure than pulsed ultrasound.

More recently, ultrasonographers have been using vaginal ultrasound, where the transducer is placed high in the vagina, much closer to the developing baby. This is used mostly in early pregnancy, when abdominal scans can give poor pictures. However, with vaginal ultrasound, there is little intervening tissue to shield the baby, who is at a vulnerable stage of development, and exposure levels will be high. Having a vaginal ultrasound is not a pleasant procedure for the woman; the term 'diagnostic rape' was coined to describe how some women experience vaginal scans.

Another recent application for ultrasound is the nuchal translucency test, where the thickness of the skin fold at the back of the baby's head is measured at around three months; a thick 'nuch (neck) fold' indicates that the baby is more likely, statistically, to have Down syndrome. When the baby's risk is estimated to be over 1 in 250, a definitive test is recommended. This involves taking some of the baby's tissue by amniocentesis or chorionic villus sampling. Around 19 out of 20 babies diagnosed as 'high risk' by nuchal translucency will not turn out to be affected by Down syndrome, and their mothers will have experienced several weeks of unnecessary anxiety. A nuchal translucency scan does not detect all babies affected by Down syndrome.

(Source: Buckley 1998–2005)

BOX 32.2 When is ultrasound helpful?

One of the most common justifications given for routine ultrasound scanning is to detect intrauterine growth restriction (IUGR). Many clinicians insist that ultrasound is the best method for the identification of this condition. In 1986, a professional review of 83 scientific articles on ultrasound showed that 'for intrauterine growth retardation detection, ultrasound should be performed only in a high-risk population'. In other words, the hands of an experienced midwife or doctor feeling a pregnancy woman's abdomen are as accurate as the ultrasound machine for detecting IUGR. The same conclusion was reached by a study in Sweden comparing repeated measurement of the size of the uterus by a midwife with repeated ultrasonic measurements of the head size of the fetus in 581 pregnancies. The report concludes: 'Measurements of uterus size are more effective than ultrasonic measurements for the antenatal diagnosis of intrauterine growth retardation'.

If doctors continue to try to detect IUGR with ultrasound, the result will be high false-positive rates. Studies show that even under ideal conditions, such as do not exist in most settings, it is likely that over half of the time a positive IUGR screening test using ultrasound is returned, the test is false, and the pregnancy is in fact normal. The implications of this are great for producing anxiety in the woman and the likelihood of further unnecessary interventions.

There is another problem in screening for IUGR. One of the basic principles of screening is to screen only for conditions for which you can do something. At present, there is no treatment for IUGR, no way to slow or stop the process of too-slow growth of the fetus and return it to normal. So it is hard to see how screening for IUGR could be expected to improve pregnancy outcome.

We are left with the conclusion that, with IUGR, we can only prevent a small amount of it using social interventions (nutrition and substance abuse programs), are very inaccurate at diagnosing it, and have no treatment for it. If this is the present state of the art, there is no justification for clinicians using routine ultrasound during pregnancy for the management of IUGR. Its use should be limited to research on IUGR.

(Source: Proud 1997)

heating, cavitation or streaming, and the brain is most susceptible to environmental effects during its development (Barnett 1998; Miller et al 1998). Although epidemiological research on possible adverse effects of ultrasound is sparse, there have been published reports of an association between non-right-handedness/left-handedness in males and exposure to prenatal ultrasound. The significance of 'handedness' studies is the higher risk of an association of left-handedness in infants with lowered intellectual abilities (Kieler et al 2005). However, in a study examining the association between prenatal ultrasound exposure and intellectual performance, Kieler et al (2005) failed to demonstrate a clear association between ultrasound scanning and intellectual performance.

Screening for Down syndrome and fetal structural anomalies

The general principle guiding all screening tests is that a risk assessment is made by combining the results of the screening test with the pre-test risk, based on the woman's age and previous history.

BOX 32.3 Ultrasound past and present

Ultrasound was developed during WWII to detect enemy submarines, and was later used in the steel industry. In July 1955 Glasgow surgeon Ian Donald borrowed an industrial machine and, using beefsteaks for comparison, began to experiment with abdominal tumours that he had removed from his patients. He discovered that different tissues gave different patterns of sound wave 'echo', leading him to realise that ultrasound offered a revolutionary way to look into the previously mysterious world of the growing baby (Wagner 1999).

This new technology spread rapidly into clinical obstetrics. Commercial machines became available in 1963 (De Crepigny 1996) and by the late 1970s ultrasound had become a routine part of obstetric care (Oakley 1986). Today, ultrasound is seen as safe and effective, and scanning has become a rite of passage for pregnant women in developed countries. In Australia, it is estimated that 99% of babies are scanned at least once in pregnancy—usually as a routine prenatal ultrasound (RPU) at 4 to 5 months. In the US, where this cost is borne by the insurer or privately, around 70% of pregnant women have a scan (Martin et al 2003), and in European countries, it is estimated that 89% of pregnant women have an ultrasound, usually once in each trimester (third) of pregnancy (Levi 1998). However, there is growing concern as to its safety and usefulness. UK consumer activist Beverly Beech has called RPU 'the biggest uncontrolled experiment in history' (Beech 1993) and the Cochrane Collaborative Database—the peak scientific authority in evidence-based medicine—concludes that 'no clear benefit in terms of a substantive outcome measure like perinatal mortality [number of babies dying around the time of birth] can yet be discerned to result from the routine use of ultrasound . . . For those considering its introduction, the benefit of the demonstrated advantages would need to be considered against the theoretical possibility that the use of ultrasound during pregnancy could be hazardous, and the need for additional resources (Neilson 1998).

The additional resources consumed by routine ultrasound are substantial. In 1997, for example, the Australian federal government paid out $39 million to subsidise pregnancy scans; an enormous expense compared to $54 million for all other obstetric Medicare costs (Senate Community Affairs Reference Group 1999), and this figure does not include the additional costs paid by the woman herself. In the US, an estimated US $1.2 billion would be spent yearly if every pregnant woman had a single routine scan.

In 1987, UK radiologist HD Meire, who had been performing pregnancy scans for 20 years, commented, 'The casual observer might be forgiven for wondering why the medical profession is now involved in the wholesale examination of pregnant patients with machines emanating vastly different powers of energy which is not proven to be harmless to obtain information which is not proven to be of any clinical value by operators who are not certified as competent to perform the operations' (Meire 1987). The situation today is unchanged, on every count.

In 1999, the Senate Committee report, 'Rocking the Cradle' recommended that the cost-benefit of routine scanning, and of current ultrasound practices, be formally assessed. Recommendations were also made to develop guidelines for the safe use of all obstetric ultrasound, as well as for the development of standards for the training of ultrasonographers . . . So far, none of these recommendations have been implemented (Senate Committee 1999).

(Source: Buckley 1998–2005)

In Australia and New Zealand

To date, there has been an 'ad hoc' approach to serum screening in Australia and New Zealand. While there have been attempts in some Australian states to make this a population-based screening program (for example, South Australia where population coverage is about 75%, and Victoria), the overall utilisation of serum screening has been low, with no more than 30% of Australian women undergoing this test. This is despite the introduction in Australia of a specific Medicare item number (MBS 66321) and rebate for the maternal serum screen. One of the reasons for this may be that antenatal care in Australian public hospitals is funded by state health departments, and only in Victoria and South Australia have public hospitals sanctioned the additional cost of introducing this test.

Recommendations for antenatal screening for Down syndrome in Australia are as follows:

> Early in pregnancy, all women should receive appropriate written information concerning available screening (including potential risks and benefits, the difference between screening and diagnostic testing and possible costs to women).
>
> The offer of screening for Down syndrome should be made available to all pregnant women, irrespective of age.
>
> Pre-screening counselling must be given by appropriately trained staff and should be specific to the age of each woman.
>
> If after counselling women choose to proceed with screening tests for Down syndrome:
>
> i Screening should include accurate pregnancy dating by ultrasound, preferably in the first trimester.
>
> ii Screening should be by either second trimester biochemistry or by nuchal translucency (alone or in combination with first or second trimester biochemistry).
>
> iii Women should be notified of their screening result, irrespective of the risk, in a format that they understand.
>
> iv Women who have an increased risk of Down syndrome should be offered further counselling and diagnostic testing within 72 hours or as soon as possible. (Three Centres Consensus Guidelines 2001)

In New Zealand, antenatal screening for Down syndrome has developed rapidly over the past 15 years. There is now a range of screening tests available, including:

- a first trimester blood test (not yet widely available in New Zealand), and /or

- a second trimester blood test (the Triple Test), a combination of three tests that measure quantities of various substances in the blood, usually done between 15 and 20 weeks of gestation (available but women pay $70 for this test) and/or
- an ultrasound scan at about 12 weeks for nuchal translucency (publicly funded). Women identified as 'high risk' following screening are offered invasive procedures, for example, chorionic villous sampling or amniocentesis. Both these diagnostic tests carry a small risk of fetal loss.

Development of diagnostic testing methods

When the first screening test for Down syndrome was introduced in the United Kingdom, approximately 5% of pregnant women were 35 years of age or older, and 30% of all Down syndrome births were to those women (Haddow 1998). The majority of children with Down syndrome are born to women who are younger than 35 years old. The identification of younger women with an increased risk became possible after Merkatz et al (1984) reported an association between a low alpha-fetoprotein level and fetal aneuploidy, launching an era of maternal serum screening to assess the risk of fetal Down syndrome. Subsequent studies showed that the maternal serum levels of three markers—alpha-fetoprotein (AFP), beta human chorionic gonadotrophin (β-hCG), and unconjugated oestriol (uE_3)—occurring between 15 and 22 weeks of gestation could be used to make adjustments to the risk based on maternal age alone (Mennuti et al 2003).

Antenatal screening for Down syndrome became possible because two components of diagnostic testing had developed to the level of clinical applicability. The first was a sampling procedure where cells were taken from the amniotic fluid (amniocentesis). Cells in amniotic fluid are fetal in origin and can be cultured for chromosome analysis. Amniocentesis was originally offered during the early second trimester and carried about a 1% risk of spontaneous fetal loss (Tabor et al 1986). The second diagnostic component that had reached clinical significance was cell culture and chromosomal analysis via karyotype. Karyotyping is still the preferred test method for most pregnancies, ascertained either through a screening program for Down syndrome or for other referral reasons. Karyotyping detects a range of numerical and structural chromosome abnormalities in addition to the common autosomal trisomies (13 (Patau's syndrome), 18 (Edwards' syndrome), and 21 (Down syndrome)) and sex chromosome abnormalities. However, since amniotic fluid and chorionic villus cells are cultured before analysis, delays of up to 14 days or longer can occur before a result is issued (Caine et al 2005). (Notwithstanding that this is currently recognised as among the most reliable diagnostic tests in clinical medicine (Haddow 1998). Culture failure is uncommon, and erroneous results from maternal cell contamination are rare (Haddow 1998).) This degree of reliability is crucial, since it forms the basis for decisions that have far-reaching consequences. During the past decade, emphasis has been placed on obtaining fetal cells earlier in gestation, by either chorionic villous sampling or earlier amniocentesis. Chromosome analysis via karyotype, however, continues to be the cornerstone of Down syndrome diagnosis (Haddow 1998).

After the landmark discovery in 1984 that AFP concentrations in maternal serum were lower in the presence of Down syndrome and could be used as a screening test (Cuckle et al 1984), screening began to be offered to pregnant women younger than age 35. The efficacy of screening with AFP was comparable to that based on maternal age (a 20–25% detection rate for a 5% false-positive rate), and since AFP was already being measured as a screening test for open spina bifida or neural tube defect, adding an interpretation for Down syndrome risk represented a negligible cost (Haddow 1998).

Further progress in screening was achieved later in the 1980s with the discoveries of hCG and uE_3. Measures of these markers were combined with that for AFP to produce a 'triple' test, capable of detecting 60% of Down syndrome pregnancies, at a 5% false-positive rate (Wald et al 1988). This substantial step-up in detection led many women over the age of 35 to choose serum screening rather than amniocentesis. More recently, the addition of a fourth serum marker, inhibin, has been shown to boost detection of Down syndrome to about 75% (Haddow 1998). With the advent of biochemical markers in combination with ultrasound, considerable attention was given in the 1990s to providing maternal serum screening earlier in gestation. Measurements of two markers—pregnancy-associated plasma protein A (PAPP-A) and either the free β subunit of hCG or hCG detected between 10 and 13 weeks gestation—have become nearly as efficient as the second-trimester 'triple' test (Haddow 1998). Studies in the 1990s showed an association between Down syndrome and increased nuchal translucency, a sonolucent space evident at the back of the fetus's neck in the first trimester. In 1995, Wald et al demonstrated the feasibility of first-trimester serum screening for Down syndrome (Wald et al 1995).

Screening combinations

The NICE Guidelines recommend the following screening combinations for Down syndrome:

- from 11 to 14 weeks:
  - nuchal translucency (NT)
  - 'combined' test (NT, hCG + PAPP-A)
- from 14 to 20 weeks:
  - 'double' test (hCG + AFP)

BOX 32.4 Serum markers

Abbreviations for serum markers:

- hCG = human chorionic gonadotrophin
- uE_3 = unconjugated oestriol
- AFP = alpha-fetoprotein
- PAPP-A = pregnancy-associated plasma protein A

- 'triple' test (hCG, SFP + uE_3)
- 'quadruple' test (hCG, AFP, uE_3 + inhibin A)
- from 11 to 14 weeks and from 14 to 20 weeks:
  - integrated test (NT, PAPP-A + hCG, AFP, uE_3, inhibin A)
  - serum integrated test (PAPP-A + hCG, AFP, uE_3, inhibin A) (NICE 2003, p 78).

The NICE Guidelines (2003) also state that:

> Antenatal screening for Down syndrome can take place during the first or second trimester of pregnancy and a variety of screening tests can be used.
>
> In the first trimester, nuchal translucency (NT), which is the measurement of the normal subcutaneous space between the skin and the cervical spine in the fetus early in pregnancy, can be used to identify women at increased risk of carrying a Down syndrome baby at around 10 to 14 weeks. Nuchal translucency may be used with or without two first-trimester maternal serum markers, human chorionic gonadotrophin (hCG) and pregnancy-associated plasma protein (PAPP-A), i.e. the combined test, or as part of the integrated test.
>
> In the early second trimester, screening techniques include biochemical marker screening at around 15 to 16 weeks. In these tests a risk assessment for Down syndrome is made based on the differences between observed and expected levels at 15 to 18 weeks of AFP, estriol and beta-hCG.
>
> Once a screening test is performed, the risk of Down syndrome is calculated, taking into account maternal age, gestational age and the levels of biochemical markers.
>
> Results are 'positive' or classified as 'high risk' if the risk is equal to or greater than a locally agreed cut-off level. This is often expressed numerically to indicate the likelihood that a woman has a baby with Down syndrome when a positive screening result is returned; e.g., a 1/250 chance that a pregnant woman is carrying an affected baby. When a high-risk screening result is returned, a woman will usually be offered a diagnostic test, such as amniocentesis, which has an excess fetal loss rate of 1% (NICE Guidelines 2003, pp 74–75).

Some women undergo chorionic villous sampling during the first trimester rather than screening or amniocentesis during the second trimester. Some women, such as those carrying multiple fetuses, are not candidates for second-trimester serum screening. Others decline screening because they do not wish to undergo prenatal diagnosis or would not consider pregnancy termination on the basis of the results. The anxiety experienced by friends or relatives who had a positive screening test followed by normal findings on amniocentesis deters some women from undergoing screening. Women who are 35 years of age or older increasingly opt to undergo serum screening and ultrasonography before deciding about amniocentesis. With the emergence of alternative approaches earlier in pregnancy, decisions about screening are becoming more complex.

Summary: screening for Down syndrome

- The screening tests involved in early or first trimester pregnancy screening for Down syndrome (DS) when the fetus is between 11 and 13 weeks gestation involve a nuchal translucency (NT) screen, which takes place within the context of a detailed ultrasound scan in addition to maternal serum screening.
- DS screening in the second trimester using a variety of combinations of maternal serum markers such as the so-called 'triple test' (hCG, uE and AFP) has become an established but controversial part of antenatal care over the past decade (Vassy 2005).
- Increasingly, however, first-trimester NT screening, particularly in combination with maternal serum screening with biochemical markers, is being proposed.
- 'Nuchal translucency' refers to the subcutaneous space between the skin and the cervical spine of the fetus. An increased NT is associated with an increased risk of aneuploidy, particularly trisomies 21 (Down syndrome), 18 (Edwards' syndrome) and 13 (Patau's syndrome).
- With the advent of DS screening in the first trimester and the application of nuchal translucency measurements (NT screening) at 10–14 weeks gestation, the potential impact of combining maternal age with fetal nuchal translucency thickness and maternal serum free β-hCG and PAPP-A seems to be increasing.
- One of the latest additions to the proliferation of screening technologies is the association of increased nuchal thickness with congenital heart defects (Ray et al 2005).

Figure 32.3 illustrates the rates of use of various diagnostic tests for Down syndrome.

What to tell women

Down syndrome is caused by the presence of an extra chromosome in a baby's cells. It occurs by chance at conception and is irreversible. Women are offered screening tests to check whether their baby is likely to have Down syndrome. You must be able to spend time explaining the implications of Down syndrome, the tests you are offering and what the results may mean. Each woman has the right to choose whether to have all, some, or none, of these tests. Each woman must be aware that she is under no obligation to have any test—and that the decision to have them must be her and her family's decision. It should be explained how to 'opt out' of the screening process at any time if she wishes. Screening tests will only indicate that a baby *may* have Down syndrome. If the screening test results are positive, the woman should be offered further diagnostic tests to confirm whether her baby does in fact have Down syndrome. The time at which the woman is tested will depend on what kinds of tests are used. Screening tests for Down syndrome are not always right. They can sometimes wrongly show as positive, suggesting that the baby does have Down syndrome when in fact it does not. This type of result is known as a 'false positive'. The number of occasions on which this happens with a particular test is called its 'false-positive rate'. The screening tests available at present have a false-positive rate of less than 5 out of 100 and detect at least 60 out of 100

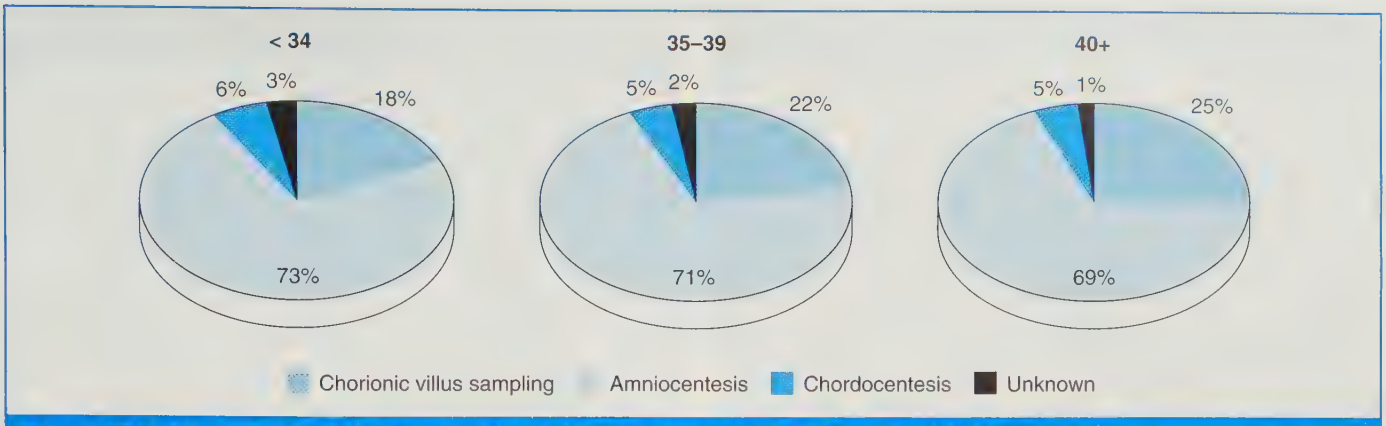

Figure 32.3 Diagnostic tests for Down syndrome (percentages) (based on Botto et al 2000)

cases of Down syndrome. The tests that meet this standard are:

- from 11 to 14 weeks:
  - nuchal translucency (an ultrasound scan)
  - combined test (an ultrasound scan and blood test)
- from 14 to 20 weeks:
  - triple test (a blood test)
  - quadruple test (a blood test)
- from 11 to 14 weeks and 14 to 20 weeks:
  - integrated test (an ultrasound scan and blood test)
  - serum integrated test (a blood test).

Use of maternal age as a primary criterion for offering amniocentesis results in very high rates of use of this invasive test and is a suboptimum use of resources. Every woman's choice to accept or reject chorionic villus sampling or amniocentesis should be based on counselling that uses the best possible estimate of her personal risk for fetal aneuploidy. Policy advisory groups in other countries should follow the UK initiative and abandon obsolete guidelines that have advocated offering amniocentesis to all women aged 35 or more, without routinely incorporating serum and ultrasound screening into their risk assessment (Benn 2003).

Birth anomalies remain a significant public health problem in Australia and are a major reason for admission to hospital during infancy and childhood. They often result in disabilities and handicaps and, in some cases, death (AIHW 2002). An estimated 5% of all Australian births and terminations of pregnancy have a major birth anomaly (Stanley et al 1995) and birth anomalies account for about 13% of the disease burden for children aged 0–14 years (AIHW 1999). Birth anomalies are also a leading cause of infant mortality in Australia, with 25% of infant deaths in 2000 caused by birth anomalies (Al-Yaman et al 2002).

Birth anomalies are caused by genetic (including chromosomal), environmental and unknown factors, or combinations of these factors. It is estimated that the cause of about 65–75% of birth anomalies is unknown. About 15–25% of birth anomalies have a genetic cause and about 10% have an environmental cause (AIHW 2004; Brent 2001).

TABLE 32.2 Expected detection rates and false-positive rates for various second-trimester protocols applied to 1999 US pregnant population

Screening protocol	Detection rate (%)	False positive rate (%)
Maternal age alone (≥ 35 years)	49	13.1
Second trimester, maternal age, plus:		
MSAFP + hCG	73	9.6
MSAFP + uE_3 + hCG	78	7.8
MSAFP + hCG + INH-A	82	6.9
First trimester, maternal age, plus:		
NT	74	5.1
PAPP-A + free β-hCG	75	8.6
NT + PAPP-A + free β-hCG	86	4.2
First and second trimester, maternal age, plus:		
PAPP-A + MSAFP + uE_3 + hCG + INH-A	87	4.9
NT + PAPP-A + MSAFP + uE_3 + hCG + INH-A	93	2.6

Future fetal diagnosis

The introduction of new screening and surveillance measures continues at such a pace that it is beyond the scope of this text to inform readers of the very latest techniques. However, one of the more promising areas of screening, although still very much in the research arena, is the analysis of fetal cells and fetal DNA and RNA from the maternal circulation. It is speculated that new technologies involving sampling maternal plasma with cell-free fetal DNA may play a bigger role in

BOX 32.5 Screening for CHD

Congenital heart defect (CHD) is more prevalent than Down syndrome, with a reported worldwide frequency of 4–9 of every 100 births (Ray et al 2005). There is no clear consensus on the definition of CHD (Ray et al 2005); however, it is defined pragmatically as a cardiac defect that could potentially require surgical intervention, intensive medical therapy or prolonged follow-up after birth. Ray and colleagues (2005) observed that less than one-third of cases with increased nuchal translucency have chromosomal abnormality. This is an area of screening in its infancy at present. However, as more biomarkers are established and our preoccupation with reproductive perfection continues, the possibilities are unimagined.

non-invasive prenatal genetic diagnosis of aneuploidy by helping to identify pregnancies at sufficient risk for trisomy 21 or 18 without women having to undergo an invasive diagnostic procedure for definitive diagnosis. This new process of risk identification may avert the need for prenatal genetic diagnosis requiring invasive procedures such as amniocentesis or chorionic villous sampling. Circulating fetal DNA has also been targeted as a marker for assessing feto-maternal wellbeing. Increased fetal DNA concentrations have been reported for several pregnancy-related complications including pre-eclampsia. So far, various forms of circulating DNA in plasma have been observed: shed cells, apoptotic bodies, nucleosomes, other nucleoproteins and free DNA (Bischoff et al 2005).

Screening for genetic disorders (muscular dystrophy)

The muscular dystrophies are a group of inherited disorders characterised by progressive muscle wasting and weakness. A unifying feature of the dystrophies is the histological analysis of muscle samples, which typically includes variations in fibre size, areas of muscle necrosis and, ultimately, increased amounts of fat and connective tissue. The diagnosis therefore requires a muscle biopsy (generally a needle biopsy under local anaesthesia) and possibly electromyography (Emery 1998).

Newborn screening for genetic and other disorders is usually confined to diseases for which there is treatment—either a change of diet (as in phenylketonuria and galactosaemia) or replacement therapy (as in hypothyroidism)—or in which there is a chance of affecting morbidity or mortality early in life, as occurs in the haemoglobinopathies (particularly sickle cell disease). Screening for disorders in which the clinical course cannot be altered is generally avoided: a program of newborn screening for disorders like Duchenne muscular dystrophy could therefore create an ethical nightmare.

Ethical dilemma

Is it justifiable to offer newborn screening for a potentially untreatable genetic disorder?

For Some would argue that newborn screening for Duchenne muscular dystrophy decreases emotional distress because it avoids delays in diagnosing the disease, and without screening two or more boys could be born with the condition before the parents realised that they were at risk of having an affected child. Accordingly, if an infant with Duchenne muscular dystrophy is identified early, the family has the option of prenatal diagnosis for future pregnancies.

Against On the other hand, neonatal diagnosis could interfere with normal emotional growth and the child's interaction with his family.

Screening newborn infants

Duchenne muscular dystrophy is a severe X-linked inherited recessive disorder that occurs in around 1 in 3500 baby boys (Emery 1998). There may be no family history of the disorder, as the large gene responsible for it is prone to mutation, but even so, subsequent sons are at risk. It is a serious condition, with progressive muscle wasting and weakness, which causes most boys to require wheelchairs by age 12 and to die in their twenties. Up to a third of boys with Duchennetype dystrophy have some degree of intellectual impairment, and in severe cases special schooling may have to be considered. Beckertype muscular dystrophy is clinically similar but milder, with onset in the teenage years or early twenties. Loss of the ability to walk may occur later and many individuals with Beckertype dystrophy survive into middle-age and beyond (Emery 1998).

Screening of newborns for Duchenne muscular dystrophy by measurement of blood spot creatine kinase activity has

BOX 32.6 Muscular dystrophies

- At least 1 in 3000 people are affected by a serious inherited neuromuscular disorder; the muscular dystrophies make up an appreciable proportion of these.
- Histological examination of muscle tissue and electromyography are used in the diagnosis of muscular dystrophy to exclude other causes of muscle wasting and weakness, such as spinal muscular atrophy, myopathies, and neuropathies.
- On the basis of clinical and molecular genetic studies, C-linked (Duchenne) type and at least two other types of muscular dystrophy are recognised.
- A precise diagnosis is essential in order to provide a reliable prognosis and accurate genetic counselling.

(Source: Emery 1998)

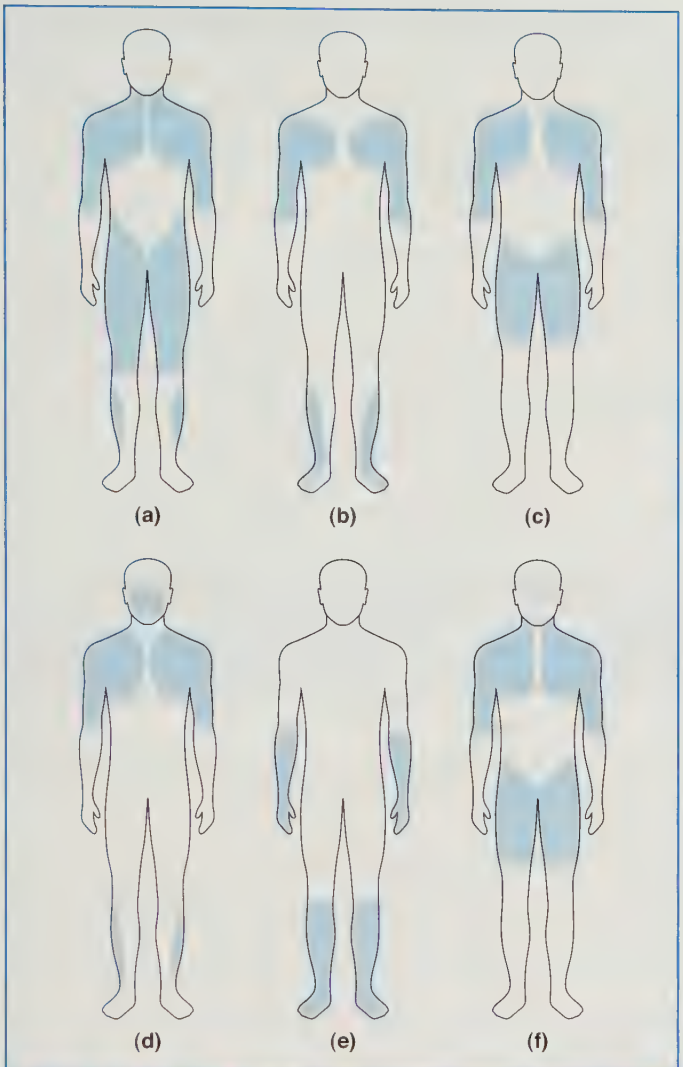

Figure 32.4 Distribution of predominant muscle weakness in different types of dystrophy: (a) Duchennetype and Beckertype (b) EmeryDreifuss (c) Limb girdle (d) Facioscapulohumeral (e) Distal (f) Oculopharyngeal (based on Emery 1998)

been technically possible since a suitable assay was devised in the mid-1970s (Bowman 1993). It is offered on a limited basis in Germany, and as a routine service in Lyons, France, and Antwerp, Belgium. Before the advent of molecular genetics, screening of newborns in the United Kingdom was generally regarded as ethically unsound because no treatment was available; it offered little advantage to the family other than the possibility of terminating all subsequent male fetuses, more than half of whom would be normal. With the isolation of the gene responsible for Duchenne muscular dystrophy it became possible to track the defective gene and to offer increasingly accurate prenatal diagnosis either by deletion analysis in many cases or by using linked markers. Consequently, although the condition was still untreatable, the neonatal identification could facilitate reproductive choice in further pregnancies in the immediate and extended family. This led to a reassessment of the ethical issues surrounding newborn screening. The common clinical experience of diagnosing two (or occasionally more) affected boys simultaneously in a single family has to be weighed against the availability of prenatal diagnosis in future pregnancies once the first case has been identified. In addition, diagnostic delay causes considerable distress to families and may result in subsequent bitterness if the child's symptoms are not taken seriously by family or health professionals, or if a second affected boy is born. Despite such considerations, there has been concern that a neonatal diagnosis would interfere with the normal social and emotional growth and interaction of child and family (Bradley et al 1993).

Screening for infections

Asymptomatic bacteriuria

Asymptomatic bacteriuria is defined as a pure culture of at least 10^5 organisms/mL of urine. Detection of all women with asymptomatic bacteriuria is important as 25% to 30% will develop symptomatic urinary tract infection while pregnant. The sequelae of urinary tract infection in pregnancy include pyelonephritis, premature labour and preterm rupture of the membranes. In view of the potential importance of asymptomatic bacteriuria it is current best practice to send a urine sample for laboratory analysis from all women who book for antenatal care (Tincello & Richmond 1998).

According to the *Three Centres Consensus Guidelines* (2001):

> Early in pregnancy, all women should be given appropriate written information about this test and be given an opportunity to discuss it with their midwife or doctor. All pregnant women should be offered screening at booking or in early pregnancy for asymptomatic bacteriuria using either a two-step protocol or microscopy and culture of a fresh mid-stream urine sample.
>
> If using a two-step protocol, women should provide a mid-stream urine sample at the first antenatal visit that is screened for blood, protein, nitrites and leukocyte esterase using a reagent strip. If there is a positive result in any of the four categories the sample should be sent for microscopy and culture.
>
> If midwives and doctors routinely screen for asymptomatic bacteriuria using microscopy and culture then they may also need to screen women for chronic renal disease (CRD) using dipstick testing, as CRD will not be picked up by culture alone (Three Centres Consensus Guidelines 2001, p 23).

What to tell women

Asymptomatic bacteriuria is a bladder infection that has no symptoms. Identifying and treating it can reduce the risk of premature birth (NICE 2003).

Asymptomatic bacterial vaginosis

Bacterial vaginosis (BV) is characterised by a changed vaginal microflora in which the normally occurring lactobacilli yield to an overgrowth of a mixed anaerobic bacterial flora. Whether it occurs spontaneously as an ecological imbalance in the

vaginal flora, and its role in both genital tract infection and in pregnancy outcome, have been the subject of study since the 1980s and still remain an enigma (Larsson et al 2005). Routine screening of all pregnant women for BV is not recommended (Kirkham et al 2005).

As BV is a possible cause of pregnancy complications as well as being socially unacceptable and disturbing for affected women, there are good reasons for finding a cure (Larsson et al 2005). The efficacy of yoghurt in treating bacterial vaginosis compared with vaginal metronidazole and vaginal placebo was tested in a trial in 1998 (Thiagarajan 1998). Although metronidazole was the most effective treatment against persistence of infection (relative risk reduction 62%, 95% CI 50–72%), yoghurt was two-thirds as effective as metronidazole when compared with the placebo group (relative risk reduction 46%, 95% CI 31–58%) (Thiagarajan 1998).

Generally speaking, treatment for BV is more effective during pregnancy because pregnant women do not menstruate and it appears that BV tends to recur during a menstrual period. Spontaneous cure among pregnant women has been noted (Larsson & Forsum 2005).

Around a dozen studies have investigated the likelihood of reducing spontaneous preterm delivery through a variety of treatments and regimens prescribed for women with BV (Larsson & Forsum 2005).

During the past 15 years there has been ongoing discussion concerning the epidemiological correlation between various complications during pregnancy and BV. Today it is clear that BV doubles the risk of spontaneous preterm birth. A meta-analysis by Leitich et al (2003) indicates that BV increases the risk of preterm delivery more than twofold (odds ratio (OR) 2.19, 95% CI 1.54–3.12). Higher risks were calculated for subgroups of studies that screened for BV at 16 weeks gestation (OR 7.55, 95% CI 1.80–31.65) or 20 weeks gestation (OR 4.20, 95% CI 2.11–8.39).

BV also significantly increases the risk of spontaneous abortion (OR 9.91, 95% CI 1.99–49.34) and maternal infection (OR 2.53, 95% CI 1.26–5.08) (Leitich et al 2003).

A recent systematic review concluded, however, that for women with bacterial vaginosis, antibiotics reduced the risk of persistent infection but did not reduce the risk of preterm birth or the incidence of associated adverse outcomes for the general population or for any subgroup analysed. For women with *Trichomonas vaginalis*, metronidazole reduced the risk of persistent infection but increased the incidence of preterm birth. Contrary to the conclusions of recent systematic reviews, there was no evidence to support the use of antibiotic treatment for bacterial vaginosis or *T. vaginalis* in pregnancy to reduce the risk of preterm birth or its associated morbidities in low- or high-risk women (Okun et al 2005)

Screening and treating healthy pregnant women (i.e. low risk for preterm birth) for asymptomatic bacterial vaginosis does not appear to lower the risk for preterm birth or other adverse reproductive outcomes. Pregnant women should not be offered routine screening for bacterial vaginosis because the evidence suggests that the identification and treatment of asymptomatic bacterial vaginosis does not lower the risk for preterm birth and other adverse reproductive outcomes (NICE 2003, p 83).

For women with a previous preterm birth, there is some suggestion that treatment of bacterial vaginosis may reduce the risk of preterm prelabour rupture of membranes and low birthweight (McDonald et al 2003).

Chlamydia trachomatis

Chlamydia trachomatis is a sexually transmitted infection. Mother-to-child transmission can occur at the time of birth and may result in ophthalmia neonatorum or pneumonitis in the newborn (Brocklehurst & French 1998).

In Australia, notification rates for chlamydia have increased fourfold since the early 1990s, with the greatest rises seen among adolescents and young adults (Chen & Donovan 2004). In New South Wales, legislation was introduced in 1998 that made the reporting of *C. trachomatis* by laboratories mandatory. Chlamydia notifications in New South Wales increased in parallel with national rates—from 39 per 100 000 population in 1999 to 88 per 100 000 in 2002 (National Centre in HIV Epidemiology and Clinical Research 2004). The extent to which these increases in chlamydia notifications represent a true rise in chlamydia incidence is uncertain: ecological studies suggest that the higher notification rates also reflect increased chlamydia testing (Chen & Donovan 2004; Chen et al 2005; Hocking et al 2003).

The rise in chlamydia notifications could largely have been the result of increased chlamydia testing. More extensive use of nucleic acid amplification tests may also have contributed. In recent years, chlamydia testing rates have increased steadily throughout Australia, with strong correlations between the intensity of testing and detection rates for *C. trachomatis*. Despite this, overall testing rates are still low, with the great majority of infections remaining undetected. This makes it difficult to know what the true incidence and prevalence of chlamydia is in the Australian population (Chen et al 2005).

Chlamydia infection during pregnancy is associated with higher rates of preterm birth (OR 1.6, 90% CI 1.01–2.5) and intrauterine growth restriction (OR 2.5, 90% CI 1.32–4.18). Left untreated, it has also been associated with increased low birthweight and infant mortality. In a review of randomised control trials, the number of women with positive cultures for *Chlamydia* was reduced by 90% when treated with antibiotics compared with placebo (OR 0.06, 95% CI 0.03–0.12). However this did not alter the incidence of birth before 37 weeks (NICE 2003, p 83).

In industrialised countries, *C. trachomatis* is the predominant infectious agent causing pelvic inflammatory disease (PID), and as a result of damage to the fallopian tubes, accounts for up to half of all ectopic pregnancies. The substantial financial costs of genital chlamydial infections result from hospital treatment for PID, ectopic pregnancy, and infertility, which may include in vitro fertilisation.

Screening should be offered to women at increased risk for sexually transmitted infections (STIs), including those younger than 25 years. There is currently no evidence to

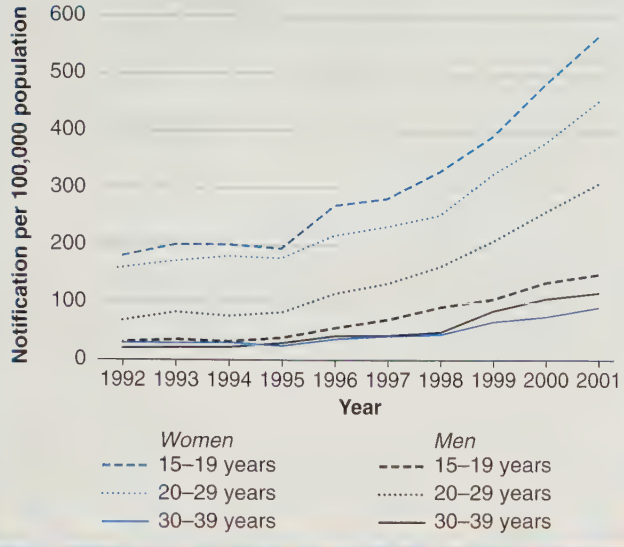

Figure 32.5 Notification rates for genital *Chlamydia trachomatis* infection in women and men by age group, Australia, 1992–2001 (based on National Centre in HIV Epidemiology and Clinical Research)

support universal screening of pregnant women for chlamydial infection. High-risk groups include women younger than 25 years; unmarried women; women with a history of STIs, new or multiple sexual partners, inconsistent use of barrier contraception; and women living in communities with high infection rates. Affected women and their partners should be treated. The optimal testing time is uncertain, but most authors recommend testing at the first prenatal visit and again in the third trimester for high-risk patients (Kirkham et al 2005).

In several remote areas in Australia, nucleic acid testing for gonorrhoea and chlamydia has been used (since 1996) and requires collection of first-void urine and an endocervical swab. Since mid-2001, self-obtained lower vaginal swabs have been available and recommended for STI screening in situations where the woman is asymptomatic, not a sexual contact of STI and does not require a Papanicolaou smear (Mak et al 2003).

Syphilis

Syphilis is a sexually acquired infection caused by *Treponema pallidum*. The body's immune response to syphilis is the production of non-specific and specific treponemal antibodies. The first notable response to infection is the production of specific anti-treponemal immunoglobulin M (IgM), which is detectable towards the end of the second week of infection. By the time symptoms appear, most people infected with syphilis have detectable levels of immunoglobulin G (IgG) and IgM.449 (NICE 2003, p 91).

Syphilis may also be asymptomatic and remain latent for many years. The availability of penicillin reduced the prevalence of syphilis significantly from 1950 onwards and the disease is rarely seen in either New Zealand or Australia. In the United Kingdom the incidence of infectious syphilis is also low. In the United States, an 'epidemic' of congenital syphilis was reported by the Centers for Disease Control in 1994, with rates increasing from 4.3/100 000 live births in 1982 to 94.7/100 000 in 1992 (CDC 1994).

Infectious syphilis is a disease of considerable public health importance, with overwhelming health effects if not treated in pregnancy. These include adverse pregnancy outcomes, such as stillbirth and congenital syphilis. Further, concurrent infection with syphilis can facilitate transmission of HIV (Doherty et al 2002). Syphilis has disproportionate effects on vulnerable or disadvantaged populations and on people involved in high-risk activities such as illicit drug use, sex work, unprotected intercourse, and sex with multiple partners (NICE 2003). Syphilis is most infectious through sexual contact during the primary or secondary stages, but transmission can also occur during the early latent stage (Doherty et al 2002).

Syphilis is preventable, and treatable with effective and inexpensive antibiotics. The possible resurgence of infectious syphilis, a disease previously believed to be close to eradication, is a matter of increasing global concern (Doherty et al 2002).

In pregnant women with early untreated syphilis, 70% to 100% of infants will be infected and one-third will be stillborn. Mother-to-child transmission of syphilis in pregnancy is associated with neonatal death, congenital syphilis (which may cause long-term disability), stillbirth and preterm birth.

According to the Three Centres Guidelines for Australia (2001):

> Early in pregnancy all women should receive appropriate written information about antenatal syphilis testing and be given the opportunity to discuss it with their midwife or doctor. Antenatal serological screening for syphilis should be offered to all pregnant women.
>
> Screening for syphilis should be undertaken at the first antenatal visit, ideally prior to 16 weeks' gestation. Syphilis has significant long-term morbidity for mothers and can seriously complicate pregnancy, resulting in spontaneous abortion, stillbirth, nonimmune hydrops, intrauterine growth restriction, malformations and perinatal death. Congenital syphilis results in serious sequelae in live born infected children. Screening pregnant women for syphilis and treating them appropriately can eliminate complications. The evidence available indicates that screening for syphilis should be part of routine antenatal care. Universal screening programs have been shown to significantly increase the detection of pregnant women who have syphilis compared with selective screening of women considered to be a high risk (Three Centres Consensus Guidelines 2001, p 36).

What to tell women

Syphilis is a rare STI that can also be passed from a mother to her baby. Mothers and babies can be successfully treated if it is detected and treated early. A person with syphilis may show no symptoms for many years. A positive test result does not always mean you have syphilis, but your healthcare providers

should have clear procedures for managing your care if you test positive (NICE 2003).

Cytomegalovirus

Cytomegalovirus (CMV) is a member of the herpes virus family. It is the most common cause of intrauterine viral infection and sensory neural deafness (Stagno & Whitley 1985). It remains latent in the host after primary infection and may become active again, particularly during times of compromised immunity.

At present, antenatal screening for this condition is thought to be inappropriate, as it is not currently possible to determine accurately which pregnancies are likely to result in the birth of an infected infant. There is no way to determine which infected infants will have serious sequelae, there are no currently available vaccines or prophylactic therapy for the prevention of transmission and no way to determine whether intrauterine transmission has occurred (NICE 2003, p 84).

In both the United States and Western Europe, CMV infection is the most common viral form of congenital infection. Intrauterine transmission of CMV takes place in approximately 40% of infections, and approximately 10% of live-born infants have symptomatic disease at the time of birth and later. Late sequelae such as sensorineural hearing loss and neurodevelopmental disorders occur in 10% to 15% of infants lacking symptoms at birth. Recurrent maternal infection contributes substantially to the rate of congenital infection (Daiminger et al 2005).

The available evidence does not support routine CMV screening in pregnant women and it should not be offered (NICE 2003, p 84).

Hepatitis B virus

The aim of screening pregnant women for hepatitis B virus (HBV) is to prevent the transmission of the virus to their children. Acute hepatitis B can cause morbidity and mortality. Perinatal infection can be prevented by prompt immunoprophylaxis at birth. The incidence of HBV is falling among infants and adults following the introduction of protocols for handling blood products, combined with immunisation and health-promotion strategies. Existing evidence supports universal screening of pregnant women for hepatitis B surface antigen by a combined prenatal and perinatal approach. This combined approach is encouraged in Australia, where antenatal hepatitis B screening is accepted practice, and the NHMRC recommends that all newborn

BOX 32.7 Viral transmission in pregnancy

The ability of viruses to spread from the infected mother to the fetus arises from the structure of the placenta, which anchors the fetus to the uterus. The human placenta is composed of villi that float in maternal blood and also villi within the uterine wall that anchor the placenta and attach the fetus to the mother.

The individual chorionic villus contains a connective core that contains fetal blood vessels and numerous macrophages (Hofbauer cells) that often lie under a thick basement membrane, depending on their location. In floating villi, they fuse to form a multinucleate syncytiotrophoblast covering attached at one end to the tree-like fetal portion of the placenta. The rest of the villus floats in a stream of maternal blood, which optimises the exchange of substances between the mother and fetus across the placenta. In the pathway that gives rise to anchoring villi, which attach the placenta to the uterine wall, cytotrophoblasts aggregate into cell columns of non-polarised mononuclear cells that attach to and penetrate the uterine wall. The ends of the columns terminate within the superficial endometrium, where they give rise to invasive cytotrophoblasts.

Placental cytotrophoblasts differentiate, assume an endothelial phenotype, breach uterine blood vessels and form a hybrid vasculature that amplifies the maternal blood supply for fetal development. Human cytomegalovirus (CMV), the major cause of congenital disease, infects the uterine wall and the adjacent placenta, suggesting adaptation for pathogen survival in this microenvironment.

(Source: Pereira et al 2005)

TABLE 32.3 Intrauterine viral transmission

Virus	Mode/rate of transmission
CMV	Prenatal infection affects 1–2% of live births. Virus replicates in the uterus, infects the placenta, then is transmitted to the fetus. Transmission rate approx 50% in women with primary infection.
HSV 2	Infrequent prenatal infection. Transmission occurs primarily at the time of birth (80%) and also possibly through an ascending infection after the membranes rupture.
HIV	Transmission primarily at the time of birth. Isolated cytotrophoblasts infected in vitro.
HBV	Transmission primarily perinatal. Some intrauterine infection from maternal blood (5%).
HCV	Intrauterine infection and at birth (2–12%).
Parvovirus B19	Placental infection associated with inflammatory cytokines. Complications in early gestation.
Rubella virus	Placental infection during primary maternal infection. Transmission in first trimester (80%) and second trimester (25%).
HPV	Infection via maternal genital secretions at birth.
Varicella zoster virus	Congenital infection low (2%). Transmission during primary infection in late gestation (25–50%).

(Source: Pereira et al 2005)

infants be offered immunisation (Three Centres Consensus Guidelines 2001, p 27).

Women should be offered a screening test for HBV early in pregnancy. The optimal time for screening appears to be at the first antenatal visit. There is no evidence to support repeat screening in the third trimester or that a repeat test for hepatitis B in late pregnancy will result in increased detection of hepatitis B.

Screening for active hepatitis B infection with hepatitis B surface antigen (HbsAg) is recommended at the first prenatal visit so that postnatal intervention can be offered to decrease mother-to-child transmission. Women at increased risk of acquiring hepatitis B can be vaccinated safely during pregnancy and should be screened again for surface antigen before they give birth (ACOG 2002). Women who were not screened during pregnancy and those at increased risk should be tested at the time of giving birth (Kirkham et al 2005, p 1557).

What to tell women

Hepatitis B virus is a potentially serious infection that can affect the liver. Many people have no symptoms, however. It can be passed from a mother to her baby (through blood or body fluids), but may be prevented if the baby is vaccinated at birth. The infection can be detected in the mother's blood.

Hepatitis C virus

Hepatitis C is a blood-borne viral liver infection. It is a slowly progressive disease with long-term sequelae, including cirrhosis and hepatocellular carcinoma. During 1999 the incidence of infection among pregnant Australian women was estimated at 13 per 1000. An estimated 55% of these women were diagnosed prior to pregnancy and 19% during pregnancy (Three Centres Guidelines 2001, p 30). As one of the major causes of liver cirrhosis, hepatocellular carcinoma and liver failure, hepatitis C virus (HCV) is a major public health concern. Hepatitis C antibody screening should be offered to women with risk factors (e.g. prison inmates, injection drug users, women exposed to blood or blood products, HIV-positive women, women with elevated aspartate transaminase levels, multiple sexual partners, or tattoos). Aside from the risk of vertical transmission, estimated as 6% if a woman is HCV RNA positive (Dore et al 1997), and negligible if she is HCV RNA negative, there does not appear to be an increased risk of adverse pregnancy outcomes in women infected with hepatitis C (Boucher & Gruslin 2005; Kirkham et al 2005, p 1557).

Human immunodeficiency virus (HIV)

The first recognised cases of the acquired immune deficiency syndrome (AIDS) occurred in the summer of 1981 in the United States. Reports began to appear of *Pneumocystis carinii* pneumonia and Kaposi's sarcoma in young men, who, it was subsequently realised, were both homosexual and immunocompromised. Even though the condition became known early on as AIDS, its cause and modes of transmission were not immediately obvious. The virus now known to cause AIDS in a proportion of those infected was discovered in 1983 and given various names. The internationally accepted term is now the human immunodeficiency virus (HIV). Subsequently a new variant has been isolated in patients with West African connections—HIV2 (Adler 2001, p 1226).

Infection with HIV begins with an asymptomatic stage, with gradual compromise of immune function eventually leading to AIDS. The time between HIV infection and development of AIDS ranges from a few months to as long as 17 years in untreated patients (NICE 2003, p 86).

In the absence of intervention, mother-to-child transmission (MTCT) may occur in one in four births to infected mothers in Europe or the United States, and 25% to 40% in Africa and Asia (Mohlala et al 2005). This figure may be substantially reduced following antiretroviral treatment, and a combination of interventions (i.e. combination antiretroviral therapy, caesarean section and avoidance of breastfeeding) can further reduce the risk of transmission to 1% (NICE 2003, p 86). It is estimated that up to 30% of MTCTs, with the exclusion of those due to breastfeeding, occur in utero, with the remainder occurring intrapartum (Minkoff et al 2003). The most potent predictors of perinatal HIV transmission are maternal HIV-1 load (viral load), severity of maternal disease (European Collaborative Study 1992), prolonged rupture of the amniotic membranes, and mode of delivery (Landesman et al 1996).

Several studies have demonstrated that giving birth by elective caesarean section before rupture of the amniotic membranes or the onset of labour, as well as the administration of zidovudine or nevirapine during the peripartum period, reduces MTCT significantly (Mohlala et al 2005).

The possible mechanisms responsible for vertical transmission during the peripartum period include transplacental micro transfusions of maternal blood into the fetal circulation during contractions, labour, and separation of the placenta before clamping of the umbilical cord; ascending infection from the vagina through the cervix after rupture of the amniotic membranes, which infects the amniotic fluid;

TABLE 32.4 Global transmission of AIDS

Type of exposure	Percentage of global total
Blood transfusion	3–5
Perinatal	5–10
Sexual intercourse	70–80
Vaginal	60–70
Anal	5–10
Injecting drug use (sharing needles etc)	5–10
Health care (needlestick injury, etc)	< 0.01

(Source: Adler 2001)

Clinical point

What should we say to women?

A study of all obstetricians and members of the RANZCOG in 2003 found that the percentage of respondents who always discuss the risk of transmission of hepatitis B through breastfeeding is 55.4%. The percentage of respondents who always discuss the risk with patients infected with hepatitis C is slightly higher at 67% and for HIV it is 82%.

More women are being offered hepatitis C screening than HIV despite a lack of evidence for effective interventions during labour to reduce perinatal transmission of hepatitis C.

Many women are not being asked about risk factors for exposure to these viruses. Only approximately one-third of obstetricians would alter their clinical practice and recommend caesarean section and avoid rupture of membranes in women infected with HIV despite evidence that this reduces perinatal transmission.

(Source: Giles et al 2003)

BOX 32.8 HIV in New Zealand

An estimated 56,000 women give birth in New Zealand each year. The risk of transmission from a mother with HIV to her baby can be reduced from as high as 31.5% to less than 2% if the mother uses a combination of interventions and treatment (Dorenbaum et al 2002; Duong et al 1999).

If a universal offer of antenatal screening was the policy in New Zealand then on an annual basis approximately 55,000 pregnant women would be tested for HIV (based on live births rather than total number of pregnancies). Nearly all pregnant women with HIV infection would be detected by the first test.

If all infected pregnant women were detected through antenatal screening:

- an additional 4–18 women would be diagnosed with HIV annually
- if interventions to prevent transmission were taken up by all of these women, it is estimated that on average 1–4 perinatal infections could be prevented annually (Dickson et al 2002).

The incidence of HIV is rising in New Zealand. There were 136 new cases of HIV in New Zealand in 2002, and in 2003 there were 188 new HIV cases—this was a 44% rise in the number of new infections in those two years.

HIV is increasingly affecting women. Between 1996 and 2002, 24% of newly diagnosed infections in New Zealand were in females. The women diagnosed with HIV in New Zealand are disproportionately from parts of the world where heterosexual transmission is relatively common, with 74% of HIV cases among women in New Zealand since 1996 acquired overseas—44% in Africa and 17% in Asia.

Each HIV test costs $14.70 but there are associated costs to run an effective screening program.

(Source: National Advisory Committee on Health and Disability (National Health Committee) 2004)

and absorption of the virus through the infant's immature digestive tract. Microtrauma to the fetal skin during birth, with exposure to blood and infected cervicovaginal secretions, may also be responsible for transmission of the virus. It is also possible that fetal exposure to HIV-infected amniotic fluid or to the cells that are found within amniotic fluid before rupture of the amniotic membranes could be responsible for a proportion of vertical transmission in utero (Mohlala et al 2005).

The most common way to diagnose HIV infection is by a test for antibodies against HIV-1 and HIV-2. HIV antibody is detectable in at least 95% of patients within three months of infection. Early HIV diagnosis improves outcomes for the mother and can reduce the rate of disease progression.

Pregnant women should be offered screening for HIV infection early in antenatal care because appropriate antenatal interventions can reduce MTCT of HIV infection (Kirkham et al 2005). In addition, all women should receive appropriate written information about antenatal HIV testing and be given an opportunity to discuss it with their midwife or doctor. Women at increased risk for HIV infection should be retested in the third trimester of pregnancy (Kirkham et al 2005; CDC 2002). Testing should be voluntary and done with informed consent (Kirkham et al 2005). A positive result should be verified through a second blood test. Women should be notified as soon as the result is verified and offered post-test counselling. The diagnosis should be delivered personally in a sensitive, supportive manner, allowing sufficient time for questions. Results should never be communicated by telephone, answering machine or through a receptionist. During post-test counselling, women's understanding of a positive diagnosis should be explored and further discussion of features of the illness, diagnostic procedures and medical care may be necessary. Referrals to clinical, social and welfare services should be offered and women should know how to access support groups (Three Centres Guidelines 2001, p 33).

A system of clear referral paths should be established so that pregnant women who are diagnosed with an HIV infection are managed and treated by the appropriate specialist teams (NICE 2003, pp 86–87).

RANZCOG recommends that all women be offered HIV testing after appropriate counselling. In contrast, the Australian National Council on AIDS, HCV and Related Diseases (ANCAHRD) advocates the selective offer of testing.

In Australia it appears that approximately half of practitioners offer HIV testing to all pregnant women in their care. The vast majority of these women are tested. The other half of practitioners offer testing on the basis of exposure assessment or on request, and as a result, only a small minority of women undergo testing. The prospect of

universal screening in Australia has raised concerns about cost-effectiveness, testing without informed consent, provision of pre- and post-test counselling and discrimination against women found to be positive in a population (Three Centres Guidelines 2001, p 34).

What to tell women

HIV usually causes no symptoms at first but can lead to AIDS. HIV can be passed from a mother to her baby, but this risk can be greatly reduced if the mother is diagnosed before the birth. The infection can be detected through a blood test. If the woman is pregnant and is diagnosed with HIV she should receive specialist care.

Rubella

Detection of rubella does not protect against MTCT in the current pregnancy. However, protection of subsequent pregnancies against the rubella virus will prevent future MTCT of rubella and reduce the risk of stillbirth and miscarriage due to rubella infection (NICE 2003, p 88).

Vaccination during pregnancy is contraindicated because of fears that the vaccine could be teratogenic. Screening for the rubella antibody in pregnancy helps to identify susceptible women so that rubella vaccination can be offered post partum to protect future pregnancies.

Rubella susceptibility screening should be offered early in antenatal care to identify women at risk of contracting rubella infection and to enable vaccination in the postnatal period for the protection of future pregnancies.

What to tell women

Screening for German measles (rubella) is offered so that if you are not immune you can choose to be vaccinated after you have given birth. This should usually protect you and future pregnancies. Testing you for rubella in pregnancy does not aim to identify it in the baby you are carrying (NICE 2003).

Herpes simplex virus

Both herpes simplex virus (HSV) type 1 and HSV type 2 can cause genital herpes. Because the infection is chronic, genital herpes has become the most common STI among women. The prevalence of the genital HSV infection can cause a large spectrum of disease. First-episode infections, which represent new acquisition of HSV, usually are most severe, and recurrent infections may be milder. However, as many as 75% of primary infections are unrecognised by either patient or care provider. Recurrences usually are limited to the genital area. Most women with HSV-2 do not know they have genital herpes because their recurrences are mild and infrequent. Such women may have nonspecific genital conditions and may have been receiving treatment for other genital conditions, such as recurrent yeast infections, urinary tract infections, or allergic rashes in the genital area. An important feature of HSV infection is intermittent reactivation, with or without accompanying symptoms, and resultant shedding of the virus in the genital tract. DNA from HSV can be detected in the genital tract 10–50% of the time among HSV-2 seropositive women. Women close to the time of acquisition or with severe clinical disease have a higher risk of viral shedding between symptomatic recurrences (ACOG 2004, p 1112).

It is estimated that 5% of the general population has a known history of genital herpes 1. This creates a large population of women known to be at risk for transmitting HSV to their infants during delivery, should they have a peripartum recurrence. To avoid intrapartum HSV exposure and neonatal infection, it is currently recommended that pregnant women with visible genital herpes lesions or prodromal symptoms at the time of labour have a caesarean delivery. Gravidas without visible lesions or prodromal symptoms should be allowed to continue in labour because they have a low risk of neonatal HSV transmission. Using these guidelines, it is estimated that one poor neonatal outcome from HSV infection is averted for every 1580 caesarean deliveries performed for maternal clinical HSV recurrences (at a cost of US$2.5 million) (Scott et al 2002).

It is difficult to make the diagnosis of genital herpes on clinical grounds alone. The classic presentation of a painful cluster of vesicles and ulcers occurs in a small proportion of women, and most women will have atypical lesions, such as abrasions, fissures, or itching without obvious lesions. Conversely, even in at-risk women with a presentation compatible with genital herpes, up to 20% of women will not have genital herpes. Thus, a definitive diagnosis should be confirmed by a laboratory test, even if the infection was established in the past on clinical grounds.

Traditionally, the laboratory test used most often has been viral culture because it is highly specific, widely available, and relatively inexpensive. Viral culture can be useful in women presenting with new or recurrent genital ulcer disease. However, viral culture is insensitive, even with a primary infection, with a false-negative rate up to 25%. In recurrent disease, the rate of viral isolation is less than 50%. This low rate of viral isolation results in the need for repeat visits or leaves the impression that the patient does not have genital herpes. In addition to viral detection methods, the detection of type-specific antibodies to HSV-1 and HSV-2 also can help to establish the diagnosis. The incubation period for HSV is short (approximately four days), and antibodies to HSV-2 are detected 2–12 weeks after acquisition of infection and persist indefinitely. Most women with genital HSV-1 or genital HSV-2 infection are asymptomatic. A small proportion may recall symptoms or lesions compatible with genital herpes when they receive a diagnosis of HSV-2. Because HSV is so prevalent among women, infection rates are very high among sexually active women, even if the number of sexual partners is not very high. Therefore, type-specific antibody testing is more accurate than assessment of infection based on symptoms or past sexual behavior (ACOG 2004, p 1113).

A vaginal birth is appropriate in the absence of recurrent genital herpes lesions or prodromal symptoms (Scott et al 2002). Pregnant women with a history of recurrent genital

herpes might decrease their risk of clinical reactivation at the time of birth by more than 50% by using suppressive acyclovir therapy (Brocklehurst & French 1998; Scott et al 2002). The significant reduction in clinical herpes recurrences amongst women treated with acyclovir could potentially reduce the caesarean section rate (Scott et al 2002). Cost-benefit analyses performed for the use of acyclovir suppression in the last several weeks of pregnancy demonstrate that suppressive therapy would cost less, would result in decreased maternal morbidity and mortality, and would result in fewer cases of neonatal herpes than deferring acyclovir treatment and resorting to caesarean section for clinical reactivations (Randolph et al 1996).

Group B Streptococcus

Group B beta-hemolytic Streptococcus (*Streptococcus agalactiae*) (GBS or GBBS) is a Gram-positive aerobic coccobacillus that was first associated with bovine mastitis, hence the name *agalactiae*, meaning 'no milk'. Unfortunately, it is not confined just to cows, and can cause invasive disease (sepsis) of the newborn in humans. GBS disease of newborns is early-onset (occurring less than seven days after delivery, usually within 24 hours) in 80% of cases, or less frequently late-onset (occurring seven or more days after delivery) (ACOG 1996). GBS is a leading cause of sepsis, meningitis and death among newborn infants in Western countries. Early-onset infections with this organism account for approximately 80% of GBS infections in infants and are usually acquired by contact with the genital tract of the mother during labour and birth (Bergeron et al 2000, p 175). Infants who have such infections may require prolonged hospitalisation, and those who survive may have mental retardation or visual loss. Among pregnant women, the prevalence of colonisation with GBS ranges from 15% to 40%. Women who are carriers are also at risk for severe infections (Bergeron et al 2000, p 175).

Early-onset GBS infection (EOGBS) in neonates usually occurs within the first 24 hours after birth, and accounts for 80% of neonatal infections, although it is defined as that occurring within the first seven days. Late-onset GBS infection occurs from seven days until three months of age, and is less aggressive.

The bacteria ascend into the amniotic fluid (once membranes are ruptured) and enter the epithelium of the lungs, or more rarely the meninges (Feldman 2001, p 16), causing pneumonia, bacteraemia and, in approximately 15% of cases, meningitis, causing permanent neurological damage (Glantz & Kedley 1998, p 45).

Incidence

The incidence of GBS varies within and between populations. In New Zealand the most recent survey found a colonisation rate of 22% in a population of 240 women swabbed recto-vaginally at 35–37 weeks gestation (Grimwood et al 2002). Recto-vaginal colonisation rates exceed vaginal colonisation rates by > 50% (Benitz et al 1999, p 5). While ethnic, geographic and socio-economic differences in colonisation rates have been documented, there is insufficient consistency in these factors to establish valid 'at-risk' subgroups.

An estimated 10–30% of pregnant women in Australia will have vaginal carriage of GBS. The incidence may be considerably higher in Indigenous populations. Transmission to the newborn may occur during labour, resulting in pneumonia, septicaemia and occasionally infant death. About 1–2% of infants born to GBS-colonised mothers will develop early-onset infection. In this group there is a 6% fatal outcome which is higher in pre-term infants (Three Centres Guidelines 2001, p 60).

Screening options

Either risk assessment or screening for GBS colonisation in pregnant women is recommended, to identify candidates for intrapartum prophylaxis.

- The risk-based protocol does not entail antepartum screening, but treats women with certain risk factors during labour.
- The screening-based protocol includes cultures at 35 to 37 weeks gestation, and offers intrapartum prophylaxis to all women with positive cultures. Uncultured women with risk factors are treated.

Both protocols involve high rates of intrapartum antibiotic use and both may significantly lower rates of neonatal GBS sepsis (screening-based more than risk-based for both). Figures 32.6 and 32.7 show the two management protocols.

Risk assessment is performed at the onset of labour, and the presence of fever, a prolonged interval between rupture of membranes and birth, or imminent preterm birth is considered indicative of the need for prophylaxis.

In New Zealand, the GBS Consensus Working Party provides the following guidance:

> The risk-based approach (above) should be used to identify those women at risk of giving birth to GBS-affected babies.
>
> Intrapartum penicillin G (1.2 g intravenously as the initial dose, then 0.6 g intravenously every 4 hours until birth) is the

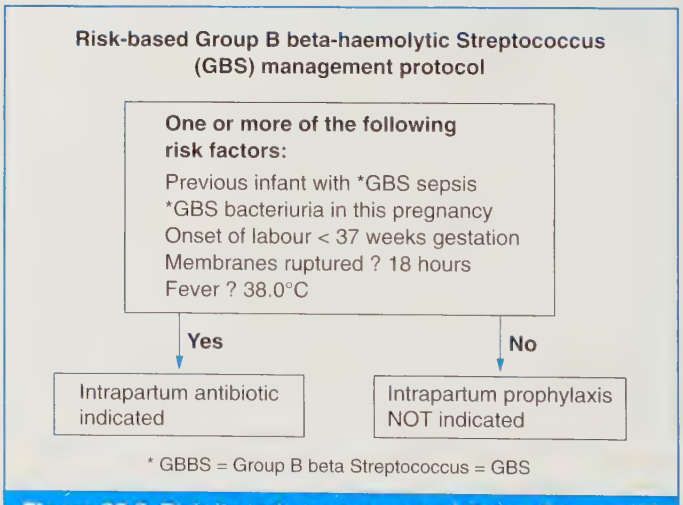

Figure 32.6 Risk-based management of Group B beta-haemolytic Streptococcus (GBS) (based on Glantz & Kedley 1998)

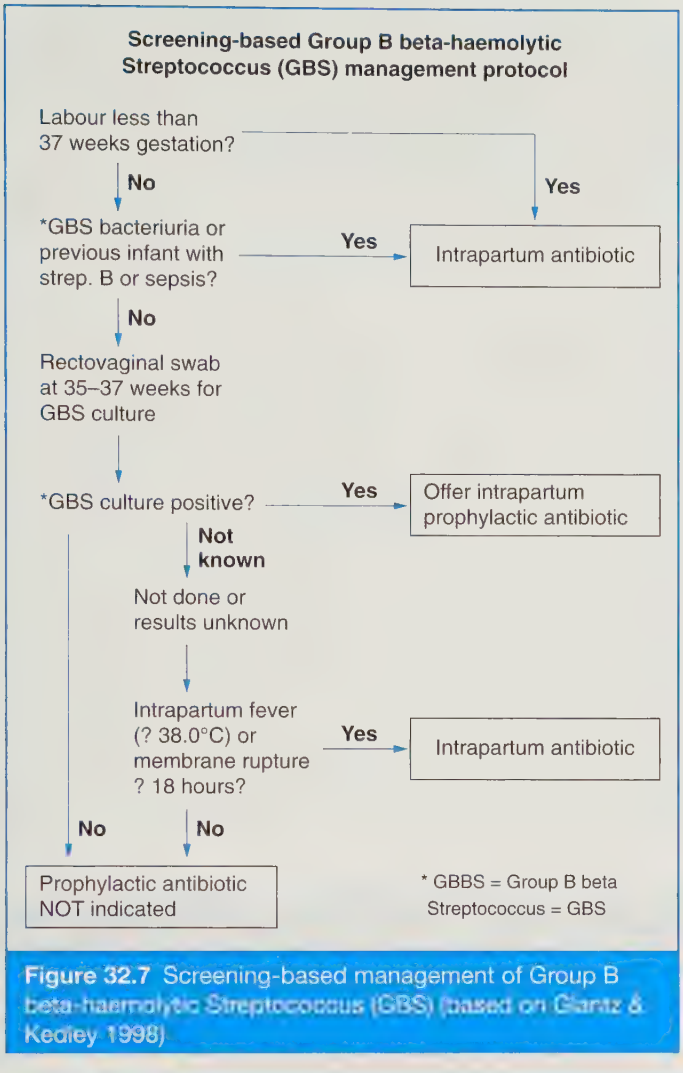

Figure 32.7 Screening-based management of Group B beta-haemolytic Streptococcus (GBS) (based on Glantz & Kedley 1998)

intrapartum antibiotic of choice. Penicillin is recommended because of its narrow spectrum of activity. An alternative is amoxycillin (2 g intravenously initially, then 1 g every 4 hours until birth occurs).

As part of antenatal assessment, a history of penicillin allergy should be sought—including details of immediate (within 24 hours) hypersensitivity reactions (e.g. anaphylaxis, angioedema, laryngospasm, bronchospasm, or urticaria). Women not at high risk of anaphylaxis should receive cephazolin (2 g intravenously initially, then 1 g intravenously every 8 hours until birth). The small group of women with a definite history of immediate hypersensitivity reactions can receive vancomycin. This should be only after seeking clinical microbiology or infectious diseases advice. The recommended dose is 1 g intravenously every 12 hours until the baby is born. Neither penicillin G nor amoxycillin alone are adequate treatment for maternal chorioamnionitis (intrapartum fever with > 2 of the following signs: fetal tachycardia, uterine tenderness, offensive vaginal discharge, or maternal leucocytosis). As *E. coli*, anaerobes, and GBS can all cause chorioamnionitis, this requires immediate aggressive management with broad-spectrum antibiotics (Campbell et al 2004, p 10).

Screening consists of obtaining vaginal and anal specimens for culture at 35 to 37 weeks gestation.

Identification of GBS colonisation in pregnant women

The identification of GBS colonisation in pregnant women is fundamental to our ability to quantify the risk of infection for any infant. GBS is a 'moving target'—'both vaginal and rectal colonisation may be persistent, transient or intermittent, limiting the predictive value of screening cultures for colonisation on any future date' (Benitz et al 1999, p 5). The most accurate swabs are taken from the low vaginal-introitus area, rather than the high vaginal or cervical region (Glantz & Kedley 1998, p 46).

Yancey and colleagues (1996) found cultured vagino-rectal swabs to have a positive predictive value of at least 88% from five weeks prior to birth, but this reduced to only 43% for more than five weeks (Yancey et al 1996, p 813). They also report a negative predictive value of at least 95% in the five weeks before birth, with a still relatively high value of 80% for negative cultures taken more than five weeks before birth (Yancey et al 1996, p 813).

Benitz and colleagues (1999, p 7) report a 64.5% prevalence of vaginal colonisation among women with vagino-rectal colonisation, and that 'virtually all infants with EOGBS disease are born to mothers from whom GBS can be recovered from vaginal cultures' (Benitz et al 1999, p 7). They argue against the use of vagino-rectal cultures, asserting that it would 'not identify additional infants who are likely to become infected but would enlarge and dilute the pool of women identified as being at risk for EOGBS infection' (Benitz et al 1999, p 7).

Two issues relating to women's experience of swabbing warrant attention. First, the degree of acceptability of rectal or anal swabbing by women is uncertain. It is currently not done in New Zealand as part of GBS screening in practice, and would need to be established as necessary for women to agree either to have it done to them, or to do it themselves. The second issue is that of self-swabbing. Taylor et al (1997) found that swabs collected by women themselves were 'highly correlated with nurse-collected samples for accuracy of culture results' (p 410).

If antenatal screening is carried out, the results need to be available when the woman is in labour, to be of any value. This issue is of course secondary to the problems associated with the unreliability of swabbing as a predictive tool in relation to GBS at present.

The standard method for the diagnosis of GBS colonisation consists of culturing combined vaginal and anal secretions in a selective broth medium that inhibits the growth of other microorganisms. After collection, swabs should be placed in a suitable, non-nutritive transport medium, such as Amies, or may be directly plated at the bedside. The swab will maintain viability for up to four days at room temperature. Transport as a dry swab or in an inappropriate medium will significantly reduce detection rates. Culture is performed using selective culture media such as Lim or SBM broth (Three Centres Guidelines 2001, p 59).

Cultures may be negative in some women whose infants subsequently have GBS infections. On the other hand, the use of antibiotic prophylaxis on the basis of risk assessment leads to unnecessary treatment in many women (Bergeron et al 2000, p 175).

Intrapartum antibiotics are recommended for:

- pre-term birth < 37 weeks
- rupture of membranes > 18 hours prior to delivery
- maternal temperature = 38°C during labour
- previous GBS colonisation
- GBS bacteriuria
- previous infant with GBS.

The recommended intrapartum chemoprophylaxis for GBS is penicillin G 1.2 g (IV) load, then 0.6 g IV four-hourly throughout labour ((Three Centres Guidelines 2001, p 59) (although the Cochrane Review by Smaill (2001) reports treatment with intrapartum ampicillin 1 g intravenously every six hours during labour as the usual regimen; and alternatives included benzyl penicillin or erythromycin (Smaill 2001)).

Wherever possible, antibiotics should be commenced at least four hours prior to birth to ensure adequate prophylaxis. In the case of suspected penicillin allergy, clindamycin (600 mg IV eight-hourly) or erythromycin (500 mg IV six-hourly until delivery) may be used (Three Centres Guidelines 2001, p 59).

Risk factors for EOGBS infection

GBS colonisation

Being able to assess the colonisation of women at the time of labour is the most significant piece of information required to assess potential risks for neonates. There is a known relationship between density of colonisation in both women and neonates, and EOGBS infection—with heavier colonisation associated with 2.54 times greater odds of infection compared with lightly colonised mothers (Benitz et al 1999, p 5).

GBS bacteriuria in pregnancy

This is believed to reflect heavy colonisation in women, but the empirical evidence for this is not conclusive (Benitz et al 1999; CDC 1996).

Previous child with GBS infection

This 'risk' is also difficult to quantify (Benitz et al 1999). GBS is extremely difficult to eliminate from the GI tract and re-colonisation of the vagina is highly likely. It may be that the low incidence is a reflection of the high rates of prophylactic antibiotic use in this group, as a result of their, and/or their caregiver's, potentially high levels of anxiety to avoid a similar experience a second time.

Chorioamnionitis

This condition is clinically defined by maternal fever and 'two or more additional signs, including fetal tachycardia, uterine tenderness, foul-smelling vaginal discharge, or maternal leucocytosis, occurs in 1–3.8% of parturients and is associated with neonatal GBS attack rates ranging from 6% to 20%' (Benitz et al 1999, p 10). It is detectable, and is a condition of high risk of neonatal sepsis whatever the causative organism. It requires empirical antibiotic treatment. Further, 'chorioamnionitis is almost universally present in mothers of infants who became septic despite intrapartum prophylaxis with an appropriate IV antibiotic' (Benitz et al 1999, p 10).

This may be due to the antibiotics chosen and/or the high level of bacterial invasion prior to treatment, and/or inadequate time of treatment from diagnosis until birth.

Intrapartum fever

This is clearly related to the chorioamnionitis risk above, as fever is often the first symptom recognised, and is the point from which other investigations are instigated. Intrapartum fever is recognised as a significant risk factor for EOGBS infection, at 5–15 times the risk (Glantz & Kedley 1998, p 46). Defining fever in labour, or the level at which it is significant, is less straightforward, with differing values used by various authors: > 37.5°C (Benitz et al 1999), >37.8°C (Feldman 2001; Langley 2000) and > 38°C (Glantz & Kedley 1998; Schuchat 1999). Most do not justify the use of a particular temperature. While it is tempting to believe that the higher the temperature the higher the risk, 'there are no objective data to quantify that relationship' (Benitz et al 1999, p 10). A critical review of the literature found that 'available data do not identify specific temperature thresholds above which prophylaxis, diagnostic screening or empiric therapy are appropriate or imperative' (Benitz et al 1999, p 10).

BOX 32.8 EOGBS risk factors

Primary risk factors for EOGBS infection:

- GBS colonisation—heavier associated with increased risk
- GBS bacteriuria in pregnancy—indication of heavy colonisation, measure varies
- previous child of the woman had EOGBS infection—colonisation and bad experience
- chorioamnionitis—maternal fever and/or fetal tachycardia, offensive amniotic fluid
- maternal intrapartum fever—range in values used, > 37.5°C, > 37.8°C or even > 38°C
- rupture of membranes—prelabour or prolonged, > 18 hours before the birth
- preterm labour and birth— < 37 weeks gestation, premature and low birthweight.

Factors associated with lower or not well documented risk for EOGBS infection:

- duration of internal fetal monitoring > 12 hours
- number of vaginal examinations > 6
- young women
- lower parity
- ethnicity—varies depending on country, may well be linked to socio-economic status
- number of sexual partners—not usually defined
- frequency of sexual intercourse.

Benitz and colleagues (1999) acknowledge the influence of epidural analgesia in intrapartum fever. They note that the maternal temperature increases at 0.08–0.14°C/hour, exceeding 38.0°C in 10–15% of women, and they suggest that the use of a higher fever threshold for women who have had an epidural analgesia may be appropriate (Benitz et al 1999). Arguably, this exposes the somewhat arbitrary nature of defining maternal fever in labour.

Ruptured membranes: prolonged or prelabour

It is now generally believed that EOGBS infection occurs after membrane rupture, although there has been debate about the bacteria's ability to pass through membranes. At issue is the length of time of ruptured membranes (ROM) required for the bacteria to ascend. The full-term baby is better able to resist infection, and 18 hours has evolved as the benchmark time beyond which neonates are believed to be at increased risk, although Yancey (cited in MMWR 1996, p 3) has proposed > 6 hours, and McLaren et al (cited in Benitz et al 1999, p 9) call for > 10 hours as appropriate. The 18 hours benchmark has not been reached by any empirical methodology: rather, it is an attempt to find the optimal time to catch infections without (over) treating an unacceptable number of women, who were at no greater risk than the normal birthing population. Preterm prelabour ROMs combine two relatively high-risk groups, with these neonates reported to have attack rates of 33% to 50% (Benitz et al 1999, p 9).

Preterm birth

This is usually defined as birth before 37 weeks gestation (Feldman 2001; Langley 2000) and combines two known risk factors: prematurity and low birthweight. A gradient of increasing risk with decreasing birthweight and gestational age has been demonstrated (Schuchat 1999; Yancey et al 1996). Glantz and Kedley (1998) claim that 'preterm delivery is associated with approximately 25% of invasive disease' (p 46).

Recommendations for midwifery practice

(by Celia Grigg)

GBS presents midwives with a number of challenges when trying to keep birth normal. It is an elusive and unpredictable bacterium that may be harmless most of the time, but with the potential to become life-threatening to neonates.

A measured approach is required, to balance the harm-versus-benefit ratio. This involves establishing acceptable boundaries for risk, which is a good idea, but theory and practice are not always easily matched. Unfortunately, there are no definitive markers, only sliding scales of known risk, with numerous indices, and a significant population affected.

Midwives contracting to be with women at the hospital are, theoretically at least, bound by the hospital recommendations and policies unless clear documentation of alternative choices exists. Midwives are in the position of sharing information with women to facilitate their making decisions for themselves. It seems appropriate to provide information about GBS and the issues, risks and options, and to work with women and their families within their 'world view', accepting that some will make choices that may not fit our 'world view'.

Within the context of midwifery practice, the following are recommended:

- Avoid taking vaginal swabs during pregnancy. This helps maintain normality and avoids unnecessary anxiety for a large number of women.
- If a woman 'falls' into a risk category for EOGBS, share information about GBS and discuss options. Give written information, as the subject is complex and it is easy to not fully grasp the issues.
- See and assess a woman after prelabour ROM as soon as possible.
- Check for signs of infection in the woman and in the fetus, including chorioamnionitis. Consider taking a low vaginal swab for immediate culturing if a woman has prelabour ROM and she is likely to choose not to have prophylactic antibiotics if she doesn't give birth in the next 18–24 hours. Culture will take 24 hours, but will give very reliable information on which to base decisions at that time.
- If there are signs of chorioamnionitis, recommend IV treatment with antibiotics.
- Discuss signs of an unwell baby with all families, including temperature taking.
- Observe all neonates for sepsis in the first two to three hours.
- Carefully monitor neonates whose mothers were in an 'at-risk' category closely for six hours, but continue for 24 hours.
- If the woman is in hospital, ask midwifery staff to monitor the baby's wellbeing.
- Consider requesting specific observations, such as taking the baby's temperature four-hourly.
- If any baby has poor Apgar scores and/or respiratory distress, consider sepsis, assess the whole situation and respond quickly if concerned. EOGBS infection usually has a rapid onset and is potentially fatal.
- Do not take gastric aspirate or ear swabs from neonates at birth, even if there are risk factors.
- Unwell babies will have blood cultures taken, and GBS skin colonisation is not a useful measure.

GBS is a common but unpredictable bacterium with the potential to cause significant illness at times. It is difficult to identify its presence reliably at the time it causes most damage for neonates, during labour and birth or once women have ROM. The 24-hour timeframe for culturing swabs is usually too slow. The great majority of affected babies are symptomatic at birth, which is usually within 24 hours of ROM or the start of labour. Unfortunately, the known risk factors have poor sensitivity and specificity, and work on a poorly defined sliding scale of risk.

Intrapartum antibiotics are not a very efficient or effective way of dealing with GBS, and have several risk factors associated with them. Allergic reactions and possible resistance are well documented, but the unnecessary medicalisation of the process of labour for a significant proportion of women

Reflective exercise

1. What do you consider the reason for the changing prevalence of GBS in the New Zealand and Australian populations?
2. How has the prevalence changed over the past 30 years?
3. Are there reasons for concern over the widespread use of antibiotics in the population?
4. What are these concerns?

giving birth is of concern, when almost all of their babies are well. There is a real danger of the general public developing a misplaced expectation of antibiotics as a risk-free, fullproof prevention, when at best they will reduce the incidence of EOGBS infection and at worst make way for more serious infections resistant to available antibiotics.

EOGBS infection is very rare and can be treated effectively in most cases. Midwives need to be well informed about GBS and the management options, and work with women to maintain appropriate perspective on the minimal risks in normal labour and birth situations.

Toxoplasmosis

Caused by the parasite *Toxoplasma gondii*, primary toxoplasmosis infection is usually asymptomatic in healthy women. Once infected, a lifelong antibody response provides immunity from further infection.

Toxoplasmosis infection is acquired via four routes in humans:

- ingestion of viable tissue cysts in undercooked or uncooked meat (e.g. salami, which is cured) or tachyzoites in the milk of infected intermediate hosts
- ingestion of oocytes excreted by cats and contaminating soil or water (e.g. unwashed fruit or vegetables contaminated by cat faeces)
- transplanted organs or blood products from other humans infected with toxoplasmosis
- mother-to-child transmission when primary infection occurs during pregnancy.

Routine antenatal serological screening for toxoplasmosis should not be offered because the harms of screening may outweigh the potential benefits. Pregnant women should be informed of primary prevention measures to avoid toxoplasmosis infection, such as:

- washing hands before handling food
- thoroughly washing all fruit and vegetables, including ready-prepared salads, before eating
- thoroughly cooking raw meats and ready-prepared chilled meals
- wearing gloves and thoroughly washing hands after handling soil and gardening
- avoiding cat faeces in cat litter or in soil (NICE 2003, p 95).

BOX 32.9 GBS and the newborn

- All newborn babies showing signs of sepsis should undergo immediate evaluation (at least a full blood count and blood cultures), and pending culture results should receive empiric therapy for at least 48 hours.
- The antibiotics are usually a penicillin and an aminoglycoside as this combination is active against common early-onset neonatal pathogens, such as GBS, *E. coli* and *L. monocytogenes*.
- When feasible, a lumbar puncture should be performed on all septic newborn babies (and especially when blood cultures are positive or, because of clinical instability, therapy is continued beyond 48 hours) as 10–15% of neonates with meningitis will have sterile blood cultures.
- All babies born to women with suspected chorioamnionitis (irrespective of their gestation, condition at birth, or exposure to intrapartum antibiotics) require careful evaluation. Antibiotic therapy (as outlined above) is not recommended unless the baby shows signs of sepsis.
- Healthy-appearing babies born at > 35 weeks gestation to women with GBS risk factors and who have received appropriate antibiotics > 4 hours before birth required no investigations or treatment, but should be observed closely for at least 24 hours post partum. This could include close observation at home after an early discharge.
- Well-appearing babies born at > 35 weeks gestation to women with GBS risk factors who have received either no or inadequate (< 4 hours) chemoprophylaxis should be observed closely in hospital for at least 24 hours.
- Well-appearing babies born at < 35 weeks gestation to women with GBS risk factors, who have received appropriate antibiotics > 4 hours before birth, should be observed in hospital for at least 48 hours. When such babies have been born to women who have not received antibiotics > 4 hours before delivery, then a full blood count, blood cultures and antibiotics should be considered.

Screening for clinical conditions

Blood group and Rhesus D status

You can find more information about this in the publication entitled 'Guidance on the routine use of anti-D prophylaxis for RhD negative women: information for patients', published by NICE in 2002 and available on the NICE website (see online resources list at the end of this chapter).

Anti-D

Overall a policy of anti-D administration at 28 and 34 weeks during pregnancy to all Rh (D) negative women (who have

not actively formed their own anti-D) will result in a reduction of alloimmunisation from about 1% to 0.3%.

Blood must be taken for Rh antibody titre prior to administration of anti-D, which the NHMRC recommends at 28 and 34 weeks. It is reasonable to vary the timing so that this can be grouped with other tests between 28 and 38 weeks gestation.

The administration of Rh D immunoglobulin (anti-D) has been shown previously (and more recently in Cochrane Reviews) to result in a significant reduction in the incidence of Rh isoimmunisation (Crowther & Middleton 2006). In 1999 the NHMRC recommended prophylactic administration (3) of Anti-D during pregnancy (NHMRC 1999).

Only Rh (D) negative women (who have not actively formed their own anti-D) having their first baby and who have reached 28 weeks gestation should be offered anti-D prophylaxis, with a repeat dose at 34 weeks—CSL 625 IU (125 μg)

For *all* Rh (D) negative women (who have not actively formed their own anti-D):

- first trimester indications—CSL 250 IU (50 μg):
  - chorionic villus sampling
  - miscarriage
  - termination of pregnancy
  - ectopic pregnancy
- second and third trimester indications—CSL 625 IU (125 μg):
  - obstetric haemorrhage
  - amniocentesis, cordocentesis
  - external cephalic version of a breech presentation, whether successful or not
  - abdominal trauma, or any other suspected intrauterine bleeding or sensitising event
- postnatally, within 72 hours, to *all* women who give birth to an Rh (D) positive baby.

RhD immunoglobulin should not be given to women with preformed anti-D antibodies except where the preformed anti-D is due to the antenatal administration of RhD immunoglobulin. If it is unclear whether the anti-D detected in the mother's blood is passive or preformed, the treating clinician should be consulted.

If there is continuing doubt, RhD immunoglobulin should be administered.

All women should have the magnitude of potential feto-maternal haemorrhage assessed and if necessary further anti-D administered as appropriate.

Gestational diabetes mellitus

Gestational diabetes mellitus occurs in 2% to 9% of all pregnancies (NICE 2003, p 96). Although the risks associated with gestational diabetes are well recognised, there has been uncertainty about the evidence available from clinical trial data regarding whether screening and treatment to reduce maternal glucose levels reduce these risks. Given this uncertainty, professional groups have disagreed on whether to recommend routine screening, selective screening based on risk factors for gestational diabetes, or no screening. Some recommend screening, whereas others do not. Recent evidence indicates a worrisome rise in the prevalence of gestational diabetes (Dabelea et al 2005) that is largely explained by the increase in maternal obesity. Efforts to reverse this trend are critical (Greene & Soloman 2005).

Results of the Australian Carbohydrate Intolerance Study In Pregnant Women

The recently published Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) trial (Crowther et al 2005) assessed whether the treatment of gestational diabetes would reduce perinatal complications, and assessed the effects of treatment on maternal outcome, mood and quality of life. The large, randomised, multicentre trial with 18 collaborating centres will give some firm evidence on which to base policy decisions for treating pregnant women considered to be at risk from gestational diabetes (Crowther et al 2005).

In the trial, pregnant women underwent a 75 g oral glucose-tolerance test between 24 and 34 weeks gestation; those with values below 7.8 mmol per litre after an overnight fast and between 7.8 and 11.0 mmol per litre at two hours were eligible for randomisation. Women were advised to follow a normal diet 48 hours before the oral glucose-tolerance test and to fast for eight hours the night before the test. Blood samples were obtained after the overnight fast and one and two hours after taking the drink of 75 g oral glucose. Women with previously treated gestational diabetes or active chronic systemic disease (except essential hypertension) were excluded (Crowther et al 2005, p 2478).

Women were told that they would be eligible for randomisation only if their blood glucose levels fell into the range specified above. If they were assigned to the intervention group, they received a slip indicating a diagnosis of glucose intolerance of pregnancy and the plan for intervention, whereas if they were assigned to routine care, they received a slip indicating that they did not have gestational diabetes. The researchers justify this approach on the following grounds:

- There remained uncertainty as to the level of glucose impairment associated with adverse perinatal outcomes.
- There was wide variation in the glucose levels used to define the need for treatment with some committees, but not others.
- There was still no clear evidence of the benefits and harms of treatment (Crowther et al 2005).

Women whose glucose levels exceeded cut-off values for eligibility were informed that they had gestational diabetes (Crowther et al 2005, p 2478).

The 490 women assigned to the intervention group were shown how to monitor their blood glucose levels (four times a day until they reached the required blood glucose levels) as well as being provided with individualised dietary counselling. They were given insulin as needed to maintain fasting and before-a-meal glucose levels below 5.5 mmol per litre and at two hours postprandial (after a meal) the levels were not to exceed 7.0 mmol per litre. This group (the intervention group) had care consistent with management approaches in which screening and treatment for gestational diabetes are routine.

The 510 women assigned to the control group received routine care that was consistent with the care provided in places in which screening for gestational diabetes is *not* standard.

In analysing the results, the researchers used an 'intention-to-treat' analysis. The results showed that among the babies born to women in the intervention group, as compared with those of women in the routine-care group, there was a significantly reduced risk of the primary outcome measures. These included one or more of the following: perinatal death, shoulder dystocia, bone fracture, and nerve palsy (1% versus 4%; adjusted relative risk, 0.33; 95% CI 0.14–0.75). There were five deaths (three stillbirths and two neonatal deaths) among the offspring of mothers in the control group, compared with none in the intervention group. Two stillbirths were unexplained intrauterine deaths at term of appropriately grown infants, and the other, at 35 weeks gestation, was associated with pre-eclampsia and IUGR. One infant had a lethal congenital anomaly, and one infant died after an asphyxial condition during labour without antepartum haemorrhage (Crowther et al 2005, p 2481).

A higher percentage of infants born to women in the intervention group than of infants born to women in the control group were admitted to the neonatal nursery (71% versus 61%, adjusted $P = 0.01$) and most babies stayed for one to two days.

Macrosomia (defined as a birthweight of 4 kg or greater) was significantly more common among the infants of mothers in the control group than among the infants of mothers in the intervention group (21% versus 10%, $p < 0.001$). There was no significant difference in the rates of shoulder dystocia between the intervention and control groups (1% and 3%, respectively). No infant in the intervention group had a bone fracture or nerve palsy, whereas in the control group, one infant had both a fractured humerus that was not related to a difficult birth and a radial-nerve palsy, one infant had Erb's palsy related to shoulder dystocia, and one infant had Erb's palsy alone.

Among the women in the study, the primary outcome measures were the rates of induction and the rates of caesarean birth. The induction of labour was significantly more common in the intervention group than in the control group (39% versus 29%; adjusted $P < 0.001$). This meant that women who were treated for gestational diabetes had a risk of 1.36 (1.15–1.62) (a third times more likely to have induction of labour after controlling for parity, maternal age and Aboriginality).

The rates of caesarean birth were similar in the two groups, as were the reasons for operative birth. More women had an elective caesarean section in the intervention group and more women had an emergency caesarean section in the control group—but these results did not reach statistical significance.

The researchers assessed the response of a subgroup of women in the trial to their perceptions of quality of life following treatment for gestational diabetes, and found no negative effect.

This trial will have major repercussions for the screening and treatment of gestational diabetes because it showed conclusively that treatment of gestational diabetes in the form of dietary advice, blood glucose monitoring, and insulin therapy to maintain control of blood glucose levels, reduces the rate of serious perinatal complications, without increasing the rate of Caesarean birth.

This trial was published just prior to this book going to press (2006). For that reason I have described the study in some detail because it will make many of the current policies redundant. See also the NICE Guidelines (2003) and the *Three Centres Consensus Guidelines* (2001).

Pre-eclampsia

Hypertensive disorders in pregnancy and pre-eclampsia remain major causes of maternal and perinatal mortality, accounting for 15% of maternal deaths and 4% of perinatal deaths. Therefore, a key aim of modern antenatal care is the timely detection and management of pre-eclampsia (Wallace & Oats 2002).

Elevated blood pressure is one of the first signs of the condition. Consequently, guidelines recommend the practice of recording blood pressure at every antenatal visit as critical in detection and management of hypertensive disorders of pregnancy. Early detection is important, as underlying conditions can progress rapidly. Current Australasian Consensus Guidelines suggest a diagnosis of hypertension when:

- systolic blood pressure is 140 mmHg
- and diastolic blood pressure is 90 mmHg,
- taken on two or more consecutive occasions over several hours,
- or an increment of 15/30.

Both diastolic and systolic pressures have been shown to be closely associated with fetal outcome. A clinical diagnosis of pre-eclampsia is usually made when hypertension occurs with one or more of proteinuria, renal insufficiency, liver disease, neurological problems, haematological disturbances or fetal growth restriction (Australian Society for the Study of Hypertension In Pregnancy 2000; Brown et al 2000; Three Centres Guidelines 2001, p 42).

Pre-eclampsia is a multisystem disorder that occurs in the second half of pregnancy and is associated with increased maternal and neonatal morbidity and mortality. The incidence of pre-eclampsia ranges from 2% to 10%, depending on the population studied and the criteria used to diagnose the disorder. Maternal symptoms of advanced pre-eclampsia may include:

- bad headache
- problems with vision, such as blurring or flashing before the eyes
- bad pain just below the ribs
- vomiting
- sudden swelling of face, hands or feet (Action on Pre-eclampsia 2004).

Although it is usually mild, it can cause serious problems for mother and baby if it is not detected and treated. It is more likely to develop in women who:

Clinical point

How to measure blood pressure in pregnancy

1. The woman should sit down with her feet supported.
2. Take measurements after the woman has been resting in this position for two to three minutes.
3. Use a standard-sized cuff for women with an arm circumference of 33 cm, a large cuff for arm circumference > 33 cm.
4. Palpate systolic blood pressure at the brachial artery and inflate the cuff to 20 mmHg above this level.
5. Deflate the cuff slowly, at approximately 2 mmHg per second.
6. Record diastolic blood pressure reading using the Korotkoff V sound. If phase V is not present, then record phase IV.

Hypertension is defined when systolic blood pressure is > 140 mmHg and/or diastolic blood pressure (Korotkoff V) is > 90 mmHg or there is an incremental rise of 30 mmHg systolic or 15 mmHg diastolic.

(Sources: Australian Society for the Study of Hypertension in Pregnancy 2000; Three Centres Consensues Guidelines 2001)

BOX 32.10 Hypertension in pregnancy

- Current definitions of hypertensive disorders in pregnancy:
  - *pre-eclampsia*—hypertension new to pregnancy manifesting after 20 weeks of gestation that is associated with a new onset of proteinuria, which resolves after delivery
  - *pregnancy-induced hypertension*—hypertension new to pregnancy that resolves after delivery but is not associated with proteinuria
  - *chronic hypertension*—hypertension that predates a pregnancy or appears prior to 20 weeks gestation.
- Most women with hypertension in pregnancy have no clinical symptoms. Hypertension is frequently the only early sign that predates serious disease.
- Blood pressure measurement is routinely performed in antenatal care to allow the diagnosis and classification of hypertension in pregnancy.
- Pre-eclampsia is though to be caused by widespread endothelial cell damage secondary to an ischaemic placenta.
- Hypertension and proteinuria are two easily measured signs associated with pre-eclampsia, although they are surrogate markers indicating end-organ damage.
- Eclampsia is rare. It occurs in nearly 1/2000 pregnancies in the UK. It is associated with high maternal morbidity and accounts for over 50% of the maternal deaths associated with hypertensive disorders in pregnancy.
- Blood pressure may be of limited importance in identifying women who are going to develop eclampsia, as about one-third of first fits occur in women with normal or a mild increase in blood pressure.
- Oedema was originally part of the triad of signs describing pre-eclampsia but it occurs in too many pregnant women (up to 80%) to be discriminatory and has been abandoned as a marker in classification schemes.

(Source: NICE Guidelines 2003, p 99)

- have been diagnosed with pre-eclampsia in a previous pregnancy
- have not been pregnant before
- are 40 years old or more
- have a mother or sister who has had pre-eclampsia
- are overweight at the time of the first antenatal appointment
- are expecting more than one baby or already have high blood pressure or diabetes.

Urine sample

Whenever blood pressure is measured during pregnancy, a urine sample should be tested at the same time for protein (as this can be another sign of pre-clampsia). Use the same type of equipment, method and conditions each time, so that the results at different times can be compared. The diagnosis of pre-eclampsia depends on the presence of significant proteinuria as well as raised blood pressure.

Reagent strips or 'dipsticks' are commonly used to detect proteinuria. The incidence of false positive results in random urine specimens may be up to 25% in trace reactions and 6% with 1+ reactions. Therefore, dipsticks can only be a screening test and will not have much utility when not used in combination with blood pressure measurements. Due to considerable observer errors involved in dipstick urinalysis, an RCOG Study Group recommended that automated dipstick readers be employed. This can significantly improve false positive and false negative rates. An initial sample of 1+ or greater should be confirmed by a 24-hour urinary protein measurement or protein/creatinine ratio determination. Although a finding of 300 mg/24 hours or more or a protein/creatinine ratio of 30 mg/mmol of creatinine is customarily regarded as significant, a proteinuria threshold of 500 mg/24 hours has been suggested to be more predictive in relation to the likelihood of adverse outcome (NICE 2003, p 101; RCOG 2003).

Placenta praevia

Placenta praevia is a condition in which the placenta is low-lying in the womb and covers all or part of the entrance (the cervix). In most women, as the womb grows upwards, the placenta moves with it so that it is in a normal position before birth and does not cause a problem.

If an earlier ultrasound scan showed the placenta extending over the cervix, another abdominal scan should be offered at 36 weeks. If this second abdominal scan is unclear, a vaginal scan should be offered.

Non-routine tests

There are a number of screening tests that have sometimes been offered to women in the past or have been suggested for routine antenatal care. The following tests should *not* be offered as a matter of routine, because they have not been shown to improve outcomes for mothers or babies:

- cardiotocography (a record of the trace of a baby's heartbeat, which is monitored through electronic sensors placed on the mother's abdomen, called a trace or CTG)
- Doppler ultrasound (an ultrasound scan that measures the blood flow between the baby and the mother)
- vaginal examination to predict whether a baby may be born too early
- routine breast and pelvic examination
- screening for gestational diabetes mellitus (a form of diabetes triggered by pregnancy) (see Crowther et al 2005 for this update)
- daily counting and recording of the baby's movements
- screening for GBS.

Women should be asked early in pregnancy if they have had any previous psychiatric illnesses. Women who have a past history of serious psychiatric disorder should be referred for a psychiatric assessment during the antenatal period.

Pregnant women should not be offered routine screening in the antenatal period to predict the development of postnatal depression (e.g. with the Edinburgh Postnatal Depression Scale). Pregnant women should not be offered antenatal education interventions to reduce perinatal or postnatal depression, as these interventions have not been shown to be effective.

Alcohol

All pregnant women and women contemplating pregnancy should be informed of the harmful effects of alcohol on the fetus. Safe levels of alcohol consumption during pregnancy are not known; therefore, pregnant women are advised to abstain from drinking alcohol. More research into the efficacy of primary care screening and behavioural intervention for alcohol misuse among pregnant women is needed.

How many visits?

In developed countries with well-established obstetrics services, small reductions in the number of prenatal visits (equal to or less than two visits) are compatible with similar good perinatal outcomes as in the standard model. However, it can be expected that women may be disappointed with fewer visits. Two trials conducted in developing countries, in which a proportionally major reduction in the number of visits was achieved, also supports this conclusion. Therefore, attempts to provide effective interventions during pregnancy by distributing them in fewer visits than usually recommended can be attempted without risking effectiveness. Such care can be provided by staff other than the obstetrics/gynaecology specialist. In light of the available evidence, the four antenatal care visits schedule tested in the largest trials appears to be the minimum that should be offered to low-risk pregnant women (Villar et al 2004).

> Effective prenatal care should integrate the best available evidence into a model of shared decision-making. Pregnant women should be counseled about the risks of smoking and alcohol and drug use. Structured educational programs to promote breastfeeding are effective. Routine fetal heart auscultation, urinalysis, and assessment of maternal weight, blood pressure, and fundal height generally are recommended, although the evidence for these interventions is variable. Women should be offered ABO and Rh blood typing and screening for anemia during the first prenatal visit. Genetic counseling and testing should be offered to couples with a family history of genetic disorders, a previously affected fetus or child, or a history of recurrent miscarriage. All women should be offered prenatal serum marker screening for neural tube defects and aneuploidy. Women at increased risk for aneuploidy

BOX 32.11 Family violence

Pregnancy is a particularly at-risk time for women to become victims of family violence and has been identified as a unique window of opportunity for identification and management of abused women. Currently, practitioners do not adequately identify cases of family violence, and abused women tend not to disclose it.

A pilot study by Lauti and Miller (2003) aimed to investigate the opinions of obstetricians and midwives regarding their perceived role in identification and management of family violence. Specifically, their opinions about possible barriers to identification and management were sought, and how these might be overcome.

Content analysis of focus group and semistructured interview discussions with obstetricians and midwives identified many issues:

- Time, failure of the medical model, lack of continuity of care, privacy and confidentiality issues were perceived as significant barriers to identification.
- All practitioners experienced uncertainty about appropriate management.
- Screening may pick up a woman's historical abuse, which may be inappropriate.
- Debriefing is needed after difficult cases.
- Midwives have a crucial role and can experience serious boundary issues.
- Midwives may become entangled in the power imbalance of a woman's abusive relationship.

Significant issues continue to exist in the area of domestic screening for both New Zealand and Australian midwives.

(Source: Lauti & Miller 2003)

should be offered amniocentesis or chorionic villus sampling. Counseling about the limitations and risks of these tests, as well as their psychologic implications, is necessary. Folic acid supplementation beginning in the preconception period reduces the incidence of neural tube defects. There is limited evidence that routine use of other dietary supplements may improve outcomes for the mother and infant (Kirkham et al 2005).

Figure 32.8 shows a summary of routine appointments during pregnancy.

SUMMARY OF YOUR ROUTINE APPOINTMENTS DURING PREGNANCY

At each appointment, you should be given information with an opportunity to discuss issues and ask questions. You should usually be asked to keep your own case notes at home with you and bring them to appointments. Your midwife or doctor should tell you the results of all tests and have a system in place to do this. As well as face-to-face information you should have access to antenatal classes or groups and written information that is based on the best research evidence available.	Wherever possible you should be cared for by a small group of people with whom you feel comfortable. They should assess your particular needs as an individual and give you continuity of care.

Have you had a baby before? — Yes: You should discuss this with your midwife or carer. You may need additional care. — No: Appointment schedule ✓ Have had a baby before ✓ For first baby

Were the pregnancy and birth uncomplicated? — No

Yes	Stage of your pregnancy			
		Before 12 weeks (may be 2 appointments)	Give information on diet and lifestyle considerations, pregnancy care services, maternity benefits, and screening test. Your midwife or doctor should: • Find out if you need additional care. • Tell you how taking folic acid (400 micrograms per day for up to 12 weeks) can reduce certain health risks for your baby.	
✓			• Offer you screening tests and make sure you understand what is involved before you decide to have any of them.	✓
✓			• Offer you an ultrasound scan to estimate when baby is due. • Measure your blood pressure, height and weight. • Test your urine for the presence of protein. • Offer you help to stop smoking if you want it. • Offer you an ultrasound scan at 18–20 weeks to check the physical development of the baby.	✓
✓		At 16 weeks	Your midwife or doctor should review, discuss and record results of any screening tests, measure your blood pressure and test your urine.	✓
		25	Checks the size of your abdomen. Measures your blood pressure and urine.	✓
✓		28	Checks on the size of your abdomen, your blood pressure and urine. More screening tests for anaemia and red cell antibodies if you wish them. If you are Rhesus negative, you should be offered the first anti-D treatment.	✓
		31	Checks on the size of your abdomen, your blood pressure and urine.	✓
✓		34	Checks on the size of your abdomen, your blood pressure and urine. If you are Rhesus negative, second anti-D treatment if you wish.	✓
✓		36	Checks on the size of your abdomen, your blood pressure and urine. Checks to see if the baby is head first – discuss options to turn the baby if it is feet first (breech position).	✓
✓		38	Checks on the size of your abdomen, your blood pressure and urine.	✓
		40	Checks on the size of your abdomen, your blood pressure and urine.	✓
		41	Checks on the size of your abdomen, your blood pressure and urine. Discuss option of membrane sweep. Discuss whether you want your labour to be induced after 41 weeks.	

7: total appointments if you've had a baby before — Total appointments if this is your first baby: **10**

Figure 32.8 Summary of routine appointments during pregnancy (based on NICE 2003)

Review questions

1. How do you explain the importance of screening to women?
2. Describe the difference between a screening test and a diagnostic procedure.
3. What is the specificity of a screening test and how is this different from the sensitivity of a screening test?
4. How would you explain the long-term side-effects of ultrasound to a woman who is anxious about the procedure?
5. Is it justifiable to offer newborn screening for a potentially untreatable genetic disorder? Why or why not?
6. What is a serum marker? Explain the various serum markers available for screening for Down syndrome. How would you explain the notion of a false-positive result to a 40-year-old woman who is pregnant for the first time? How and when would you conclude that the test result was a false positive?
8. What is the incidence of hepatitis B in your area? What do you tell families who want to weigh up the pos and cons of hepatitis B vaccination of their baby at the time of birth? What are the long-term effects of hepatitis B? Does hepatitis B affect different populations differently?
9. Should there be a universal offer of antental screening for HIV? Do you agree with the New Zealand Ministry of Health directive? Why or why not?
10. Describe the various viral infections that may be screened for in pregnancy. What are some of the risk factors that you would describe in relation to each viral infection? How many of these viruses may be transmitted through breast milk?

APPENDIX: Checklist of tests

Tests recommended at the first antenatal visit

1. **Blood group and antibody screen**
   Where the blood group has already been performed it does not need to be repeated. However, the antibody screen should be repeated at the beginning of each pregnancy.
2. **Full blood examination**
3. **Rubella antibody status**
   Although a previous high rubella antibody titre is generally used to exclude this investigation from first visit testing, there is some evidence that antibody levels may decline after rubella immunisation, especially since antibody levels are rarely boosted by exposure to wild viruses in the community.

Other tests that may be considered

1. **Cervical cytology**
   Documented normal cervical cytology within the preceding 18 months may be used to delay repeat screening if there is no clinical indication for another Papanicolaou smear.
2. **Screening for haemoglobinopathies**
   Each unit should have a defined policy for screening for haemoglobinopathies, taking into account the ethnic mix of patients screened. As a minimum, all women should be screened with MCV and MCHC. Haemoglobin electrophoresis and iron studies should be performed in the event of thresholds not being reached. Consideration should also be given to the further screening of patients with DNA analysis for alpha-thalassaemia. Testing of normal-MCV women for haemoglobinopathies may be considered if they are members of high-risk groups.
3. **Varicella**
   Consideration should be given to checking varicella antibodies at the first visit where there is no history of previous illness.

Tests after the first antenatal visit

1. **Obstetric ultrasound scan**
   All women should be offered an obstetric ultrasound before 20 weeks gestation. This will include an ultrasound for fetal morphology and placental localisation usually at 18–20 weeks gestation. Other scans may be indicated depending on individual circumstances and to assess/confirm dates.
2. **Screening for Down syndrome**
   Antenatal screening for Down syndrome and other fetal aneuploidy.
3. **Gestational diabetes**
   'Screening for GDM should be considered in all pregnant women. However, if resources are limited, screening may be reserved for those at highest risk.' (ADIPS 2002)
4. **Group B streptococcal disease**
   Swabbing for GBS
5. **Rhesus negativity blood group antibody screenings**
   Guidelines for the use of Rh-D immunoglobulin (anti-D) in obstetrics in Australia. Further screening is recommended for Rh-negative women at 28 weeks gestation. Screening of Rh-positive women is at the discretion of the clinician/managing health service.
6. **Iron deficiency**
   The haemoglobin level and platelet count should be repeated at 28 weeks gestation. If anaemia is detected, further investigation is warranted.
7. **Cytomegalovirus/toxoplasmosis**
   Screening is recommended only for those women at a substantially increased risk of acquiring an infection.
8. **Syphilis**
   Syphilis screening should be repeated at 28 weeks in high-risk populations.
9. **Late pregnancy tests of fetal wellbeing**
   Late pregnancy tests for assessment of feto-placental function should be performed when indicated on clinical grounds—either through a suspicion of placental insufficiency, a predisposing factor for placental insufficiency or through an inability to clinically ascertain fetal growth (e.g. obesity). Tests of fetal wellbeing should be considered after 41 weeks gestation. Detailed and frequent assessment of fetal wellbeing, including an assessment of liquor volume, is mandatory in pregnancies at or beyond 42 weeks gestation.

CHAPTER 33

Challenges in pregnancy

Christine Griffiths and Carol Thorogood

Key terms

choriadenoma, choriocarcinoma, chronic hypertension, complete miscarriage, cystitis, dizygotic (binovular), endometritis, gestational diabetes, gestational hypertension, hyperemesis gravidarum, hypoglycaemia, inevitable miscarriage, ketoacidosis, ketonuria, molar pregnancy (hydatidiform mole), monozygotic (uniovular), oligohydramnios, placenta praevia, placental abruption, polyhydramnios, pre-eclampsia, pregnancy-induced hypertension, pyelonephritis, recurrent miscarriage, silent miscarriage, threatened miscarriage, thrombo-embolic disease, Type 1 diabetes, Type 2 diabetes

Chapter overview

For most women, pregnancy progresses normally and she and her unborn baby remain well. For some, however, pre-existing problems, challenges or complications that arise during the pregnancy put the woman and her baby at risk of adverse outcomes. These complications can lead to serious illness, trauma, and even the death of the woman, her baby or both. Irrespective of the final outcomes, challenges in pregnancy place tremendous stress on the family. It is essential that midwives have the knowledge and skills to recognise the physical signs that a pregnancy is not progressing as it should and can identify psycho-social and environmental stressors that create or exacerbate complications in pregnancy. It is not enough just to recognise that all is not well. Midwives have a professional, legal and ethical responsibility to act on their findings. Irrespective of the practice setting, the woman—not clinicians or institutions or the woman's 'disease'—remains the primary focus of maternity care.

Many of the problems, challenges and complications considered in this chapter may be ones that the midwife, working in partnership with the woman, manages in a primary setting. However, when complications fall outside the scope of midwifery practice, midwives, still working in partnership with the woman, consult colleagues in a timely manner and work collaboratively with them to jointly manage secondary and tertiary levels of care.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe the effects that complications in pregnancy have on the woman, her family, the pregnancy and the unborn baby
2. To discuss the pathophysiology, diagnosis, evidence for treatment of, and expected outcomes associated with, common complications in childbearing
3. To identify strategies to support women as they are challenged by and deal with the physical and psychological complications of 'high-risk' birthing.

Introduction

This chapter focuses on an exploration of the most common complications arising in pregnancy—some pre-exist pregnancy, others are exacerbated by pregnancy and a few occur de novo. All pose challenges for the parents and their unborn baby, and the clinicians' role is to ensure best practice and outcomes. This chapter cannot cover every complication, and so you are advised to use journals, the internet and others' expertise to expand on the knowledge and skills obtained from this text. This chapter builds on the philosophy, principles and actions of Chapter 20: Working with women in pregnancy, on the understanding that if a midwife is to understand the 'abnormal' she must first know the 'normal'. Chapter 20 makes the point that antenatal care consists of more than just a series of medical tests and monitoring procedures. In the same way, 'high-risk' antenatal care is not just about investigations, diagnoses, conditions and medical treatment, but is also about women from different ethnic, socio-economic and cultural backgrounds who, while pregnant, must still face common life stressors and at the same time deal with pregnancy complications and stressors, including anxiety and fear about their own and their baby's health and the wellbeing of their family. Thus midwifery care is also about supporting women as they make the uncertain journey towards birth, one sometimes complicated by obstacles that result in actual or potentially life-threatening situations. The complications discussed in this chapter include the specifics of hyperemesis gravidarum, bleeding, medical conditions, hypertension and multiple pregnancy, as well as the social and psychological variables that affect these conditions and their outcomes.

Vomiting in pregnancy

Morning sickness

Nausea and vomiting (morning sickness) is a common complication of pregnancy, occurring in approximately 80% of pregnant women. It usually begins between the fourth and seventh week and resolves by the sixteenth week of pregnancy without treatment. Between 0.05% and 2% of sufferers require hospitalisation. Morning sickness is often called a minor disorder of pregnancy, probably by clinicians who have never tried to care for small, non-toilet-trained children, cook nutritious meals and then travel to work via public transport for an efficient day at the office, while feeling very ill. Women with morning sickness are often expected to accomplish all these tasks and endure nausea and vomiting for weeks, sometimes months. It is little wonder that some women seek to end this misery by terminating the pregnancy.

Hyperemesis gravidarum

Hyperemesis gravidarum is a debilitating illness, affecting one in 200 pregnant women (Quinlan & Hill 2003), beginning at about the fourth week of pregnancy and usually improving by the twentieth week, although some women continue to have recurring periods of severe nausea and vomiting throughout the whole pregnancy. It is characterised by: persistent and intractable vomiting leading to fluid and electrolyte imbalance; marked ketonuria; and nutritional deficiency and rapid weight loss, often greater than 5%. The pathophysiology of nausea and vomiting in pregnancy and hyperemesis gravidarum is poorly understood but is likely to be multifactorial (Hyperemesis Education and Research (HER) Foundation 2004; Quinlan & Hill 2003). These are:

- elevated pregnancy hormones (e.g. human chorionic gonadotrophin (hCG), oestrogen and progesterone)—hCG levels are higher than usual in some conditions associated with hyperemesis and nausea and vomiting in pregnancy (molar pregnancy and multiple pregnancy)
- displacement of the gastrointestinal tract, delayed gastric emptying, lower oesophageal sphincter pressure and increased levels of hydrochloric acid
- autonomic nervous system disturbance related to the physiological changes in pregnancy in blood volume, temperature, heart rate and vascular resistance
- nutritional deficits (e.g. trace elements, vitamin B_6)
- liver dysfunction—however, it is possible that elevated liver function (bilirubin, aminotransferase and alkaline phosphatase) may be secondary to the condition rather than a cause of it
- lipid metabolism—a slow adaptation of the liver to the increased levels of hormones in pregnancy may cause hyperemesis gravidarum and result in abnormal levels of serum lipids and lipoproteins
- chronic infection with *Helicobacter pylori*—this may play a role in hyperemesis gravidarum (Hayakawa et al 2000)
- psychogenic factors (e.g. ambivalence or rejection of the pregnancy)
- high thyroxine levels—these may be associated with hyperemesis gravidarum.

The 5% of women who develop hyperemesis gravidarum are often offered little sympathy, let alone practical or effective solutions to a debilitating problem, one that has a major impact on their self-esteem and daily living activities and is therefore a condition of great significance to those who have it. There have been a number of explanations for this neglect, centering around clinicians' views about women, their nature and what is considered 'important'. In one study, Fairweather (1968) administered the Cornell Medical Index to 44 pregnant women with hyperemesis and 49 pregnant women without the condition. Inexplicably, the Minnesota

Critical thinking exercise

Using a physiology textbook (such as Stables & Rankin's *Physiology in Childbearing*), revise the structure and function of the 'pregnancy hormones' such as hCG, oestrogen and progesterone. Make sure you understand their relationship to hyperemesis gravidarum.

Multiphasic Personality Inventory (MMPI) was given only to the group with hyperemesis, making the findings meaningless, but saying a great deal about the researchers' beliefs about women in general and the mental health state of women with hyperemesis in particular. The results suggested that women with hyperemesis had hysteria, were overly dependent on their mothers and had infantile personalities. Despite the methodological weaknesses of studies such as this during the 1960s and 1970s, medical and midwifery students were taught that women with hyperemesis gravidarum were hysterics who were trying to eject their fetus by vomiting it out of their bodies. Forty years later, discussion with women with hyperemesis reveals that some clinicians have not moved beyond these ways of thinking.

Collaborative support for a woman with hyperemesis

When a pregnant woman contacts her midwife with a history of persistent vomiting for most of the day, is unable to tolerate fluids and voids only small amounts of concentrated urine, an immediate midwifery assessment is warranted. In severe cases the woman will be dehydrated, show signs of electrolyte imbalance, initially alkalosis from the loss of hydrochloric acid. Later, as her condition worsens, she will become acidotic and develop ketonuria, hypovolaemia, hypotension and tachycardia. Once any of these signs are observed, medical referral and hospital admission are indicated. The goals of treatment for hyperemesis gravidarum are to reverse the effects of fluid and weight loss and to provide emotional support for the woman, who must deal with the stress related to the hyperemesis.

It is important to consider and rule out other pregnancy and non-pregnancy-related causes such as pyelonephritis, drug toxicity, biliary tract and liver disease. Pregnancy-related differential diagnoses include multiple pregnancy or a hydatidiform mole. The woman needs support, understanding, and perhaps counselling, as well as education and advice about measures that can ameliorate the symptoms. Traditionally the treatment of hyperemesis has been supportive, with

WOMAN'S STORY

I am a successful career woman who wanted a baby very badly. After many years of infertility treatment, I became pregnant, and then the horror began. I so wanted to 'glow', like the books tell us we should. I was desperate to keep my baby safe but all I could do was stick my head in the toilet and chuck—all day, every day. I felt so helpless and out of control. There was I, a senior executive in a male-dominated, not overly sympathetic field. In the middle of meetings, I had to rush out, vomit in the loo and then come back and behave as though nothing had happened and then take up where I had left off. I needed to work, as money was very tight. I didn't want to take drugs but I knew that this persistent vomiting posed immense risks for my baby and me. A colleague, a nurse, told me that research showed that hyperemesis was all in the head and that I needed to calm down. I didn't need this! I was overwhelmed, guilty, anxious and so frustrated that I could not make myself stop vomiting—but I couldn't control it, no matter what I did. Eventually I found a doctor who believed me and, even better, acknowledged my misery, not that she could stop me vomiting. I took anti-emetics and they worked a bit but I still vomited all day, every day, week after week, month after month. I was so dehydrated that my doctor would admit me to hospital every Friday night for rehydration with IV fluids so that I could go to work on Monday. I did this for five months, and had a Caesarean section at 34 weeks. I love my baby but I can't go through that again, and so my son will have no siblings. It's sad, really. I come from a family of eight kids and I always thought that I would be like my sisters and just pop 'em out.

Critical thinking exercise

Francesca is 12 weeks pregnant. She comes to your clinic for her first antenatal check, and tells you that she vomits all day and 'can't keep anything down'.

Formulate questions for Francesca that will help you determine the severity of her nausea and vomiting, and the potential for hyperemesis gravidarum. Your questions should centre on:

- the frequency of vomiting
- risk factors
- pain or pyrexia
- tolerance of food and fluid.

Clinical point

Education for women with severe nausea and vomiting in pregnancy

- Eat a diet high in complex carbohydrates (such as bread, rice, potatoes) and protein, and low in fat.
- Drink plenty of fluids.
- Eat five to six small meals a day, including a late-evening snack. Low blood sugar can cause nausea and shakiness. Some women find sucking on hard sweets helpful.
- Try eating a small snack before getting up.
- Eat many small meals each day but avoid lying down immediately after eating.
- Get plenty of rest. Being overly tired can set off nausea.
- Consider taking ginger supplements.
- Limit stressful events.
- Avoid noxious odours that trigger vomiting, cigarette smoke and tastes that trigger nausea, such as coffee.
- Consider acupuncture or acupressure to assist in relieving nausea.

reassurance, dietary modifications and lifestyle changes, but there is no evidence of the benefits of such dietary modifications (Jewell & Young 2002).

Hospitalisation is usually required for hyperemesis gravidarum. All food and drink are stopped temporarily, to rest the digestive tract. Intravenous fluids and electrolytes are almost always needed to replace fluids and correct imbalances in electrolytes. A few women will require enteral or short-term total parenteral nutrition (TPN) via a PICC line but these should be last-resort treatments for pregnant women who continue to vomit and lose weight despite active treatment with less interventionist strategies. Both TPN and central venous access can result in significant complications, including sepsis. However, an advantage is that women can manage these therapies at home.

Since the thalidomide tragedy, anti-emetic therapy is generally reserved for those whose symptoms are so persistent and severe that they prevent daily activities and pose a threat to the safety of the mother and her unborn baby. Because of concerns about the teratogenic effects of drug treatment there have been relatively few studies on the efficacy and safety of anti-emetics used for nausea and vomiting in pregnancy.

Treatments

A Cochrane Review (Jewell & Young 2002) as well as a number of other reviews of a range of pharmaceutical and non-pharmaceutical treatments for nausea and vomiting have been published (Mazzotta & Magee 2000; Meltzer 2000; Moran & Taylor 2002; Nelson-Piercy et al 2001). In summary, these show that there is no firm evidence that the administration of pyridoxine (vitamin B_6) alone or with doxylamine has a clinically significant effect on severe vomiting in pregnancy. However, according to a Cochrane Review (Jewell & Young 2002), it may be the most effective drug with the fewest side-effects. Although steroid therapy may resolve nausea and vomiting in pregnancy, concern has been raised recently about a marginally increased risk of congenital malformations (Quinlan & Hill 2003). Anti-emetics such as promethazine are widely used and it is considered the drug of choice in pregnancy because it is the most-studied. Therapy should be stopped two weeks before birth, as withdrawal symptoms in the infant can occur. Although frequently used for the treatment of nausea and vomiting, no randomised controlled trials (RCTs) have been published to support the effectiveness of metoclopramide as a treatment for nausea and vomiting in pregnancy (Mazzotta & Magee 2000). Extrapyramidal reactions sometimes occur, particularly in young women. Similarly, no RCTs have investigated the effectiveness of domperidone to treat nausea and vomiting of pregnancy (Mazzotta & Magee 2000). Serotonin antagonists such as ondansetron (Zofran) have also been used to decrease stimulation to the vomiting centre in the brain, but as yet there is no evidence that this medication makes a significant difference to outcomes, although it is possible that it makes some women less sensitive to odours and movements, which are common triggers of bouts of vomiting (Mazzotta & Magee 2000).

Clinical point

For more in-depth information about hyperemesis gravidarum, see 'International consensus on standards for studying the efficacy of pharmacological therapies for nausea and vomiting of pregnancy' by Berkovitch et al (2001).

Non-pharmaceutical treatments

Some women and clinicians doubt the safety and efficacy of pharmaceutical treatments for hyperemesis and regard complementary therapies as less toxic and more natural than synthetic remedies. It is therefore important for midwives to be knowledgeable about the evidence that supports their efficacy and, if they are to use them, are deemed competent to administer complementary therapies. Often fewer trial data exist for both safety and efficacy of complementary therapies than for drugs conventionally used to treat nausea and vomiting of pregnancy. In brief, ginger may reduce nausea and vomiting in pregnancy (Mazzotta & Magee 2000). According to Meltzer (2000) there is concern that ginger has an adverse effect on fetal brain development, and that by inhibiting thromboxane synthetase, ginger used in therapeutic quantities could increase bleeding in early pregnancy.

The acupuncture point most frequently used in traditional Chinese medicine for anti-emetic action is point 6 (P6) on the pericardium channel. Clinical trials on the use of acupressure and acupuncture including the use of Sea-Bands have not produced consistent results. A Cochrane Systematic Review (Jewell & Young 2002) showed that Neiguan point (P6) acupressure does have beneficial effects for nausea and vomiting in pregnancy. However, data from one of the largest RCTs were not included in the review, and this trial showed no benefit from acupressure (Jewell & Young 2002). Nevertheless, it has the advantage of being inexpensive and does not require consultation with the doctor or midwife.

Case reports of the efficacy of hypnosis, hypnotherapy, psychotherapy and behaviour modification on the treatment of hyperemesis have been published but as yet none have reported significant benefits (Jewell & Young 2002; Mazzotta & Magee 2000). Herbal remedies for nausea and vomiting in pregnancy, such as red raspberry or wild yam, have been used to treat hyperemesis, but again there is no evidence to support their efficacy or safety. Finally, there are no published trials regarding the efficacy of homeopathic remedies as a treatment for hyperemesis gravidarum.

Ongoing treatments

Left untreated, the woman with hyperemesis gravidarum may develop renal, neurological or hepatic damage. In severe cases, splenic avulsion, oesophageal rupture, peripheral neuropathy and pre-eclampsia as well as fetal intrauterine growth restriction and increased mortality occur (Quinlan & Hill 2003). Termination of pregnancy may be the woman's choice, especially if severe renal, neurological or hepatic

BOX 33.1 Support for women with hyperemesis

Clinical support

Most sufferers with hyperemesis gravidarum (HG) require multiple admissions for each pregnancy. Women with HG are very miserable and deserve to be treated with great compassion. Extra measures that are beneficial, both physically and psychologically, are required to give comfort and relief. Intravenous fluids may be warmed before administration to avoid discomfort and calorie loss due to shivering. Warmed blankets will also help. If multiple IV sites are required it is important to use local anaesthetics and to use the most skilled personnel to site them, to avoid undue pain and scarring. A PICC line is useful if total parental nutrition is required.

Multiple intramuscular injections should be avoided because of muscle atrophy and general discomfort. It is important to minimise stimuli (light, noise and odours), as well as interruptions to the woman's rest. Occupational or physiotherapy consultations can be used to develop progressive exercise regimens that minimise muscle atrophy. Daily weigh-ins are unnecessary for women during extended hospital stays. Women with HG need the chance to express their feelings in an atmosphere of compassion and empathy. These feelings should be taken seriously, and the woman with HG needs to know that her midwife will do all she can to help her cope with the misery, stress and discomfort of HG.

HER Foundation

The Hyperemesis Education and Research (HER) Foundation is dedicated to those suffering from HG and those who have survived it. HER can be contacted at: http://www.hyperemesis.org.

(Source: adapted from HER 2005)

involvement becomes apparent. If not, investigation of other associated factors causing hyperemesis gravidarum, such as multiple gestation or hydatidiform mole, are required. Social and financial assistance is often required to help the woman care for herself and her other children, especially if she cannot work until this incapacitating condition is resolved.

Bleeding in pregnancy

Any bleeding in early pregnancy—that is, the first or second trimester—is considered a threatened or an actual miscarriage (abortion) until proved otherwise. A miscarriage can be an intensely sad and frightening experience for everyone. A pregnancy that seemed normal suddenly ends, leaving the expectant parents devastated. About 20% of women with clinically diagnosed pregnancies will experience bleeding at some time in early pregnancy (Bryan 2003). Overall, up to 50% of all pregnancies end in miscarriage although many more losses occur before a woman realises she is pregnant (ACOG 2001). Of these, about 20% of recognised pregnancies end in an actual miscarriage (Bryan 2003).

Definition and classification

For most women, pregnancy loss is associated with emotions of fear, grief, guilt and sorrow, and the feeling that their body has failed them. The traditional, medical term for a miscarriage is 'spontaneous abortion', but such language should be avoided. Terminology such as 'spontaneous abortion', 'habitual abortion' and 'pregnancy failure', or 'abnormal pregnancy', may exacerbate the negative self-perceptions that women already may have—a sense of failure, even shame, guilt and insecurity. Midwives need to be aware of the language they use when talking to women and ensure that it is acceptable to both the woman and her midwife. When unsure, it is preferable to adopt the language the woman uses. The use of a common language is a step towards offering positive support for women.

There are many confusing terms and moments that accompany a miscarriage. It is best considered a process rather than an event, but for ease of understanding, the different 'types' of miscarriage are presented here as separate entities.

Threatened miscarriage (abortion)

Vaginal bleeding (spotting) before the twentieth week of pregnancy and possibly accompanied by low back or abdominal pain are usually the first signs of a threatened miscarriage. The amount of bleeding and the presence of pain have little predictive value in terms of the viability of the pregnancy (Bryan 2003). Women experiencing a threatened miscarriage have an approximately 85% chance that the pregnancy will progress to term. The bleeding is usually self-limiting, and is sometimes attributed to trophoblastic implantation within the endometrium rather than a miscarriage per se. On examination, the cervix remains closed, the uterus is soft and non-tender and of appropriate size for gestational age.

Inevitable (imminent) miscarriage

When vaginal bleeding and cramping persist and are accompanied by dilatation of the internal os or rupture of the fetal membranes, a miscarriage is inevitable. Bleeding is usually more severe than with a threatened miscarriage and is often associated with mild to moderate uterine contractions.

Complete miscarriage

In a complete miscarriage, the products of conception are expelled. Women report a history of vaginal bleeding,

BOX 33.2 Miscarriage support

Miscarriage Support Auckland Inc. (http://www.miscarriagesupport.org.nz/support.html, www.sandsvic.org.au/services.html) is a team of volunteers who have all experienced the loss of a baby. Sharing their experience with others has assisted many women with the grieving progress and set them on the road to healing. This can be via the internet on the Bulletin Board at www.everybody.co.nz/bulletinboard.html (or via email at support@miscarriagesupport.org.nz).

abdominal pain, and passing tissue (products of conception). Once miscarriage is completed, the bleeding and pain usually subside, the uterus contracts and the cervix closes. A completed miscarriage can be confirmed visually, by an ultrasound showing an empty uterus with close apposition of relatively thin and regular endometrial interfaces. Urine or serum β-hCG values will be falling or below the discriminatory threshold levels determined by the healthcare service.

Incomplete miscarriage

An incomplete miscarriage is more likely to occur between 6 and 14 weeks of pregnancy. Bleeding and pain may persist if the miscarriage is not completed, and this increases the risk of infection. Vaginal bleeding is usually heavy and accompanied by increasingly severe uterine contractions. The cervical os is open. The woman may say that she has passed fetal or placental fragments. Ultrasonography may reveal that some products of conception are still present in the uterus; these typically appear as echogenic material.

Silent or delayed miscarriage (missed abortion, blood mole, carneous mole or stony/fleshy mole)

Women can experience a miscarriage without knowing it. In a silent (missed) miscarriage, the fetus has died but is retained in the uterus. Uterine and breast growth cease and the woman may report vaginal 'spotting' or a brown, sometimes offensive, vaginal discharge. With widespread use of transvaginal ultrasonography, a silent miscarriage (presence of a non-viable fetus) or an anembryonic pregnancy (absent fetal echo) are now believed to reflect different aspects or stages of the same clinical process. A blighted ovum (anembryonic pregnancy) occurs when a fertilised egg implants into the uterine wall but fetal development does not begin. Often there is a gestational sac with or without a yolk sac, but there is an absence of fetal growth. Chromosomal abnormalities are a common cause of an anembryonic pregnancy. The woman may notice that her pregnancy symptoms have stopped and she may develop dark-brown vaginal bleeding. Diagnosis is confirmed by the woman's story, physical examination, laboratory tests and ultrasonography. Blood and urine tests will show a drop in β-hCG levels or a negative over-the-counter pregnancy test. An ultrasound examination shows early evidence of an intrauterine pregnancy but only an empty pregnancy sac. The miscarriage may not be completed for weeks and this may lead to fetal autolysis, which results in the release of thromboplastin and disseminated intravascular coagulation.

Molar pregnancy (gestational trophoblastic disease)

Following a silent miscarriage, a few women develop gestational trophoblastic disease. This term covers a spectrum of disorders characterised by abnormal and rapid growth of trophoblastic tissue, ranging from a molar pregnancy (hydatidiform mole) to a malignant choriocarcinoma. Trophoblastic disease is rare, occurring in 1 out of every 1000 pregnancies, but the condition varies between regions and age groups. The reasons for these geographic and age differences are unknown but may be related to poor nutrition, particularly a low intake of carotene (vitamin A precursor). The main risk factor for a molar pregnancy is advanced maternal age—women over 40 have a five- to ten-fold greater chance of a molar pregnancy. In addition, women who have had a prior molar pregnancy have a 1:100 chance of having another in a subsequent pregnancy.

Complete and partial molar pregnancies (hydatidiform moles)

Molar pregnancies are the result of a genetic error during fertilisation and comprise two distinct entities. Irrespective of whether they are complete or partial, a molar pregnancy poses a threat to the woman not only because it produces an abnormal pregnancy, but also because it may cause life-threatening complications. A complete mole differs from a partial one according to chromosomal patterns, karotype, gross and microscopic histopathology and clinical presentation. Complete moles arise from the fertilisation of an 'empty egg'—one that has lost its maternal genetic material. There is no embryo and no normal placental tissue. However, the placenta continues to grow and produces β-hCG, so the woman thinks and feels that she is pregnant. A complete mole demonstrates a characteristic vesicular pattern (resembling a bunch of grapes). However, in a partial mole, there may be some normal placental tissue and the embryo, although abnormal, begins to develop. A partial mole has duplicate paternal genetic material, although the maternal chromosomal complement is intact, so the genetic material is in triplicate. Therefore the embryo has 69 chromosomes instead of the normal 46. The fetus nearly always dies in utero.

Signs of a molar pregnancy

A molar pregnancy begins like a normal pregnancy and may entail common symptoms of pregnancy, including a missed period, positive pregnancy test and nausea. From about the 10th week of pregnancy, most women with a complete molar pregnancy experience vaginal bleeding that is dark brown in colour, and may pass vesicular tissue. These symptoms usually

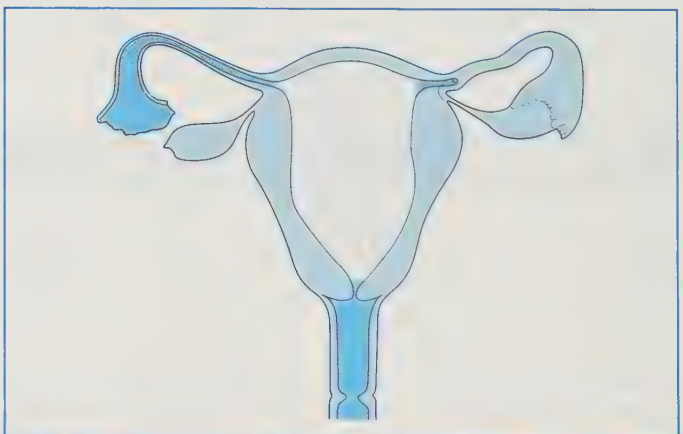

Figure 33.1 Molar pregnancy: a grapelike cluster of tissue (called a hydatidiform mole) forms around the area that normally would become the placenta, and may cause life-threatening complications.

mimic those of a miscarriage, although about 50% of women with a complete mole have uterine enlargement that is too advanced for the expected gestational age. Pre-eclampsia may develop before the 20th week of pregnancy. A few women have signs of hyperthyroidism: tachycardia, tremulousness, and feeling excessively warm.

Women with partial molar pregnancies in general have fewer symptoms and so their condition is often only confirmed following histological examination after treatment for a silent or inevitable miscarriage. They rarely have abnormally excessive uterine enlargement, hyperthyroidism or pre-eclampsia. Occasionally the fetus survives beyond 16 weeks and diagnosis is confirmed by the appearance of the placenta on ultrasound.

Medical diagnosis of a molar pregnancy

The gold standard of diagnosis remains the characteristic vesicular appearance of the placenta on ultrasound scan, typically a 'cluster of grapes' or a 'snowstorm' appearance (see Fig 33.1). Initially levels of β-hCG although not diagnostic are often higher than normal with a complete mole, but lower than normal with a partial mole.

Septic (infected) miscarriage

In a septic miscarriage, the fetus has died and the products of conception have become infected. Septic abortion was once a leading cause of maternal death across the world, and still is in countries where termination of pregnancy is illegal. The risk of death from an infected miscarriage rises with advancing gestation. If not treated, the infection may spread further into the myometrium and parametrium and cause peritonitis. The woman may develop generalised septicaemia and will require aggressive antibiotic therapy. Pelvic inflammatory disease (PID) and infertility are common long-term complications of this life-threatening disorder.

Recurrent pregnancy loss (habitual abortion)

While miscarriage is usually a one-time occurrence, about 1–2% of couples have two, three or more consecutive miscarriages (Hogge 2003). If three consecutive pregnancies end in miscarriage, the couple require referral to an obstetrician and probably a fertility specialist in an effort to determine the cause of the recurrent pregnancy loss. Possible causes for recurrent miscarriage are chromosomal or other genetic abnormality, progesterone deficiency, infection, uterine abnormality, cervical 'incompetence' or systemic disease. Any miscarriage is distressing for the parents but recurrent miscarriages are devastating, especially if it is not possible to identify a cause and therefore a 'cure'. Parents need to know that despite the battery of tests usually ordered during investigation of recurrent miscarriage, only 50% of couples will be given an answer for their inability to carry a live baby beyond two trimesters (ACOG 2001).

Implantation bleeding

It is commonly believed, even among health professionals, that as the trophoblast implants into the endometrial layer of the uterus, bleeding can sometimes occur and escape from the uterine cavity into the vagina—hence the term implantation bleeding (Harville et al 2003). However, Harville et al (2003) found no evidence that implantation causes vaginal bleeding. Vaginal loss is usually light and occurs a few days before menstruation would have been due and is probably a threatened miscarriage. Women may mistake this bleeding for menstruation, particularly if they normally experience minimal blood loss. It is therefore important for the midwife to take an accurate menstrual history that enables her and the woman to eliminate miscalculations in the estimated birth date.

BOX 33.3 Signs of infected miscarriage

Any woman of childbearing age presenting with fever, tachycardia, abdominal pain, vaginal discharge or bleeding should be evaluated for a possible septic miscarriage. Immediate referral to a medical practitioner is warranted.

Warning signs include:

- history of recent pregnancy
- pyrexia and general malaise
- abdominal pain
- vaginal discharge which may be purulent
- vaginal bleeding.

Decidual bleeding

During pregnancy, menstruation ceases. Occasionally, however, there is a slight blood loss from the decidua in the first 10 weeks of pregnancy, usually at the time the period would be due. Decidual bleeding may be mistaken for a menstrual period and affect the accuracy of estimations of the expected birth date. Most pregnancies will proceed without further complication.

Causes of miscarriage

The causes of miscarriage are not thoroughly understood and clinicians are frequently unable to give grieving parents a precise response to questions about why the miscarriage occurred. Up to 70% of first-trimester miscarriages are caused by fetal chromosomal abnormalities (Hogge 2003). These become more common with increased maternal age, and women over the age of 35 are at much higher risk of miscarriage than younger women. There is good evidence that auto-immune diseases play a significant role in miscarriage. Autoantibodies associated with repeated miscarriage include anticardiolipin antibodies, which are associated with thrombo-embolic disorders. Studies suggest that this and related antiphospholipid antibodies cause between 3% and 15% of repeat miscarriages (ACOG 2001). In addition, a Factor V Leiden mutation, which affects blood clotting, may also play a role in repeat miscarriages (ACOG 2001).

Acute and chronic infectious diseases are well documented as causative factors in miscarriage. Bacterial vaginosis is the most common genital infection among women of reproductive age.

The US-based Centers for Disease Control (CDC) estimates that as many as 16% of pregnant women have bacterial vaginosis (CDC 2004). Although having a new sex partner or multiple partners increases the chances of infection, the exact role that sexual activity plays in the infection is unclear. A recent study found that women with bacterial vaginosis were nine times more likely to have a miscarriage than uninfected women (Leitich et al 2003). Young women of childbearing age are increasingly infected with *Chlamydia trachomatis* but as the research box below shows, the precise relationship between genital infection and early and late miscarriage is still unclear. Numerous other microbial organisms have been blamed for miscarriage, such as cytomegalovirus (CMV), herpes simplex virus (HSV), rubella, parvovirus, *Treponema pallidum* and HIV. CMV is a common viral infection of the herpes family. It is transmitted through blood, saliva, breast milk and other bodily fluids. Between 40% and 85% of people are infected with CMV during their lifetime, but most do not have any symptoms.

Chronic illnesses

Chronic illnesses, including diabetes, severe hypertension, kidney disease and auto-immune diseases, are frequent causes of miscarriage. Other postulated causative factors include low progesterone levels and thyroid dysfunction as well as anatomic defects, such as a septate or bicornuate uterus or uterine fibroids. Finally, environmental hazards (exposure to cigarette smoke, formaldehyde, pesticides), exposure to anaesthetic gases, chemotherapy and trauma are associated with miscarriage, as are maternal illness and dietary deficiencies.

Research

Association between bacterial vaginosis or chlamydial infection and miscarriage before 16 weeks gestation: prospective community-based cohort study (Oakeshott et al 2002).

The objective of this UK study was to assess whether bacterial vaginosis or chlamydial infection is associated with early miscarriage (before 16 weeks). Of the 1201 women in the study, 14.5% had bacterial vaginosis. The infection was more common in participants who: were under 25, of Afro-Caribbean or black African ethnicity, from social classes 3–5, single, and had previously used oral contraception or none, and smoked during pregnancy; and those with a history of termination of pregnancy and who had a concurrent chlamydial infection. Compared with women who were negative for bacterial vaginosis, women who were positive had a relative risk of miscarriage before 16 weeks gestation of 1.2 (0.7 to 1.9). Only 29 women had a chlamydial infection, one of whom miscarried. The authors concluded that, at least in this study, bacterial vaginosis was not strongly predictive of early miscarriage. Therefore, early screening and treatment of asymptomatic bacterial vaginosis are unlikely to improve first-trimester miscarriage rates.

In summary

Many of these factors are summarised in Box 33.4. However, in many cases there is no obvious cause of early reproductive losses. Pregnancies that proceed following a threatened miscarriage have an increased risk of complications and poor outcome compared to pregnancies where there is no bleeding (Bryan 2003).

Management of early pregnancy loss

The following summary of 'best-practice' recommendations for the collaborative management for early pregnancy loss is based on the Royal College of Obstetricians and Gynaecologists' Green Top Guidelines (RCOG 2001).

Early pregnancy assessment units

The RCOG guidelines recommend that all maternity centres provide an early pregnancy assessment service with direct access for women, midwives and medical personnel. A

BOX 33.4 Bleeding in early pregnancy

- Implantation bleeding
- Decidual bleeding
- Miscarriage
- Ectopic pregnancy
- Termination of pregnancy
- General maternal causes:
  - chronic maternal disease
  - infection (bacterial vaginosis)
  - hormonal deficiencies
  - nutritional deficiency
  - poorly controlled diabetes
  - thyroid disease
  - auto-immune disease—systemic lupus erythematosus
- Local maternal causes:
  - weakened cervix
  - abnormally shaped uterus
  - rarely a retroverted gravid uterus
  - polycystic ovary syndrome
- Other maternal causes:
  - lifestyle factors (smoking, illicit and licit drug and alcohol abuse)
  - environmental and workplace hazards
  - increased maternal age
- Hydatidiform mole
- Cervical pathology:
  - dysplasia
  - polyp
  - carcinoma
- Vaginal bleeding from non-pregnant horn of a bicornuate uterus
- Urinary tract infection
- Haemorrhoids
- Ruptured vulval varicosities

dedicated early pregnancy assessment unit (EPAU) can streamline the management of women with early pregnancy bleeding or pain and thus improve the quality of care, in the presence of a supportive, multidisciplinary team (Bigrigg & Read 1991). An effective EPAU requires:

- an efficient appointments system
- an appropriate setting (with an area for counselling)
- up-to-date ultrasound equipment (including transvaginal probes)
- easy access to laboratory facilities (for Rhesus antibody testing and selective serum β-hCG estimation)
- effective systems of communication facilitated by standardised referral and discharge letters.

Collaborative care

In many cases, and if the bleeding is not severe, women prefer to wait at home, supported by their midwife, 'to see what happens' rather than attend the local hospital or EPAU. In most cases, the woman spontaneously passes the products of conception. There are three different management options for women with an incomplete miscarriage:

- surgical evacuation
- medical therapy
- expectant treatment.

According to Bryan (2003) the choice of management options depends largely on the clinicians' and woman's preferences. However, in a partially randomised study comparing surgical and medical evacuation, 20% of women expressed a strong preference for medical management (Hinshaw 1997). The main reasons given for their choice was that they wanted to avoid general anaesthesia and felt more in control of the procedure and outcomes.

Since the 1800s, when illegal abortion was common and antibiotics were unavailable, surgical uterine evacuation (dilatation and curettage) has been the standard treatment offered to all women who have miscarried. This decision was based on the assumption that retained tissue increased the risks of infection and therefore haemorrhage and sometimes death. In recent years, with the advent of technology such as transvaginal sonography (TVS) (Bryan 2003), clinicians have questioned the need for surgical evacuation of the uterus for all women who miscarry. The consensus is that in women in whom no retained products of conception are detected by TVS, the complication rate from dilatation and curettage is higher than in women in whom no operative intervention is made and therefore a conservative approach to management is preferable (Bryan 2003). Thus a curettage is no longer considered mandatory but may be required if the woman is bleeding heavily or has an infection, or if an ultrasound examination shows that there is placental tissue remaining in the uterus.

Studies of the efficacy of the antiprogestogen mifepristone or the prostaglandin analogue misoprostol for the medical management of incomplete miscarriage (Beal & Simmonds 2002; Forna & Gulmezoglu 2004) show that these therapies are beneficial for ripening the cervix and encouraging uterine contractions and, therefore, expulsion of the pregnancy.

Clinical point

Referral to a medical centre

Most women who have an early miscarriage do not need medical treatment, although they always need supportive care. However, if vaginal bleeding is heavy, there is pyrexia, tachycardia or bradycardia and hypotension, if products of conception have been passed, or if there is severe abdominal pain, the woman must be referred for immediate gynaecological assessment. The possibility of ectopic pregnancy should always be considered if a woman in early pregnancy complains of abdominal pain or exhibits signs of peritoneal irritation.

Nevertheless, Bryan (2003) points out that misoprostol offers no advantage over either the surgical or expectant management option, mostly because of the high incidence of gastrointestinal side-effects. Expectant (conservative) management is also an accepted management alternative. Irrespective of the choice of technique used to empty the uterus, tissue obtained at the time of miscarriage should be examined histologically to confirm pregnancy and to exclude other complications such as ectopic pregnancy and gestational trophoblastic disease.

Women who miscarry should:

- be offered the opportunity to attend for follow-up care, possibly with EPAU staff or the lead carer in the community (midwife, GP or obstetrician)
- have plans for follow-up clearly recorded in the discharge letter from the EPAU to the lead carer
- be informed that they can expect a grief reaction
- be informed that lactation may need to be suppressed
- be given the contact details of their local miscarriage support group
- understand that it may take weeks to a month or more to recover physically from a miscarriage, which may be considerably longer than the time other family members think the woman needs to recover
- know that they will probably experience a menstrual period four to six weeks after the miscarriage.

Clinical point

Retained products of conception

During an incomplete miscarriage, products of conception may be caught in the cervix, causing profound vagal stimulation, bradycardia and shock. If this is suspected, the woman needs urgent hospital admission. Removal of retained products of conception will lead to rapid clinical improvement and reduction in bleeding. Any tissue passed should accompany the woman to hospital.

Clinical point

According to Weinberg (2001), approximately 4% of women who have a miscarriage will have a transplacental haemorrhage of > 0.2 mL of fetal red blood cells. Since the late 1960s, anti-D immunoglobulin has been used successfully for Rhesus prophylaxis. Non-sensitised Rhesus (Rh)-negative women should be offered anti-D immunoglobulin in the following situations: ectopic pregnancy; all threatened or diagnosed miscarriages over 12 weeks; all miscarriages; and when the uterus has been surgically evacuated. Sensitisation can occur after a transplacental haemorrhage of < 0.1 mL and so there is a potential for sensitisation in pregnancies of less than 12 weeks gestation, although research has yet to confirm this suspicion. Currently, the routine administration of anti-D immunoglobulin is not recommended in threatened miscarriages below 12 weeks gestation or if the fetus is viable. However, if the bleeding is heavy or associated with abdominal pain, Rhesus D sensitisation is more likely to occur. Weinberg's UK study (2001) shows that many women who present to emergency departments with a threatened miscarriage such that there is an increased risk of Rhesus D isoimmunisation were not offered anti-D immunoglobulin. Discharge documentation should always clearly state whether or not anti-D immunoglobulin was offered, given, and by whom.

Collaborative management of a molar pregnancy

A molar pregnancy is a very frightening experience. Not only does the woman lose a pregnancy, but she also learns that she has a risk, albeit a slight one, of developing trophoblastic disease and perhaps metastatic choriocarcinoma, a fast-growing but rare malignant growth of the chorion. In order to protect the woman, all molar tissue must be removed from the uterus. In the first trimester this is usually done with suction curettage, sometimes followed by surgical curettage, under general anaesthesia. In the second trimester, uterine stimulation with prostaglandin E_2 and oxytocin before surgical evacuation to avoid uterine perforation and severe haemorrhage are often recommended.

Occasionally, when the mole is extensive and the woman has decided against future pregnancies, she may choose a hysterectomy.

Follow-up

All women who have had a molar pregnancy are followed up regularly for the next one to two years for regular β-hCG urine tests, because molar pregnancies can recur, and to ensure that no chorionic tissue remains in the uterus because of the risk of choriocarcinoma. Follow-up consists of a baseline chest X-ray, review of the pathology specimen, and regular physical examinations of the uterus until it returns to normal size, then three-monthly check-ups for at least a year. Most importantly, to ensure no chorionic tissue remains in the uterus, the woman is advised to have weekly β-hCG levels until there are two consecutive zero results. For the next 12 months, levels are taken every month for the first six months and second-monthly for the following six months. Waiting one or two years before attempting another pregnancy is important, because a rise in β-hCG levels may indicate a normal pregnancy but may also indicate a recurrent molar pregnancy. Some physicians recommend prophylactic chemotherapy as well as or instead of the usual follow-up but this remains controversial (Khoo 2003). Chemotherapy regimens using low doses of methotrexate and folinic acid have improved survival rates.

As the pregnant woman undergoes diagnosis and treatment for a molar pregnancy, she may be concerned mainly about her own health and survival. Afterwards, she and her partner feel relief that she has come through the ordeal. Grief over the loss of the pregnancy may not become apparent for some time. As with any couple whose unborn baby has died, the family needs time to grieve and to recover emotionally. If a woman has a molar pregnancy, her outlook for a future successful pregnancy is good. It is important for women to undergo regular ultrasound in subsequent pregnancies to confirm normal fetal and placental development. The placenta is sent to the pathologist after the birth to make sure there are no abnormalities.

Emotional recovery from early pregnancy loss

The comprehensive management of pregnancy loss will be enhanced by psychological support and follow-up counselling (Boyce et al 2002). This can be provided by the woman's lead carer, who can address medical as well as psychological issues. All clinicians should be aware of the psychological sequelae associated with miscarriage and be prepared to provide support and follow-up, as well as access to a counsellor who is experienced in dealing with pregnancy loss. For some couples, a miscarriage causes both severe and protracted distress at a level not appreciated by all professionals involved.

The purpose of follow-up counselling, according to Boyce et al (2002), is to:

- allow open discussion about the loss, monitor progress and counsel the woman about future pregnancies
- provide an opportunity for her to talk about her loss and have her grieving acknowledged
- provide information about the normal grief process. This may help a woman who is masking her grief or does not believe it is legitimate.
- facilitate the grief process by enabling the woman to talk about feelings of guilt and self-blame, particularly when there is no medical explanation for her loss
- provide an opportunity for the woman and her family to discuss their dissatisfaction, if there is any, with their care, as the woman may feel angry and blame her medical practitioner for her loss.

Often women want to know how long they must wait after a miscarriage before attempting another pregnancy.

The response to this question is that the couple should not attempt another pregnancy until the woman is physically and emotionally ready and they have completed any tests recommended to determine the cause of the miscarriage. Clinicians often advise the couple to wait until the woman has had one normal menstrual cycle but it may take considerably longer before she is ready to attempt pregnancy, especially if there has been a molar pregnancy. Many women who have experienced miscarriage worry that they will miscarry again. Fortunately, the great majority of women will go on to have a subsequent successful pregnancy.

Ectopic pregnancy

An ectopic pregnancy occurs if a fertilised ovum implants at a site other than the endometrial lining of the uterus, most commonly in a fallopian tube, although ovarian, cervical and abdominal pregnancies are also possible. The incidence of ectopic pregnancy is estimated to be 1 in 200–500 pregnancies but is increasing (Tay et al 2000). The rise is greatest in women over 35 years of age. The diagnosis of ectopic pregnancy can now be made by non-invasive methods due to sensitive pregnancy tests (in urine and serum) and high-resolution TVS. Improvements and greater efficiency in diagnosis have resulted in a range of both conservative and radical treatment options. Nevertheless ectopic pregnancies are still a major cause of maternal morbidity and mortality and remain the leading cause of pregnancy-related maternal deaths in the first trimester. Most deaths result from delayed diagnosis, and inappropriate investigation and treatment.

Pathophysiology

Normally the fertilised ovum travels along the fallopian tube to the uterus via the peristaltic action of the cilia. In an ectopic pregnancy there is a delay in the passage of the ovum to the uterus, commonly due to previous tubal infection (salpingitis), which destroys the cilia that propel the blastocyst to the endometrium. Instead the blastocyst embeds in the epithelium of the fallopian tube, burrowing into blood vessels in the same way that it does in a normal implantation, and continues to develop and increase in size. This is known as a tubal pregnancy. Depending on which part of the fallopian tube the embryo has embedded in, the tube will either rupture between five and seven weeks gestation because the fallopian tube cannot stretch to accommodate the growing pregnancy, or alternatively, it is expelled from the fimbriated end of the fallopian tube into the peritoneal cavity at eight to ten weeks gestation (a tubal abortion). In both cases bleeding surrounding the embryo usually results in its demise. Rarely, transmigration of the ovum and/or sperm may occur, so that the ectopic occurs in the fallopian tube contra-laterally to the corpus luteum. Occasionally when the embryo dies it is retained within the fallopian tube surrounded by layers of blood clot, which blocks the fallopian tube, resulting in a tubal mole or haematosalpinx, similar to a uterine molar pregnancy. The 'tubal mole' may remain in the fallopian tube or be expelled as a tubal abortion.

Risks for ectopic pregnancy

Ectopics are primarily associated with an earlier tubal infection or structural abnormalities that obstruct or slow the passage of the blastocyst as it passes through the fallopian tube to the uterus where it embeds in the endometrium. Up to 50% of women with ectopic pregnancies have a medical history of salpingitis or pelvic inflammatory disease (PID). Women who have had surgery to reverse previous tubal sterilisation in order to become pregnant also have an increased risk of ectopic pregnancy when reversal is successful. In some cases, the cause is unknown. Ectopic pregnancy is more common in women with a history of:

- infertility
- endometriosis
- congenital fallopian tube abnormalities
- sexually transmitted infections (these can cause infection and scarring in the pelvis)
- previous tubal infection or surgery
- intrauterine contraceptive devices (IUCDs)
- oral contraception.

It should be remembered that the last two risks only refer to the tiny proportion of women who become pregnant while using IUCDs or when taking oral contraceptives—they do not refer to all women who have in the past used these methods and later became pregnant. Of note is that the 'morning-after pill' is associated with a ten-fold increase in ectopic pregnancy, but again this risk refers only to the proportion of women who become pregnant in spite of taking

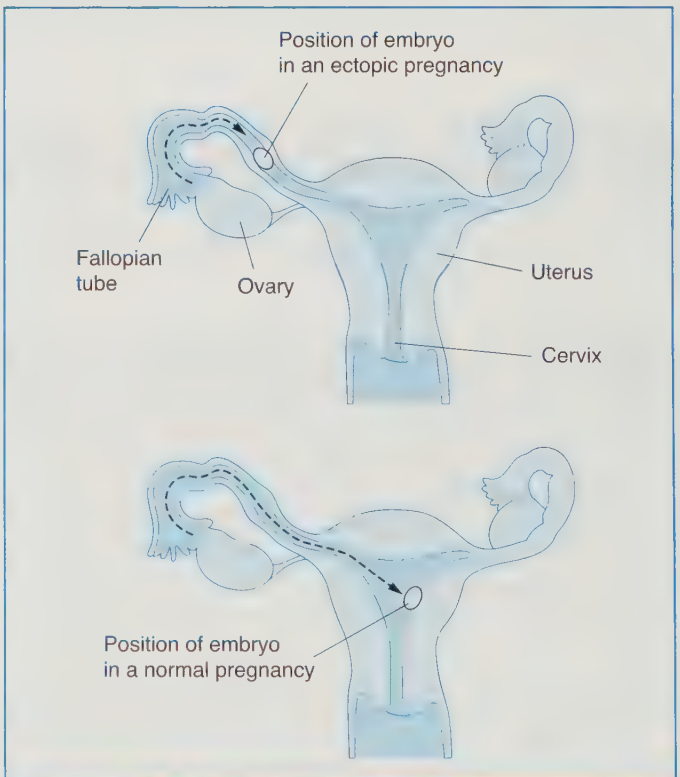

Figure 33.2 Ectopic pregnancy

the medication, rather than to women who in the past have used the drugs.

Clinical presentation

Most ectopic pregnancies are diagnosed before they rupture. Tay and colleagues (2000) state that diagnosis can be difficult and can be confused with signs of miscarriage, an ovarian cyst or PID.

In the initial stages of an ectopic pregnancy although the fertilised ovum embeds into the fallopian tube, the uterus still undergoes the normal changes of early pregnancy, and so the woman experiences the normal symptoms of pregnancy.

Tubal rupture is rarely sudden and so women who present to hospital in severe shock usually report warning signs that have been overlooked. Typically the woman presents with non-specific signs similar to those of a threatened miscarriage, but unlike miscarriage the woman complains of lower abdominal pain that precedes bleeding. On examination, abdominal pain and rigidity and rebound tenderness are palpated. These signs, especially if they are accompanied by vaginal bleeding, which may be minimal or torrential, together with signs of haemodynamic compromise/shock—hypotension, tachycardia, pallor, cold clammy skin, faintness and vomiting—should always alert the lead carer to the possibility of a ruptured ectopic pregnancy. In addition, shoulder-tip pain may be present, or pain may be referred to an iliac fossa. A mass may be felt to one side of the uterus. Any woman presenting with these signs requires immediate transfer to hospital and specialist consultation. If the clinical diagnosis is still unclear, an ultrasound scan will confirm or exclude the presence of an extrauterine gestational sac and occasionally a viable fetus.

Clinical point

Up to 9% of women with an ectopic pregnancy report no pain even if the fallopian tube is close to rupturing, and 36% lack adnexal tenderness (Tay et al 2000).

Clinical point

Always consider the possibility of ectopic pregnancy in women of childbearing age with abdominal pain. A sexually active woman with abdominal pain and vaginal bleeding after an interval of amenorrhoea has an ectopic pregnancy until proved otherwise! If there is no history of a missed period, check whether the last period was normal in duration and blood loss. The index of suspicion rises if the woman reports a history of infertility, has missed a period while using an IUCD or has been sterilised. Always ask about contraception use and remember that not all women admit to being sexually active. Others may not be aware that they are pregnant.

Incidence and rate of presenting signs of ectopic pregnancy

Tay and colleagues (2000, p 916) list the following frequencies the signs of ectopic pregnancy:

- abdominal pain (97%)
- vaginal bleeding (79%)
- abdominal tenderness (91%)
- adnexal tenderness (54%)
- history of infertility (15%)
- use of an IUCD (14%)
- previous ectopic pregnancy (11%).

Laboratory studies

Serial β-hCG levels vary in ectopic pregnancy, but compared to a uterine pregnancy the levels rise more slowly than expected and usually plateau at about six weeks gestation. Evaluating test results is complicated by the fact that at least two laboratory reporting standards are still in common use: International Reference Preparation (IRP) and the Second International Standard (2IS). IRP values are approximately twice the value of the 2IS values (Botash & Spirt 2000). Although β-hCG levels and their rate of increase may vary, a negative test result effectively excludes the diagnosis of an intra- or extrauterine pregnancy. In contrast, a positive result is highly suggestive of pregnancy. Serial testing is usually needed:

- to differentiate from a completed miscarriage
- for women in whom ultrasonography examinations are inconclusive
- to determine whether the β-hCG has reached a plateau.

A positive serum β-hCG test in combination with ultrasonographic evidence of an intrauterine pregnancy is strongly suggestive of an ectopic pregnancy or a recent miscarriage. Serum creatine kinase levels have been advocated as another marker of ectopic pregnancy but are now rejected because of their inadequate diagnostic sensitivity (Darai et al 1996).

Imaging studies

Serum β-hCG levels are most helpful if they are performed in conjunction with ultrasonography. The usefulness of ultrasound in general and TVS in particular are well documented in the assessment and diagnosis of early pregnancy complications. According to Tenore (2000), compared with abdominal ultrasonography, TVS diagnoses intrauterine pregnancies on average one week earlier because it is more sensitive and has a lower discriminatory zone. Once the β-hCG level is > 1500–2000 mIU per mL, an intrauterine pregnancy should be visible on TVS. An intrauterine pregnancy is

BOX 33.5 Warning signs

Warning signs of fallopian tube rupture:

- severe, sharp and sudden pain in the lower abdominal area
- feeling faint or fainting in the presence of significant bleeding
- signs of haemodynamic compromise/shock
- referred pain to the neck and shoulders.

confirmed when a gestational sac with a sonolucent centre (> 5 mm in diameter) surrounded by a thick, concentric, echogenic ring located within the endometrium and containing a fetal pole, yolk sac, or both, is visible. A probable abnormal intrauterine pregnancy is diagnosed when gestational sac > 10 mm in diameter is present without a fetal pole or when a definite fetal pole is present without cardiac activity (Tenore 2000). Finally, on ultrasound an ectopic pregnancy is characterised by the presence of a thick, brightly echogenic, ring-like structure lying outside the uterus together with a gestational sac containing an obvious fetal pole, yolk sac, or both (Tenore 2000).

Confirmation of an ectopic pregnancy

The absence of an intrauterine gestational sac on abdominal ultrasound in conjunction with a β-hCG level of greater than 6500 mIU per mL suggests the presence of an ectopic pregnancy. The ultrasound scan results combined with serial β-hCG levels > 6500 mIU per mL that do not double in 48 hours usually confirm the diagnosis.

Laparoscopy

Laparoscopy can be used for both diagnosis and treatment of ectopic gestation, although the diagnosis is missed in 2–4% of women who have very small ectopic gestations.

Collaborative management of a woman with an ectopic pregnancy

A woman presenting with classic signs of a ruptured ectopic pregnancy needs rapid transfer to an appropriate health facility with the resources to support a critically ill, shocked patient. High flow oxygen is commenced and venous access obtained before transport or en route for cross-matching of blood and to administer intravenous (IV) fluids to maintain the radial pulse and blood pressure. However, no intervention should hinder transfer to expert medical care. The receiving unit is alerted so that immediate resuscitation followed by surgery occurs on arrival.

On arrival at the medical facility, treatment consists of resuscitation followed by immediate surgery, possibly with laparoscopy, to remove the blood and blood clot and to stop the bleeding. It is often necessary to remove the fallopian tube.

Medical management of an ectopic pregnancy

Medical or expectant management with methotrexate is possible but only with haemodynamically stable women who have had minimal bleeding or pain, have no evidence of tubal rupture, and have a β-hCG level below 1000 and falling (Hajenius et al 2005). Methotrexate is an antimetabolite that inhibits the synthesis of DNA and RNA, thus decreasing cell proliferation. According to Bryan (2003), medical management with methotrexate has a success rate of 75–96%, with best outcomes in small ectopic pregnancies with lower initial β- hCG levels. Gazvani and colleagues (1998) found that unruptured tubal pregnancies resolve faster in women given methotrexate in combination with mifepristone, compared to methotrexate only. Not all authors are as enthusiastic about

Clinical point

The ABC of all primary resuscitative efforts hold true for a woman in shock from a ruptured ectopic pregnancy. If the radial pulse is palpable, the blood pressure can be assumed to be adequate. If it is not palpable, restore circulation volume by giving IV fluids until the radial pulse is palpable again.

Research

Interventions for tubal ectopic pregnancy: a Cochrane Review (Hajenius et al 2005)

Background: The diagnosis of ectopic pregnancy is often made by non-invasive methods such as with sensitive pregnancy tests and high resolution TVS. As a consequence, various treatment options are now available: radical (salpingectomy) or conservative surgical treatment (salpingostomy); drug therapy and expectantly.

Objectives: In this review, the effects of various treatments were summarised in terms of treatment success, need for re-interventions, tubal patency and future fertility.

Main results: Laparoscopic conservative surgery is significantly less successful than the more radical approach in the elimination of tubal pregnancy due to a higher persistent trophoblast rate of laparoscopic surgery. Long-term follow-up shows similar tubal patency rates. The number of subsequent intrauterine pregnancies is comparable, but the number of repeat ectopic pregnancies is lower, although these differences are not statistically significant. Compared to laparoscopic conservative surgery, local and systemic methotrexate is significantly less successful in the elimination of tubal pregnancy. Methotrexate is not as effective in eliminating the tubal pregnancy as laparoscopic salpingostomy. Methotrexate treatment regimens are also associated with a greater impairment of health-related quality of life and are more expensive due to prolonged hospital stay and loss of productivity.

Authors' conclusions: Laparoscopic surgery is still the cornerstone of treatment in the majority of women with tubal pregnancy. If the diagnosis of tubal pregnancy can be made non-invasively, medical treatment with systemic methotrexate in a multiple-dose intramuscular regimen is an alternative treatment option but only in haemodynamically stable women with an unruptured tubal pregnancy and no signs of active bleeding presenting and with low initial serum hCG levels, after properly informing them about the risks and benefits of the available treatment options.

the efficacy of methotrexate (see the research box on the previous page). Expected management of ectopic pregnancies assumes that some of these pregnancies will resorb or resolve spontaneously (Bryan 2003).

Fertility after treatment

The prognosis for women with an ectopic pregnancy is good, provided there is early diagnosis and prompt, effective treatment. Fertility may be preserved, especially if there is early diagnosis followed by conservative management.

Local causes of vaginal bleeding

Vaginal bleeding may occur at any time in pregnancy, from benign conditions such as implantation, cervicitis or polyps, or after coitus, or from more serious conditions such as carcinoma, miscarriage, ectopic pregnancy or placenta praevia and abruption. In most non-pathological cases, treatment can be left until after the woman has had her baby.

Cervical pathology

In pregnancy the increased vascularity of the cervix may result in slight bleeding from cervical ectropian (previously called erosion). A cervical polyp may also be the cause of minimal, irregular bleeding in pregnancy. These are seen as bright red, fleshy protrusions that extend out from the cervical canal. Treatment, if required, is left until after pregnancy has been completed.

Carcinoma

Carcinoma of the cervix is a serious but rare occurrence in pregnancy, usually detected by a Papanicolau smear in pregnancy. On examination the cervix is hard and irregular and bleeds when touched. It requires immediate management. A caesarean section followed by hysterectomy is usually performed once the fetus is viable.

Cervicitis and/or vaginitis

An increased vaginal discharge is normal in pregnancy. Normal pregnancy discharge, known as leukorrhoea, is non-irritating and has no odour. Vaginal discharge may also be a symptom of genital infection. Vaginitis and cervicitis are usually due to STIs and infection with trichomoniasis or candidiasis (thrush). Microscopic examination of the discharge isolates the cause of the infection, which is then treated with antibiotics.

Bleeding from the non-pregnant horn of a bicornuate uterus

Bleeding is minimal and no treatment is required.

Haemorrhoids/vulval varicosities/urinary tract infection

While not strictly pregnancy-related bleeding, a urinary tract infection (UTI) presenting as haematuria can be the cause of a woman presenting with bleeding in pregnancy. Similarly, bleeding from haemorrhoids or vulval varicosities needs to be excluded in any assessment of bleeding in pregnancy.

Bleeding in late pregnancy: antepartum haemorrhage

Antepartum haemorrhage (APH) is defined as any bleeding into or from the genital tract after the twentieth week of pregnancy. It complicates approximately 2–5% of all pregnancies. The primary causes of APH are placental abruption (30%) and placenta praevia (20%).

Other causes of bleeding in the third trimester include: a heavy, bloody show, bleeding occurring during labour (intrapartal haemorrhage), cervical carcinoma, polyps, cervical or vaginal infection or trauma, varicosities and vasa praevia. Box 33.6 details the causes of vaginal bleeding in the third trimester.

Decisions about the management of a mild or severe APH depend on:

- whether the bleeding has settled or stopped
- whether the bleeding continues but is not life-threatening
- whether the bleeding continues and is life-threatening
- the condition of the fetus
- the gestational age of the pregnancy (Higgins 2003, p 228).

Placental abruption

A placental abruption is bleeding as a result of premature separation of a normally situated placenta from the uterine wall. Separation may be partial or complete. The aetiology is unknown but the strongest associations are trauma and hypertension. Other factors that have been associated with abruption are:

- past obstetric history of abruption
- gestational or essential hypertension
- multiple pregnancy
- increasing age
- high parity
- low socio-economic status
- renal infection
- drugs (smoking, cocaine)
- uterine anomaly or tumour
- sudden uterine decompression following rupturing membranes in polyhydramnios
- short umbilical cord
- pressure from the enlarged uterus on the inferior vena cava.

Clinical point

Placenta praevia and placental abruption can produce massive obstetric haemorrhage without any warning. With placental abruption, the clinician may not be aware of the full extent of the blood loss because a proportion of the blood may be concealed behind the placenta. Pregnant women may remain haemodynamically stable until they lose between a third and a half of their circulating blood volume.

BOX 33.6 Antepartum haemorrhage

Classification of causes of APH:

- bleeding from a normally situated placenta (accidental haemorrhage):
  - placental abruption (concealed, revealed, combined)
- bleeding from an abnormally situated placenta (unavoidable or inevitable haemorrhage):
  - placenta praevia
  - placenta percreta/accreta/increta
- extraplacental/incidental causes:
  - ruptured uterus/dehiscence of uterine scar (complete or incomplete)
  - ruptured vasa praevia
  - excessive bloody show
  - cervical erosion, polyp, carcinoma
  - vaginitis
  - urinary tract infection
  - haemorrhoids
  - bleeding from the non-pregnant horn of a bicornuate uterus
  - ruptured vulval varicosities.

It has been suggested also that abruption may be caused by folate deficiency, because:

- it is found more often in multiparous women with low socio-economic status
- there is an association between megaloblastic anaemia and abruption.

However:

- megaloblastic anaemia is common in developing countries but abruption is not
- folate supplements are not protective.

For most women, however, especially when bleeding is minimal, the cause is never found.

Classification of placental abruption

In placental abruption, bleeding may be:

- *central or concealed*—the separation occurs near the centre of the placenta and blood is retained between the uterine wall and the placenta as a retroplacental haematoma. In severe cases, the blood may infiltrate the myometrium until the uterus becomes swollen and engorged with blood, known as a Couvelaire uterus, increasing the woman's risk of postpartum haemorrhage (PPH) due to the inability of the uterus to contract and retract post partum.
- *revealed or marginal*—the separation occurs near the edge of the placenta and blood tracks down between the membranes and the decidua, through the cervix and into the vagina
- *partially revealed*—this is a combination of concealed and revealed bleeding, where some of the blood escapes into the vagina, the rest remaining trapped in the uterus.

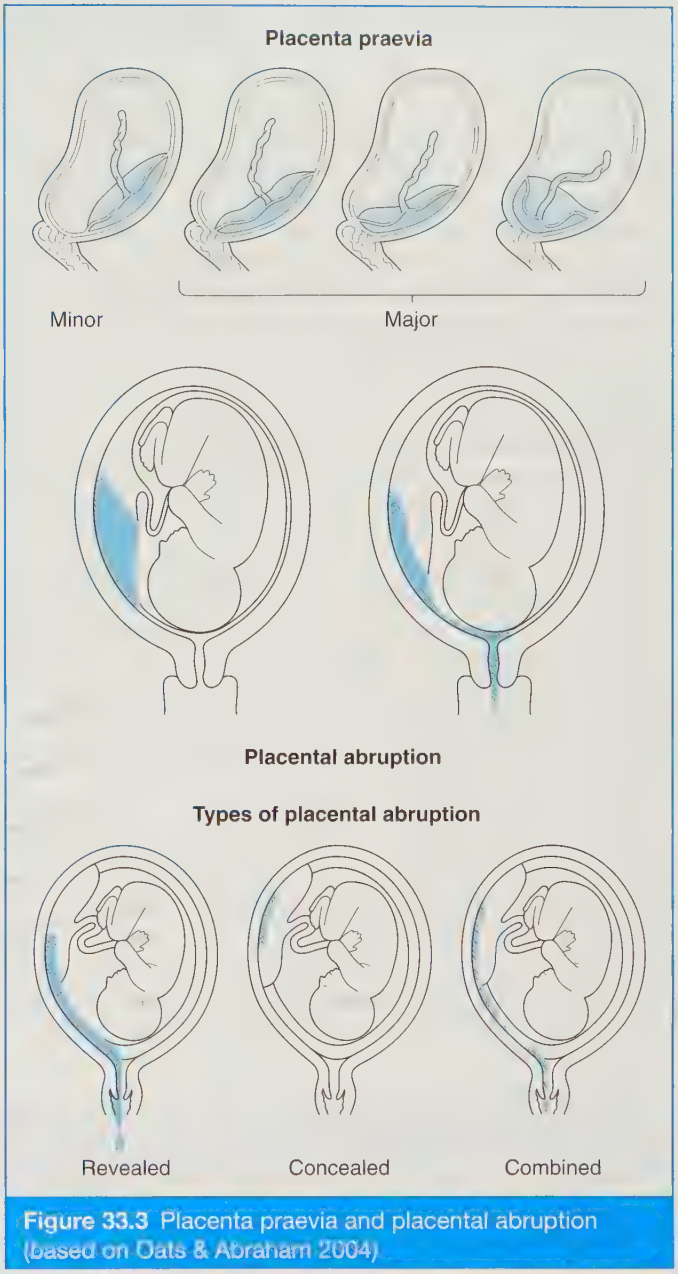

Figure 33.3 Placenta praevia and placental abruption (based on Oats & Abraham 2004)

Incidence

The incidence of placental abruption is 1:120 pregnancies but it accounts for 15% of perinatal mortality (Gaufberg 2001).

Clinical presentation and diagnosis

The classic manifestations of a placental abruption are dark, vaginal bleeding, and abdominal or low back pain and uterine tenderness. There may be a sudden onset of vaginal bleeding. The bleeding may be:

- *mild* with some abdominal pain, a non-tender uterus and a live fetus. The woman shows no signs of haemodynamic compromise.
- *moderate* with stronger abdominal or back pain, perhaps uterine contractions and a firm, tender uterus.

A cardiotocogram (CTG) shows a non-reassuring fetal heart rate tracing and the woman will exhibit some degree of shock.

- *profuse* with severe abdominal pain, a 'board-like', enlarging, tender uterus that fails to relax. Usually no fetal heart tones are heard on auscultation and usually real-time scan shows that the fetus is dead. The woman will be shocked, to a degree often out of proportion to the amount of visible blood loss. In severe cases significant amounts of thromboplastin are released into the circulation, making the woman at risk of disseminated intravascular coagulation (DIC).

Management

Any bleeding during pregnancy requires investigation and the pregnant woman needs to contact her lead maternity carer immediately. Should she lose more than 30 mL of blood, hospital assessment is necessary. Combined abruption is suspected if the degree of shock is out of proportion to the amount of bleeding visible. Management is dependent on the amount of bleeding, the degree of maternal haemodynamic compromise and the condition of the fetus. Careful initial assessment is required to differentiate placental abruption from placenta praevia, and to estimate the degree of maternal and fetal compromise. In contrast to placenta praevia, the fetal lie and presentation is normal.

The woman with mild bleeding may have mild abdominal pain with or without a history of precipitating factors such as some exertion, trauma or severe hypertension. Delivery of the fetus and placenta are the definitive treatments. However, if the degree of abruption is minor, and there is no fetal or maternal compromise, the pregnancy may be allowed to continue, especially if the fetus is viable but preterm.

- Venous access is obtained and blood taken for haemoglobin estimation, group and cross-matching of blood, coagulation studies and a Kleihauer Betke test.
- A careful speculum examination of the vagina may exclude other causes of bleeding. However, the clinician must be very careful to ensure that the vaginal bleeding is not from a placenta praevia.
- Tocolytic agents may be employed to stop uterine contractions.

Clinical point

During the initial assessment following an antepartum haemorrhage, look for signs of:

- cardiovascular collapse
- shock
- sepsis
- rigid abdomen
- heavy vaginal bleeding
- complications of labour
- fetal compromise.

No vaginal examinations are undertaken until the cause of the bleeding is found.

- A CTG trace of the fetal heartbeat is performed to assess fetal wellbeing.
- Depending on gestation, corticosteroids may be administered to enhance lung maturity.
- An ultrasound scan is performed to confirm placental localisation.
- Bed rest and close monitoring in hospital for at least 24 hours is recommended.
- Non-sensitised Rhesus-negative women will require anti-D immunoglobulin.
- A viable fetus near full term is often electively delivered to avoid a larger abruption later.

Every attempt should be taken to alleviate the family's anxiety and fears in honest and empathetic ways where the woman and her family feel comfortable about having their questions answered and trust that they will be given accurate, honest and up-to-date information. Diversional activities may assist the woman in dealing with the frustrations associated with prolonged bed rest and hospitalisation. Once bleeding stops and provided the maternal and fetal condition are satisfactory, the woman may go home, provided there are back-up and community resources available so that she can return to hospital if there are further signs of bleeding or if she begins labour. Assistance and support at home are often required.

The woman with moderate or profuse bleeding requires stabilisation, blood transfusion, and delivery. Resuscitation of the mother is the first objective, followed by delivery of the fetus. In many cases the fetus will be dead and vaginal delivery is preferred as the complications of serious coagulation defects are less dangerous than with a caesarean section. Provided her condition is stable, the woman's labour may be induced and a vaginal delivery attempted. There is, however, a significant danger that consumption coagulopathy (DIC) may develop with hypofibrinogenaemia. If the fetus is alive and viable, a caesarean section will be performed unless the woman is in active labour and progressing well with a reassuring fetal CTG recording. Epidural analgesia may be provided for those women, provided coagulation studies are normal and there is no evidence of hypovolaemia. Persistent haemorrhage after delivery may be due to coagulopathy or a Couvelaire uterus, or failure of the myometrium to contract once it is empty, which is a common post-delivery risk following an APH and an emergency Caesarean section. Chapter 36 discusses management of PPH in more detail.

Complications of abruption

Initial and ongoing management depends on the onset of complications, which may include:

- haemorrhagic shock
- disseminated intravascular coagulation (DIC)
- acute renal failure
- fetal compromise
- preterm labour
- intrauterine fetal death
- primary and secondary PPH
- sepsis

- anaemia.

These are dealt with in more detail later in this chapter and in Chapter 36.

Rare and ongoing complications

Sheehan's syndrome (anterior pituitary necrosis) is a rare complication following massive haemorrhage. Women with this condition demonstrate the symptoms of amenorrhoea, failure to lactate, coarsening of the hair and skin, feeling cold and, later, genital atrophy and premature sterility.

Placenta praevia: bleeding from an abnormally situated placenta

In *placenta praevia*, part of or the entire placenta is abnormally sited in the lower uterine segment (Higgins 2003). Placenta praevia may be further classified as:

- *low-lying*—lying within 2 cm but not extending to the internal cervical os
- *marginal*—extending to but not covering the internal cervical os
- *complete*—completely covering the internal cervical os.

BOX 33.7 Emergency treatment of abruption

Treat the shock

- Call for help and arrange escorted transfer to obstetric unit for further assessment even if bleeding seems to settle, as the fetus may still be compromised.
- Give oxygen via face mask at 6–8 L/min.
- Insert IV lines (two wide-bore cannulae).
- Cross-match six units of blood, coagulation profile and Kleihauer tests.
- Evaluate blood loss.
- Restore blood loss quickly with IV fluids—replace estimated losses plus 2 L of IV fluid. Give isotonic solutions followed by colloids until packed cells are available.
- Consider urinary catheterisation to monitor output and keep output at > 30 mL/hr.
- Ultrasound examination if the placenta is unsited or features suggest placenta praevia.
- Continuous monitoring of fetus, mother and labour.

Deliver the fetus

- Assess fetal maturity.
- Observe for the onset of labour—rupture of membranes and uterine contractions.
- By Caesarean section (if fetus compromised and viable).
- By rupturing the membranes and induction of labour (if ripe cervix or fetus nonviable).
- Diagnose and treat coagulopathy and disseminated intravascular coagulation (DIC).
- Urgent haematological consultation.
- Check platelet count.
- Transfusion—may require fresh frozen plasma and cryoprecipitate.

Maternal and fetal morbidity and mortality from placenta praevia are considerable.

The low-lying placenta

Many women in industrialised countries have one or more ultrasound scans during pregnancy and so are aware that they may be at risk of placenta praevia before the initial or sentinel bleed occurs, and have been informed about the urgent need for medical attention if they have any vaginal bleeding until the diagnosis has been confirmed. Nevertheless, in more than 98% of cases, a 'low-lying placenta' diagnosed on an early ultrasound will be found at term to have 'migrated' to the upper uterine segment. The placenta does not actually move but the growth of the uterus relative to the size of the placenta means that it appears to 'move'. Women with a low-lying placenta should have a repeat scan at about 32 weeks gestation for placental localisation.

Incidence

The incidence of placenta praevia at term is about 1% of all pregnancies. The risk increases by 1.5- to five-fold in women with a history of caesarean section. With repeated caesarean deliveries, this risk can be as great as 10%. Risks also increase with parity and there is a 4–8% recurrence of placenta praevia in subsequent pregnancies.

Causes

There is no known 'cause' of placenta praevia, but predisposing factors are well documented. Any condition that stops the blastocyst from embedding in the endometrium increases the risk of placenta praevia. The predisposing factors include:

- past history of placenta praevia
- a large placenta (e.g. with fetal erythroblastosis and multiple pregnancy)
- high parity

Clinical point

Bhide and colleagues (2003) recommend that the phrase 'placenta praevia' be restricted to diagnoses where the placental edge is equal to or less than 2 cm from the internal cervical os, as the woman will probably require a caesarean section and the risk of PPH is high. In situations where the placenta is more than 2 cm from the internal cervical os, the woman's chance of giving birth vaginally is greater than 60%, so these conditions should be defined as 'low-lying' rather than placenta praevia. The authors maintain that if a vaginal birth is to be considered, a vaginal examination is performed as a 'double set-up' and the site of the edge of the placenta is determined digitally, and a final decision reached following artificial rupture of the membranes. Once labour has commenced, or if the bleeding is severe and cannot be controlled and the maternal and/or fetal condition is compromised, a caesarean section is performed.

- an abnormally shaped uterus (e.g. fibroids, bicornuate uterus)
- previous uterine scar (myomectomy, caesarean section)
- scarring from previous uterine surgery and caesarean section
- smoking
- advancing maternal age.

Pathophysiology

As the lower uterine segment forms and the cervix begins to efface and dilate in later pregnancy (around 32 weeks gestation), there is partial separation of the inelastic placenta embedded in the lower uterine segment near or over the cervix from elastic uterine wall, and painless bleeding occurs. The closer the placenta is to the internal cervical os, and the greater the proportion of placenta covering the cervix, the earlier bleeding begins. Because these physiological changes are gradual, initial blood loss is slight and always painless and bright red in colour. Uterine contractions are rarely palpable. Bleeding may be triggered by coitus or digital examination, but usually there are no precipitating causes. It is not possible to predict when the next bleed will occur, or its severity.

Clinical presentation and diagnosis

There are two classic findings associated with placenta praevia: APH and fetal malpresentation. An APH from placenta praevia usually begins in the third trimester. It presents with recurrent, bright red, painless vaginal bleeding, although it is not uncommon for women to experience some painful uterine contractions after the bleed (Higgins 2003). The amount of blood lost is highly variable—from a few spots to several litres. The initial bleed usually ceases spontaneously as soon as the blood clots. Unlike an abruption, gentle abdominal palpation does not cause the woman pain and fetal parts are easily palpable. The presenting part usually does not engage in the pelvis and remains high, because the placenta occupies the lower uterine segment, preventing it from descending into the pelvis.

Diagnosis is confirmed by ultrasonographic imaging techniques revealing the relationship of the leading edge of the placenta to the cervical os and the leading fetal pole.

Management

The goal of management for a woman with placenta praevia is to obtain the maximum fetal maturation while minimising the risk to both fetus and mother. Management is determined by the degree of placenta praevia present, the gestational age of the fetus and the presence and amount of vaginal bleeding. Following any episode of bleeding after 20 weeks gestation, it is important that the woman be transferred to the nearest hospital for immediate assessment. In the presence of significant haemorrhage it may be necessary to summon an ambulance and initiate resuscitative measures.

On admission to hospital and depending on her haemodynamic status:

- the woman's general condition and vital signs are assessed and her records are reviewed
- an accurate history is taken that includes information about the onset of bleeding, its volume and precipitating factors
- for a diagnosis of placenta praevia to be confirmed, the location of the placenta must be determined. A transabdominal ultrasound or transvaginal ultrasound facilitates this process and should be performed as quickly as possible.
- unless bleeding is such that the woman's haemodynamic status is compromised, following a gentle abdominal palpation the fetal condition is assessed through a CTG of the fetal heart rate
- a speculum or vaginal examination must never be performed until localisation of the placenta is known.
- if the diagnosis cannot be confirmed by ultrasound, a vaginal examination using a speculum may be required. This should be performed in an operating theatre as a 'double set-up'—so the team can proceed to an immediate caesarean section should the haemorrhage become torrential.

Emergency management

Optimal outcomes depend on prompt diagnosis and appropriate, timely intervention to prevent further complications, by:

- maternal resuscitation
- continuous assessment of blood loss and maternal and fetal response to treatment;
- rapid blood-product replacement
- confirmation of the position of the placenta
- administering corticosteroids if the fetus is between 24 and 34 weeks gestation
- ruling out other causes of bleeding
- determining gestational age.
- assessing for signs of preterm labour. Tocolytic therapy may be used to inhibit labour for 48 hours.

Once the diagnosis is established, the clinical team must then decide whether the woman is a suitable candidate for expectant management, or whether in order to save the life of the mother and her baby an immediate caesarean section is needed.

Clinical point

In the presence of vaginal bleeding, do not perform a vaginal examination until placenta praevia is ruled out, as severe haemorrhage may be provoked if blood vessels lying across the os are damaged.

Clinical point

Resuscitation of the mother should always take precedence over resuscitation and delivery of the fetus.

Ongoing care

Once the initial haemorrhage is controlled, decisions about ongoing care depend on the mother's haemodynamic status, the fetal gestational age and the extent and frequency of bleeding. If the risks of preterm birth outweigh the risks of another potentially catastrophic bleed, expectant management is the preferred option because it allows more time for the fetal lungs to mature. The mother remains in hospital for at least 48 hours and an elective caesarean section is planned for about 36 weeks gestation. She is closely monitored for signs of another bleed, the onset of labour, and evidence of fetal wellbeing and/or compromise. In addition:

- blood samples for cross-match are always available at the blood bank
- an IV cannula is inserted but it may be luered
- fetal wellbeing is monitored (non-stress test and biophysical profiles)
- corticosteroids are administered if the mother is < 34 weeks pregnant
- preparations for an immediate caesarean section are always in place
- Rh D immunoglobulin (anti-D) is given to Rh D-negative women.

Measures are put in place to support the family as they deal with fear and anxiety related to the threats to the woman's life and that of her baby. These measures include:

- education about placenta praevia and treatment plans
- diversional and supportive activities to help with the boredom and anxiety associated with prolonged hospitalisation as well as the difficulties associated with being away from the family
- education about the signs of bleeding and the onset of labour.

Home versus hospital

There is little evidence of any clear advantage or disadvantage of a policy of home versus hospital care (Neilson 2004). After an APH the woman usually stays in hospital until there has been no further evidence of bleeding for about 72 hours. Before going home, the woman and her family are advised about the steps they can take to reduce the likelihood of another bleed (avoid sexual intercourse or any activity that may trigger labour). However, if they are to go home it is crucial that the woman always has access to transportation and can, if necessary, return to hospital within 20 minutes of the start of another episode of bleeding.

Clinical point

When a woman presents with vaginal bleeding, the history should also include the following questions:

- When did the bleeding start, how much bleeding, and did the bleeding stop?
- Was this the first episode of bleeding?
- What was the colour of the blood (dark or bright red), were any clots present, and what was their size?
- What was the woman doing at the time of the bleed?
- Did she bleed with any of her other pregnancies?
- Does she feel the baby move?
- When did she last have sexual intercourse?
- Does she feel any contractions?
- How is her general health?
- Does she have any abdominal pain?

BOX 33.6 Mortality and morbidity

Maternal mortality (1%) and morbidity from:

- hypovolaemic shock
- postpartum haemorrhage
- invasive placenta (accreta, increta and percreta following severe haemorrhage due to major placenta praevia)
- Rhesus iso-immunisation
- disseminated coagulopathy
- anaemia
- sepsis

Perinatal mortality (4.4–67.3%) and morbidity from:

- malpresentation
- asphyxia
- prematurity and intrauterine growth restriction
- fetal anaemia from feto-maternal haemorrhage.

Mode of delivery

The mode of delivery needs to be planned in partnership between the woman, her family, and her care providers. Expectant management is terminated as soon as the fetus is mature, in the presence of excessive bleeding, if active labour begins or if signs of other complications such as chorioamnionitis develop.

- If the placenta praevia covers the entire os, a caesarean section is always indicated.
- If haemorrhage is life-threatening/profuse, immediate caesarean section is required.
- If the placenta is within 2 cm of the os (a low-lying placenta), a vaginal birth may be possible.
- If the fetus is dead or is not viable but there is an engaged fetal head, vaginal delivery is often attempted.

Postbirth complications

Complications include:

- coagulation disorders
- acute renal failure
- anaemia
- infection—prophylactic antibiotics should therefore be used for emergency caesarean section and considered for elective procedures
- manual removal of the placenta (often necessary)
- postpartum haemorrhage
- thromboembolism.

Research

Major placenta praevia should not preclude outpatient management (Love et al 2004)
Objective: To review current management of women with major and minor placenta praevia to assess whether outpatient care was detrimental to pregnancy outcome.
Study design: One hundred and sixty-one women with major and minor placenta praevia were separated into those who experienced an APH and those who had no bleeding during pregnancy (non-APH). Women with a major degree of praevia were not significantly more likely to experience bleeding. Women with APH were significantly more likely to be delivered early, by emergency caesarean section, of lower birthweight babies who required neonatal admission, than the non-APH group.
Conclusion: There is a place for outpatient management of women with placenta praevia. Caution is required with increasing number of bleeds but not degree of praevia.

Placenta accreta, percreta and increta, and vasa praevia

These potentially catastrophic complications are dealt with in Chapter 36.

Maternal medical conditions in pregnancy

Various medical diseases may preclude women from achieving a successful pregnancy and birth. Often, medical complications affect the mother's pregnancy, her illness and her fetus's wellbeing. It is not possible to cover all the medical disorders in a textbook of this nature, and so only the most common have been selected: diabetes, thyroid disease, heart disease, respiratory disease, renal disease, obstetric cholestasis, epilepsy, thrombo-embolic disease, genital infections, and hypertension in pregnancy.

Diabetes mellitus

Diabetes refers to a group of disorders characterised by impaired carbohydrate metabolism, all of which pose significant threats to maternal and perinatal health. Diabetes is on the rise worldwide (Amos et al 1997). The Australian Institute of Health and Welfare (2002) estimates that 940,000 Australians have diabetes but about half are unaware that they have the condition. The number of sufferers has doubled since the early 1980s and is expected to pass one million by 2010. Pregnancy presents particular challenges for women with diabetes irrespective of whether they have just been diagnosed with gestational diabetes or have been living with diabetes since childhood. Advances in medical, obstetric and intensive care of the diabetic woman have resulted in significantly better outcomes. Most women with diabetes can and do have healthy pregnancies.

Glucose homeostasis and carbohydrate metabolism are complex processes and so, before proceeding with this section, you are advised to refresh your knowledge of these topics by referring to a text such as Stables and Rankin (2004) *Physiology in Childbearing*. Briefly, energy metabolism is controlled by hormones including insulin, glucagon, epinephrine, growth hormone and the glucocorticoids. Normally the interplay

Critical thinking exercise

Why is a woman more at risk of PPH if the placenta is embedded in the lower rather than the upper uterine segment?

What is the significance of a 'low-lying' placenta?

TABLE 33.1 Comparisons between an abruption and a placenta praevia

	Abruption	Placenta praevia
Pain	Constant	Painless
Haemodynamic compromise	The actual amount of bleeding may be far in excess of observed vaginal blood loss.	Placenta praevia—the degree of shock is in proportion to amount of vaginal loss.
Uterus	Uterus is tender and tense.	Uterus is non-tender.
Fetus	Normal presentation and lie.	May have abnormal presentation and/or lie.
Fetal condition	Fetal heart trace non-reassuring/absent.	In general, fetal heart trace reassuring.
Associated problems	May be a complication of pre-eclampsia, may cause disseminated intravascular coagulation.	Small APH may occur before larger bleed.

These comparisons are generalisations and specific cases may vary in their clinical features.

between insulin and glucagon maintains blood glucose levels within a very narrow range (3–5 mmol/L). Glucagon produced by the alpha cells of the pancreas increases blood sugar levels, and insulin from the beta cells of the pancreas decreases the amount of circulating blood glucose. In contrast, insulin is required by almost all the body's cells. The stimulus for increased insulin secretion is a high blood glucose level; as blood glucose levels fall, the amount of insulin secreted by the beta cells decreases.

Glucagon is called a counter-regulatory hormone because it increases blood glucose levels: if blood glucose levels are high, glucagon is not secreted. Its most dramatic activity is its ability to initiate glycogenolysis. A reduction in circulating blood glucose stimulates the pancreas to release glucagon, which facilitates the breakdown of liver glycogen as a means of raising blood sugar levels. Glucagon also increases the transport of amino acids to the liver and stimulates their conversion, a process called gluconeogenesis.

Carbohydrate metabolism in pregnancy

Pregnant women are normally in a diabetogenic state, which ensures that the fetus has an adequate and continuous supply of glucose. It is characterised by insulin resistance with compensatory hyperinsulinaemia, beginning in the second trimester and remaining throughout the pregnancy. All pregnant women experience mild fasting hypoglycaemia and after-meal hyperglycaemia. Increased secretion of insulin between meals and during sleep enables the fetus to continue to draw glucose across the placenta from the maternal bloodstream, even during periods of maternal fasting. In the second and third trimesters, increased placental steroids and peptide hormones exacerbate tissue insulin resistance. However, if the maternal pancreatic insulin response to food intake is inadequate, first maternal and then fetal hyperglycaemia occurs.

Causes of diabetes mellitus

In diabetes mellitus there is an absolute or relative deficiency of insulin produced by the pancreas. Glucose cannot be converted to glycogen or released as energy, so it accumulates in the bloodstream, causing hyperglycaemia, some of which is excreted in the urine. Glucose is osmotically active and draws water after it, causing polyuria and thirst. Faced with a lack of glucose, the body tries to mobilise energy from fats and proteins, which leads to the production of ketones by the liver, and ketosis.

BOX 33.9 Role of insulin

Insulin:
- facilitates the uptake of glucose by facilitating its movement from the blood into target cells (liver, skeletal and muscle)
- stimulates formation and storage of lipids and glycogen
- lowers circulating blood glucose.

It does this by:
- increasing glucose transport by target cells
- accelerating glucose utilisation (target cells) and enhanced ATP production
- stimulating glycogen synthesis (skeletal muscles and liver cells)
- decreasing glucogenesis.

BOX 33.10 Role of glucagon

Glucagon:
- mobilises energy reserves and promotes glucose synthesis and glycogen breakdown
- elevates blood glucose concentrations.

It does this by:
- stimulating the breakdown of glycogen in skeletal muscle and liver cells
- stimulating the breakdown of triglycerides in adipose tissues
- stimulating the production of glucose in the liver.

Diabetes is associated with:
- production of defective insulin
- over-production of insulin antagonists
- increased resistance to insulin (auto-immune response)
- underproduction of insulin (impaired cell function)
- inappropriate timing of insulin release.

Classification

There are three types of diabetes that affect pregnancy.
- *Type 1 diabetes* (formerly called 'insulin-dependent diabetes' (IDDM) or 'juvenile diabetes'). According to the Australian Institute of Health and Welfare (AIHW 2002), 10–15% of people diagnosed with diabetes will be Type 1. It is characterised by β cell destruction caused by an auto-immune process, usually leading to absolute insulin deficiency.
- *Type 2 diabetes mellitus* (formerly called 'non-insulin diabetes mellitus' (NIDDM), 'type II' or 'adult-onset') is the most common form of diabetes (80–90%) and is characterised by insulin resistance in peripheral tissues and an insulin secretory defect of the beta cells. Recently a new, rare form of Type 2 diabetes, known as 'maturity onset diabetes of the young' (MODY) has been identified. MODY is caused by an autosomal-dominant gene. Sufferers are usually women, of normal weight and under 25 years old. During pregnancy, women with MODY do not require insulin.
- *Gestational diabetes* (GDM) develops in pregnancy. It is characterised by carbohydrate intolerance that begins or is first recognised in pregnancy. However, most women classified with GDM have normal glucose homeostasis during the first half of the pregnancy and only develop a relative insulin deficiency (and hyperglycaemia) during the last half of the pregnancy. The hyperglycaemia resolves in most cases after birth but places them at significant risk of developing Type 2 diabetes later in life.

The following sections focus on the most common forms of diabetes affecting maternal and fetal health.

Aetiology of Type 2 diabetes

The aetiology of Type 2 diabetes mellitus is multifactorial and, like Type 1 diabetes, probably genetically based, but there are also strong behavioural components. In Australia and New Zealand, it is more common in women:

- of advancing age
- with a sedentary lifestyle
- with a family history of Type 2 diabetes
- with impaired glucose tolerance
- from low socio-economic backgrounds
- with a history of gestational diabetes
- with an 'apple-shaped figure'
- from Chinese, Indian, Maori, Pacific, Aboriginal or Torres Strait Island background.

Pathophysiology of Type 2 diabetes

People can develop Type 2 diabetes at any age—even during childhood, although usually when older. A reduced capacity for insulin secretion and insulin resistance, combined with the effects of obesity, ageing and physical inactivity, are crucial factors in determining who develops Type 2 diabetes. A relative lack of endogenous insulin plus pancreatic beta cell dysfunction reduces glucose uptake by cells, resulting in hyperglycaemia.

Diabetes, pregnancy and complications

Whatever its causation, diabetes can result in a range of complications for the mother, her baby and the progress of her disease. In women with Type 1 or 2 diabetes, glycaemic control worsens and insulin requirements change as the pregnancy progresses. Poorly controlled Type 1 diabetes causes life-threatening metabolic reactions, such as ketoacidosis and diabetic coma. In addition, hyperglycaemia is the prime determinant of the following microvascular and metabolic complications:

- diabetic ketoacidosis
- cardiovascular disease
- peripheral vascular disease
- retinopathy
- diabetic nephropathy and end-stage renal disease
- peripheral nerve disease
- cancer of the pancreas
- liver disease
- depression.

Metabolic complications

During pregnancy, lack of knowledge about the effects of pregnancy on diabetes, as well as the effects of pregnancy on glycaemic control, increases the risks of hypoglycaemic episodes as well as diabetic ketoacidosis. Women and their partners need ongoing, evidence-based information and education about the management of these conditions, including the use of glucagon to alleviate hypoglycaemia and how to recognise and prevent ketoacidosis. Midwives are well placed to work with the family to develop an emergency plan that they know works and is kept in an accessible place. This plan should contain a list of local emergency contacts.

BOX 33.11 Diabetes in New Zealand

Maori and Pacific populations are among the highest-risk groups for diabetes and for cardiovascular disease and related conditions.

In New Zealand by 2011, the prevalence of diabetes is predicted to increase by 58%, 132% and 146% in European, Maori and Pacific populations respectively. This increase reflects changing demographic factors (including increased population size and changes in population age structure) and epidemiological factors (such as obesity and physical inactivity).

Effective primary prevention programs for Type 2 diabetes are largely based on programs to reduce diabetes risk factors, such as reducing overweight/obesity, stopping smoking and increasing physical activity. Such programs extend beyond the health sector, involving local government, employers, education and community groups, amongst others.

Maori and Pacific populations are among the highest-risk groups for diabetes and for cardiovascular disease and related conditions. These populations traditionally have strong community links, which are important to the success of health programs targeting the above risk factors.

(Source: New Zealand Ministry of Health, http://www.newhealth.govt.nz/toolkits/diabetes/reducing.htm)

Clinical point

Recent work suggests that an in utero environment leading to low birthweight may predispose some individuals to Type 2 diabetes mellitus in later life. Poor growth before birth may produce permanent changes in glucose metabolism. Diabetes may be linked to the so-called 'thrifty gene' that once helped hunter-gatherers survive when food was in short supply (Gautier et al 2003).

Microvascular complications

Retinal and renal disease associated with diabetes can worsen during pregnancy. Retinopathy alone is not associated with a poorer outcome for the fetus unless concurrent nephropathy is evident as well. Poor glycaemic control in the first trimester and pre-eclampsia or chronic hypertension are independently associated with the progression of retinopathy. Good glycaemic control preconceptually and during pregnancy effectively reduces the long-term risk of retinopathy.

Diabetic retinopathy may develop or worsen during pregnancy. Women are encouraged to consult an ophthalmologist before they become pregnant, and to plan further follow-up consultations during the course of the pregnancy.

Nephropathy

There is an association between pre-existing nephropathy and adverse maternal and perinatal outcomes, although not congenital malformations. As pregnancy progresses, there is an increased risk that women with diabetes will develop pre-eclampsia and experience worsening chronic hypertension. Complications associated with nephropathy and pre-eclampsia, especially if it is superimposed on chronic hypertension, are strongly associated with pre-term birth.

Effects of diabetes on the fetus

Poorly controlled diabetes may have catastrophic effects on the fetus. Temple and colleagues (2002) found a significant relationship between poor glycaemic control in early pregnancy and adverse pregnancy outcomes with Type 1 diabetes. Poor glycaemic control during fetal organogenesis is associated with increased rates of spontaneous miscarriage plus a number of congenital anomalies, such as malformations of the nervous, cardiovascular, skeletal and renal systems. In contrast, the incidence of spontaneous miscarriage for diabetic women with good glycaemic control is no different from the rate experienced by women without diabetes. Indeed, the perinatal death rate of babies born to women with diabetes is increased 1.5–2 fold compared to those without diabetes.

The main causes of perinatal death are:

- unexplained stillbirth in the third trimester
- prematurity due to a high incidence of spontaneous preterm labour and of elective premature delivery to prevent stillbirth
- low birthweight due to IUGR where the mother has diabetic nephropathy
- congenital malformations
- birth trauma due to a high incidence of macrosomic babies.

Pre-pregnancy care

Pre-pregnancy counselling should begin well before the onset of pregnancy; it is a key component of good maternity care for the woman with diabetes. Statistically, the level of risk for a woman with Type 1 or Type 2 diabetes and for the baby is determined largely by the woman's health just before conception and during the first trimester. Attendance at a pre-pregnancy clinic is associated with a reduction in the rate of spontaneous miscarriage, in risk of congenital malformations and in complications of pregnancy. Infants of mothers attending pre-pregnancy clinics have fewer problems and are kept in special care for shorter periods than infants of non-attending mothers (Kitzmiller et al 1991).

Pre-conceptional care should include consultation between an endocrinologist or physician experienced in the care of women, obstetrician, dietician, midwives and perinatologist. If glycaemic control is suboptimal, women are counselled regarding the risks of pregnancy and, in particular, the risks of fetal malformation. Contraception should be continued until glycaemic control is considered adequate.

Clinical point

Macrosomia due to poor diabetic control refers to a baby that is considerably larger than normal. The diagnosis can only be made with any certainty after birth. Fetal macrosomia has been defined in several different ways, including birthweight of 4000–4500 g or greater than the 90–95th percentile for gestational age after correcting for neonatal sex and ethnicity. Based on these definitions, macrosomia affects 1–10% of all pregnancies.

Management of Type 1 diabetes during pregnancy

The management of Type 1 and frequently Type 2 diabetes involves daily delivery of exogenous insulin by injection or an insulin pump, combined with carefully designed meal plans and exercise regimen. This, however, assumes that the insulin regimen is the guiding component of therapy. In reality the individual's typical eating pattern and lifestyle should be the key factors and the determinants of the best insulin regimen. Antenatal care for the woman with diabetes involves teamwork. Health professionals working collaboratively and in partnership with the woman plan her care during pregnancy and labour. The woman should always be referred to a consultant unit attached to a neonatal nursery. Diabetes specialist nurses and midwives have an important role in educating women about the need for home blood glucose monitoring, urine testing, intensive insulin regimens, dietary management and regular exercise.

Screening in early pregnancy

Because of the increased risk of congenital anomalies, women should be offered combined first trimester screening for aneuploidy with β-hCG and a pregnancy associated plasma protein test (PAPP-A) measured at 10 weeks gestation, followed by an ultrasound examination for dating, nuchal transparency, gross morphology and plurality at 12 weeks gestation. It is generally recommended that ultrasound be carried out at least three times in pregnancy: early or at first booking, to recognise possible early growth delay or congenital malformations as described above; later at about 28 weeks, to determine fetal size, hydramnios and further possible malformations; and finally at about 36 weeks, to identify the presence of macrosomia.

Insulin

In 1921, Frederick Banting and Charles Best discovered insulin while they were working in the laboratory of John Macleod at the University of Toronto. In 1923, Banting and Macleod were awarded the Nobel Prize for medicine. The US Food and Drug Administration first approved its use in 1939. Insulin was the first hormone to be synthesised completely in the laboratory, a feat accomplished in 1966 by Michael Katsoyannis of the United States and scientists in China. Before the advent of insulin, very few diabetic women conceived, and in those who

did, perinatal mortality ranged from 40% to 60%. In the first 50 years of insulin use in diabetic pregnancy, considerable advances were made.

Insulin requirements change during pregnancy because of the effects of insulin-antagonistic placental hormones. Regimens vary but the consensus seems to be that a 'tight control' plan (Box 33.12) with frequent administration of insulin (up to four times daily) and the use of different insulin types (e.g. rapid- and long-acting insulin analogues), as well as more frequent blood glucose measurements, are better able to achieve normal blood glucose levels. Insulin therapy is usually basal-bolus with one dose of medium-acting insulin each day and short-acting insulin before each main meal.

Blood glucose monitoring

Monitoring blood glucose levels is fundamental to achieving tight diabetic metabolic control. Self-monitoring of blood glucose levels (SMBG) empowers women who have diabetes, enabling them to actively achieve their goals. In addition, the instant feedback that SMBG provides enables women to learn more about portion sizes, foods that cause hyperglycaemia, maintenance of stable temporal patterns of elevated blood glucose levels, and when exercise is most likely to help keep blood glucose in the targeted range. With this information, women are better able to make choices about their diet and activities and to see the effects of these in a timely manner. SMBG allows adjustments to be made to the meal plan/exercise/treatment regimen aimed at normalising blood glucose levels. Without SMBG these activities cannot be individualised to the different responses that many women have at any given time during their pregnancy.

Women should aim to maintain blood glucose levels as near to their non-diabetic range as possible without increasing the risk of hypoglycaemia. This usually means targeting levels between 4 and 7 mmol/L and measuring blood glucose levels four or five times a day. The glycated haemoglobin HbA_{1c} should be measured at the first visit and repeated monthly, with a target level of < 6.5%.

Laboratory tests that use plasma for measurement of blood glucose give results that are 10% higher than levels obtained from the finger prick method.

BOX 33.12 'Tight control' plan

Working with pregnant women with diabetes

The type of diabetes treatment program that aims to normalise blood glucose levels is referred to as a 'tight control' plan.

Cornerstones of tight glycaemic control are:

- administering insulin and adjusting the doses, depending on results of self-monitoring of blood glucose (SMBG)
- frequent SMBG
- following an appropriate meal plan
- adding or maintaining an appropriate level of physical activity
- controlling/treating hypoglycaemia.

Clinical point

Women with diabetes should aim for near-normal glucose levels, or as close to normal as possible—ideally for three months before becoming pregnant and just as importantly for at least the first three months of pregnancy, when the fetus is developing rapidly and thus a time during which congenital malformations can occur if glucose levels are high. Studies have shown that when the glycated haemoglobin (HbA_{1c}) level is within 1% of normal levels, the rates of congenital deformities and spontaneous abortion are no different from those in women without diabetes. Above that, however, the incidence rises.

Dietary advice

Diet is another cornerstone of therapy in the management of all forms of diabetes. Expert nutritional advice should be available in all diabetic antenatal clinics in order to encourage the entire family to have a diet low in saturated fat, with high levels of complex carbohydrates, soluble fibre and vitamins. As do most women pre-pregnancy, women with Type 1 diabetes mellitus are advised to take a folic acid supplement, 4–5 mg daily, one month prior to pregnancy and for the first trimester, as the risk of neural tube defects is higher for this group of women.

Exercise

The benefits of exercise include cardiovascular fitness and psychological wellbeing. Women with Type 1 diabetes are rarely overweight but exercise is still beneficial. For women with Type 2 or gestational diabetes, the benefits of exercise also include a decrease in body fat, better weight control and improvements in insulin sensitivity. Exercise, perhaps a brisk walk for about 30 minutes a day four times a week, is an important component in establishing and maintaining 'tight' glucose control.

Maternal and fetal monitoring

Diabetic pregnancies are 'high risk' and therefore regular monitoring is appropriate. It is recommended that women with all forms of diabetes attend the antenatal clinic every two weeks. The risk is greater in women with complications of diabetes (e.g. vascular or renal disease) or hypertension in pregnancy (e.g. pre-eclampsia). A suggested minimum monitoring provision is every two weeks and then from 36 weeks weekly for clinical assessment and regular CTG. Doppler flow studies and/or biophysical profiles are recommended. The use of Doppler ultrasound in high-risk pregnancies may improve a number of perinatal care outcomes and appears promising in helping to reducing perinatal deaths (Neilson & Alfirevic 2001). Some clinicians encourage women to assess—and, if necessary, report—a perceived reduction in fetal movements during pregnancy, although there is no evidence to support the efficacy of this activity.

BOX 33.13 Type 2 diabetes support

A woman's weight influences her body image. Women with Type 2 diabetes or gestational diabetes mellitus are often overweight. Obesity makes it more difficult to maintain tight glycaemic control and this is especially true for the woman with Type 2 diabetes. In contrast, some women with Type 1 diabetes may find it very difficult to achieve their desirable weight. Women with diabetes are often advised to 'maintain a healthy weight' but this is easier said than done. It may be helpful to separate the issue of how much the woman weighs from the behaviours required for the woman to become and remain healthy. One strategy is for the woman to work with a dietician or other health professional to develop a plan of action that contains goals and strategies to meet them. In this way it is possible to focus on the plan rather than body size and weight gain or loss.

Ongoing laboratory tests

Ongoing evaluation of glycaemic control and the assessment of diabetic complications are essential components of any management plan for women with diabetes. Tests include:

- HbA_{1c}—as red blood cells are made, they combine with glucose in the blood to make HbA_{1c}. How much HbA_{1c} is produced depends on the blood glucose level at the time each red blood cell is made. Erythrocytes live for only a few months, so an HbA_{1c} test measures the average blood glucose over the previous two to three months. HbA_{1c} levels of 7% or less are associated with a reduced risk of microvascular complications, while levels > 9% are associated with increased risks. It is advisable therefore to aim for levels of 7% or less.
- serum creatinine and urinary excretion of total protein and/or albumin-to-creatinine ratio or 24-hour excretion rate—women with a protein excretion rate of > 190 mg/24 hrs are at increased risk of hypertension in pregnancy. Women with protein excretion rates > 400 mg/24 hrs are also at risk of IUGR.
- random plasma glucose and SMBG
- in the third trimester, ultrasound examination at 30 weeks for assessment of fetal growth—this should be repeated as clinically indicated, or at 36 weeks if the initial estimated fetal weight is > 80th percentile.

Self-management skills

Practical self-management skills for good glycaemic control include:

- counselling and education about the risks and prevention of congenital anomalies, maternal and perinatal complications, the effects of pregnancy on diabetes and the effects of diabetes on pregnancy, the need for effective contraception and pre-conceptual care, the importance of tight glycaemic control and its relationship to maternal and perinatal complications
- selection of appropriate anti-hyperglycaemic therapy
- development of a workable and acceptable plan to achieve low-risk glycaemia—< 1% above the normal range
- an appropriate diet and meal plan
- self-monitoring of blood glucose levels
- self-administering of insulin and self-adjustment of insulin dose
- treatment of hypoglycaemia (woman and her family members)
- development of an emergency plan to deal with hypoglycaemia
- incorporation of daily physical activity—at least 30 minutes a day
- development of techniques to reduce stress and help cope with the condition and its potential complications.

Labour and birth

During labour, supervision by an experienced team is essential to regulate diabetic control. As yet there is no clear evidence to inform decisions about the optimal timing for birth, although common practice is that the pregnancy does not proceed past 40 weeks. The timing of birth is determined on an individual basis. If there is a risk of preterm delivery, antenatal corticosteroids are administered in line with local protocols. Even after controlling for confounding factors, women with diabetes have a high rate of caesarean section (Remsberg et al 1999). This is possibly because of clinicians' concerns about the relationship between macrosomia and shoulder dystocia. An estimated fetal weight > 4.5 kg is generally regarded as an indication for delivery by elective caesarean section, although there is no firm evidence to support the optimal fetal weight at birth. During labour and birth, evidence-based protocols for IV dextrose and insulin are necessary to maintain maternal plasma glucose between 4 and 7 mmol/L.

Post partum

Post partum, there will be a rapid reduction of insulin requirements. Usually the same meal plan used during the pregnancy is adequate to meet the needs of the breastfeeding mother with diabetes. Adjustments are made in consultation with the woman's endocrinologist and dietician. Early breastfeeding is important and adjustment of the mother's food intake to accommodate this must be recognised. There are well-documented health benefits for diabetic women in breastfeeding their babies. Six-week postpartum fasting plasma glucose levels of women with Type 1 diabetes who exclusively breastfeed have been found to be significantly lower than those who bottle feed (Ferris et al 1993). For some women with Type 1 diabetes breastfeeding may complicate their glycaemic control—they have erratic blood-glucose levels and an increase in insulin reactions. For others, it is easier to maintain tight glycaemic control; some women can eat more and take less insulin. However, others find that symptoms of hypoglycaemia are different while they are breastfeeding; perhaps these symptoms appear more quickly or without any warning. Such women may need to take extra precautions and have some form of glucose (non-diet soft drink, or glucose tablets) nearby so that they do not

have to interrupt breastfeeding if a hypoglycaemic episode occurs.

Postnatal follow-up

Postnatal follow-up is a good opportunity for the team to begin pre-pregnancy care for any subsequent pregnancy, to support the woman as she works to attain good glycaemic control and to assist the family develop lifelong good health habits. The woman is advised on the necessity to make sure that the next pregnancy is planned. Effective communication between the hospital-based team, family doctor and diabetes clinic is essential. It is at this stage that a carefully documented outcome assessment for both mother and baby must take place, and this is then forwarded to the relevant clinicians responsible for the woman's ongoing care.

Management of Type 2 diabetes mellitus

Management is similar to that described for Type 1 diabetes and pregnancy.

In contrast to Type 1, Type 2 diabetes may be controlled by diet, insulin and/or medications such as metformin. Until recently it was believed that pregnant women with Type 2 diabetes who were taking oral agents such as metformin should switch to insulin as soon as their pregnancy was diagnosed, as these common medications were considered to be teratogenic and also because of concerns about the effect of transport of glucose across the placenta causing prolonged neonatal hypoglycaemia. Insulin is not associated with teratogenesis, nor does it have adverse fetal effects. In any case, many women with Type 2 diabetes require insulin during pregnancy if they are to achieve good glycaemic control.

Simmons and colleagues (2004) conducted a review of the available research and confirmed that although metformin does cross the placenta, necessitating a cautious approach to its use in pregnancy, as yet there are insufficient data to substantiate the belief that harm will always occur. They confirmed that tight glycaemic control in the pre-conceptional period and during early pregnancy is vitally important (Simmons et al 2004). If women taking metformin plan to become or are pregnant, it is crucial to ensure that the change in therapy occurs without deterioration in glycaemic control. Further, ceasing metformin may result in greater teratogenic risk by exposing the fetus to increased hyperglycaemia. Moreover, Simmons et al (2004) assert that some studies suggest that there are reduced rates of spontaneous miscarriage in women who continue taking metformin in the first trimester or throughout pregnancy. Further, there was also a reduced subsequent risk of gestational diabetes if metformin was continued during pregnancy. Simmons and colleagues (2004) conclude that it is reasonable for some women to continue metformin (e.g. if they refuse insulin therapy), or begin metformin (e.g. if they are very insulin resistant), when the likely benefits from improved glycaemic control outweigh the potential for harm.

During the postpartum period, some women will require or perhaps choose insulin as the preferred agent to maintain good glycaemic control. Metformin is not recommended if the woman breastfeeds because oral hypoglycaemic agents including metformin are passed, albeit in very small doses, into the breast milk. Some authors believe that because the quantity of the drug passing into the breast milk is so small it is safe to use in lactation. Nevertheless, others including Simmons et al (2004) assert that the safety of metformin cannot be assumed because the studies on which these conclusions were made were

Clinical point

Information on pregnancy and contraception should be given to all diabetic women of childbearing age. No contraceptive methods are specifically contraindicated in women with diabetes. Methods with proven high degrees of effectiveness are preferred.

BOX 33.14 Indigenous people and diabetes

Overall, compared to Europeans, Indigenous people from New Zealand and Australia as well as women from the Pacific Islands have a higher prevalence of risk factors known to be important in the development of Type 2 (non-insulin) diabetes. These include obesity, impaired glucose tolerance, hypertriglyceridaemia, hypertension and hyperinsulinaemia. Of importance also are the poor socio-economic circumstances of many Indigenous people (Colagiuri et al 1998; Simmons et al 2001a). The effect of socio-economic factors (low levels of education, unemployment, low incomes, and poor housing and related environmental conditions) are compounded through psychosocial pathways, involving stress, social support and social cohesion, social affiliations, early emotional development and social status (Marmot & Wilkinson 1999).

BOX 33.15 Reducing insulin resistance

Insulin resistance may be decreased with dietary modification, weight loss, perhaps anti-diabetic agents such as the biguanide metformin.

Clinical point

Metformin therapy should not be used routinely in women with pregnancies complicated by diabetes. The data regarding metformin use in pregnancy should be discussed with the woman before a decision is made regarding ongoing treatment. If a woman with Type 2 diabetes and taking metformin presents to the antenatal clinic already pregnant, she should be reassured that there is no evidence of teratogenesis with its use and that she should continue taking the medication until ongoing treatment options are discussed with her and clinicians in her team.

very small. Infant exposure to metformin can be minimised by breastfeeding just before taking the drug and avoiding feeding for a minimum of two to three hours after taking it.

Gestational diabetes mellitus

Gestational diabetes mellitus (GDM) affects 5% of all pregnancies and is a controversial disorder because of the uncertainties surrounding the best management. There is no consensus on the definition, management or treatment of gestational diabetes. GDM can be defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy. This definition includes women with abnormal glucose tolerance that reverts to normal after birth as well as those with previously undiagnosed Type 1 or Type 2 diabetes, and rarely in women with maturity-onset diabetes of the young (MODY).

GDM generally resolves once the pregnancy is completed, although 50% of women will develop Type 2 diabetes in later life. The disease is usually first noticed in the last 12 weeks of pregnancy and about 50% of women diagnosed with GDM will require insulin during pregnancy. Women with GDM are more likely to experience repeated miscarriage and develop hypertensive disorders, although some of this additional risk may be associated with underlying risk factors for GDM (e.g. increased maternal age or obesity). They are also more at risk of caesarean delivery. Clinicians' fears about perceived associations between fetal macrosomia, shoulder dystocia and GDM probably account for this finding. Other potential complications for the woman include polyhydramnios, preterm labour and birth, as well as genital tract infections from *Candida albicans*, and UTIs.

Research

A New Zealand study (Simmons et al 2001b) confirms earlier findings that insulin pump therapy in Type 2 diabetes and gestational diabetes mellitus is well tolerated. Such therapy is associated with no significant hypoglycaemia, and control of hyperglycaemia is achieved to a level unlikely with large boluses of subcutaneous injections of insulin. Perinatal outcomes were comparable to those in women with less hyperglycaemia and lower insulin requirements. However, use of insulin pumps was associated with substantial weight gain and a greater likelihood of admission to the Special Care Baby Unit.

BOX 33.16 Type 2 diabetes in Australia

The likely prevalence of Type 2 diabetes among Indigenous Australians is between 10% and 30%—around two to four times that among non-Indigenous Australians. The disease also occurs at younger ages among Indigenous than non-Indigenous people (de Courten et al 1998; see also Australian Indigenous HealthInfoNet 2003).

Some studies (Turok et al 2003) assert that the fetus is at greater risk of congenital abnormalities, particularly neural tube defects. Episodes of fetal hyperglycaemia and hyperinsulinaemia may lead to fetal macrosomia, possibly traumatic birth followed by growth restriction, neonatal hypoglycaemia, hypocalcaemia, hyperbilirubinaemia, polycythaemia and intrauterine death.

Risk factors for GDM

Risk factors for GDM include obesity, family history of diabetes, being of Aboriginal or Torres Strait islander background, or of Maori, Pacific, Middle-Eastern or Asian ethnicity.

Other risk factors include previous unexplained stillbirth, poor obstetric or social history, polycystic ovarian syndrome, obesity, previous diagnosis of GDM, having a previous baby with a birth weight over 4500 g and maternal age > 25 years. In a current pregnancy, accelerated weight gain, polyhydramnios, newly detected glycosuria and multiple pregnancy are all associated with GDM.

Diagnosis of GDM

The most appropriate strategies for screening, diagnosing and managing asymptomatic GDM remain controversial (Turok et al 2003). Screening for GDM is widely practised despite a lack of evidence that it prevents adverse outcomes (Turok et al 2003). Nevertheless, many medical centres including the RANZCOG recommend a random (non-fasting) 50 g glucose challenge test as an initial screening test for GDM. If the one-hour plasma glucose is ≥ 7.8 mmol/L, women are recalled for a glucose tolerance test.

The Australasian Diabetes Society (ADIPS) (Hoffman et al 1998) has endorsed the diagnostic criteria based on modified WHO criteria. After a positive screening test, the diagnosis is confirmed with a 75 g oral glucose tolerance test (fasting) with a venous plasma glucose level at 0 hours of 5.5 mmol/L and/or at 2 hours of ≥ 8.0 mmol/L. In New Zealand, the two-hour oral glucose tolerance test (OGTT) cut-off value for a positive diagnosis is a venous plasma glucose level of 9.0 mmol/L.

Collaborative management of a woman and her fetus with GDM

The keystones of therapy—control of blood glucose levels, monitoring, diet and exercise—have already been discussed, and this section only explores material that is of direct

Research

New Zealand Polynesians, Maori and people from the South Pacific have a high prevalence of GDM and Type 2 diabetes, diagnosed at an increasingly young age, and obesity (Simmons et al 2001a). Compared with European women, Polynesians with GDM are older, heavier, have worse hyperglycaemia at diagnosis, are more likely to have Type 2 diabetes postnatally, and are prone to worse perinatal outcomes (Simmons et al 2000).

relevance to GDM. Women at significant risk of, or with, GDM require an interdisciplinary team approach. Ultimately the woman with GDM must become the most active member of her care team, calling on the other members for specific guidance and expertise to help her achieve her goal of a healthy pregnancy, birth and baby. If the woman has been diagnosed with GDM in earlier pregnancies, it may be possible to begin her care before conception so that she and her team can develop evidence-based strategies aimed at maintaining the maternal blood sugar levels as near to normal as possible. It is possible to stabilise the GDM by diet alone but 50% of women require insulin or a combination of both as the pregnancy progresses. Each woman requires regular antenatal assessment, including a management plan. This is usually achieved through a combination of hospital and home visits, with hospital admission if the woman's diabetes becomes unstable or if she presents with any infection or other complication such as pre-eclampsia.

After the initial visit and once she becomes pregnant (or once the condition is diagnosed), the woman is seen at four- to eight-week intervals, depending on her ability to keep to her plan of management and the presence or absence of pre-existing complications.

Insulin

Most studies involving insulin therapy in women with GDM (Turok et al 2003) have shown a reduction in the incidence of fetal macrosomia. Consequently, insulin therapy is traditionally commenced when, despite nutrition therapy and the initiation of an exercise regimen, capillary blood glucose levels exceed 5.8 mmol/L in the fasting state and 6.7 mmol/L two hours after meals (Turok et al 2003, p 1769). The combination of food diaries, SMBG records and weight changes are also used to determine whether insulin therapy is required. Women are advised to contact their lead carer if blood glucose levels exceed target goals on two or more occasions over a 1–2 week period without some obvious explanation identified in the food records, or if the blood glucose levels are consistently elevated. There is no evidence that supports the efficacy of one type of insulin regimen over another.

Dietary modification

Dietary management, with or without insulin, causes a modest but consistent reduction in neonatal birthweight. Unfortunately, the optimal distribution of calories as carbohydrates, fats and protein for women with GDM is unknown, and there is little consensus and wide variability in clinical practice. Working in partnership, the mother and midwife aim to meet the following goals for nutrition:

Reflective exercise

What would you say to a woman who says, 'My doctor says my ultrasound shows that my baby is much larger than he should be. He says he thinks this is because I have diabetes and that I will need a caesarean section.'?

BOX 33.17 Managing a GDM pregnancy

Over-zealous treatment with diet or insulin may compromise babies of mothers with GDM, especially if they are not macrosomic. Following counselling and nutritional advice, and if pre- and post-prandial glucose levels are normal and there is no evidence of excessive fetal growth, the pregnancy should be managed as a 'normal' pregnancy.

- optimal nutrition for the developing fetus
- optimal nutrition for the pregnant woman and mother
- maternal euglycaemia without distortion of dietary patterns
- good nutrition for all the family
- nutritional patterns that prevent or forestall recurrence of GDM and the onset of Type 2 diabetes mellitus in later pregnancies.

Frequency of visits

If the diabetes is well controlled, the pregnancy is treated as 'normal' and proceeds to term. It is, however, most likely to proceed to term if the woman's GDM is well controlled by diet alone. As the third trimester begins, a woman with GDM is more at risk of complications and so the schedule of antenatal visits increases—for example, for women who do not require insulin, three-weekly until 28 weeks, then two-weekly until 38 weeks, then weekly until delivery. Women receiving insulin should be seen weekly from 34 weeks. The frequency of consultations is increased if there are other complications, such as:

- pre-existing or pregnancy-induced hypertension
- fetal macrosomia

Clinical point

Community-based care

Telephone/fax/email management can be a financially and time-effective way for the midwife to maintain close contact with a woman with GDM during the intervals between face-to-face consultations with the diabetic team. Women are asked to call/fax/email records weekly. A midwife skilled in working with women with GDM can use these records to assess the woman's health and to reinforce health education, answer questions and monitor records to identify those in need of extra support. Self-maintenance of these records is empowering for the woman and also reinforces their importance. This type of monitoring also identifies the high blood glucose levels that are not necessarily brought to the attention of the diabetic team, perhaps from fear or denial of their significance. Telephone calls, rather than the more impersonal email or fax management, are probably more likely to lead to the formation of a trusting relationship between woman and midwife.

- intrauterine growth restriction
- poor glycaemic control
- inability to stop smoking.

Labour and birth

In women with good glycaemic control and no complicating factors, there is no need to induce labour before term. The chosen method of giving birth depends on choice and obstetric factors. The woman's need for exogenous insulin by itself is not an indication for earlier delivery or a caesarean section, which is often the preferred option if the estimated fetal weight at the time of delivery is > 4250 g, because of a perceived risk of shoulder dystocia. Only if there are concerns about the woman's health, her labour or the fetus is a caesarean section indicated. During labour, blood sugar levels are monitored regularly. Once the woman is in established in labour she is often commenced on an IV infusion of glucose in one line and insulin in another. The dosage required is dependent on her blood sugar levels and the unit's guidelines. The woman's condition and that of her fetus are observed and monitored as in any normal labour, although the fetal heart rate is usually continuously electronically monitored once labour commences.

Postnatal care and follow-up

Management during the early postnatal period includes frequent blood sugar estimations to detect hypoglycaemia, as the postpartum woman's insulin requirements fall rapidly after birth. If she is on insulin, the dose is reduced, depending on the blood sugar levels. Early breastfeeding is recommended and encouraged, although it does alter the woman's blood glucose levels, as it is associated with better neonatal outcomes, maternal weight loss post partum, as well as improved fasting blood glucose levels, glucose tolerance and lipid levels (Kjos et al 1993).

Before going home, the woman is counselled about family planning and advised that oral contraceptives may affect carbohydrate metabolism and hence insulin requirements. A follow-up glucose tolerance test (GTT) is recommended at six to eight weeks post partum using a standard 75 g GTT and evaluative criteria for non-pregnant women. Those with an abnormal GTT (diabetes, impaired glucose tolerance or impaired fasting glycaemia) should be reviewed by an endocrinologist. Women with a normal postnatal GTT should be advised about a healthy lifestyle, and to have a GTT every two years.

Thyroid disease

Numerous hormonal changes occur during pregnancy, resulting in complex metabolic adaptations in maternal thyroid function. Despite this, normal pregnancy is considered to be a euthyroid state. Auto-immune thyroid dysfunctions remain a common cause of both hyperthyroidism and hypothyroidism in pregnant women and these are covered briefly here. Patients with either hyper- or hypothyroidism tend to be infertile, although it is certainly possible to have these diseases and still become pregnant. Graves' disease (hyperthyroidism) accounts for more than 85% of hyperthyroid cases, while Hashimoto's thyroiditis remains the most common cause of hypothyroidism.

Critical thinking exercise

What will you say to a woman with Graves' disease who says, 'I really want to breastfeed. Can I do this while taking propylthiouracil (PTU)?'

Hyperthyroidism

Graves' disease is an auto-immune disease characterised by hyperthyroidism due to circulating autoantibodies. If left untreated, severe thyrotoxicosis, a life-threatening thyrotoxic crisis (i.e. thyroid storm), can occur. Fortunately, pregnant women often experience temporary remission of their symptoms. Treatment of Graves' disease focuses on restoring normal thyroid function with antithyroid medication. Treatment of hyperthyroidism during pregnancy is different from that in non-pregnant women, because radioactive iodine cannot be given and surgery should not be performed because of am increased risk of miscarriage. Because of the immunosuppressive effect of pregnancy, antithyroid drugs (e.g. carbimazole) can be given in lower doses than with non-pregnant patients. Propylthiouracil is not recommended in pregnancy. Radioactive isotopes are secreted in milk and no isotope tests or isotope scans should be performed on a woman who is breastfeeding. Propylthiouracil can be used when breastfeeding, as only negligible amounts pass into the milk.

Hypothyroidism

Hypothyroidism or its associated hormonal changes are associated with anovulation, infrequent menstruation and amenorrhea. In severe cases the pituitary gland produces increased amounts of prolactin, which 'turn off' normal menstrual cycles. Thus, hypothyroidism is associated with infertility and, if pregnancy does occur, there is an increased risk of miscarriage. Very little thyroxine crosses the placental barrier so there is no contraindication to taking thyroxine in pregnancy. Many specialists increase the dose slightly during pregnancy because they feel that pregnancy increases the requirements for thyroxine and thyroid stimulating hormone levels rise. Thyroxine is also secreted in the milk, but provided the dosage in the mother is maintained in the physiological range, it appears to be quite safe for the mother on thyroxine to breastfeed. After birth, the dose of thyroxine is gradually returned to pre-pregnancy levels. The frequency of thyroid function tests is reduced and finally reviewed two months after thyroxine levels reach pre-pregnancy levels.

Heart disease

Fifty years ago, women with heart disease were advised to avoid pregnancy. Now it is not unusual for women with heart disease

WOMAN'S STORY

Type 1 Diabetes and pregnancy: one mother's story
By Kim Barwise

I was 31 years old, happily married and had no health problems despite having had Type 1 diabetes for seven years. It seemed like the right time to have a baby. But on further thought, I worried whether the risks were too high. I was aware of some of the risks to a baby caused by high blood sugars. Would my baby be okay or would he or she develop diabetes? Some of these concerns are typical to anyone with diabetes, but the fear of being responsible for the health and development of another little being was somewhat overwhelming to me. I wanted to have some guarantee that everything would turn out well.

I spoke with my endocrinologist to determine which fears were real. Statistically, the level of risk for a woman with Type 1 or Type 2 diabetes and for the baby is largely determined by the health of the woman just before conception and within the first 11 weeks of pregnancy. Women with diabetes are typically not discouraged from having a baby unless they have experienced eye complications, damage to their kidneys or have heart disease. Good blood sugar control is crucial within the first five to 11 weeks as the baby's organs are beginning to develop. If the mother's blood sugar level is high during this time period, the baby's spinal cord and heart could be affected. There are various tests offered to women at 16 weeks and at 20 weeks to determine the risk for spina bifida, Down syndrome and heart deformities.

Knowing that my blood sugar control was within a good range, and having the support of my endocrinologist and husband, I felt ready to get pregnant. It was a big disappointment. I had put a lot of effort into improving my blood sugar control, attempting to exercise, testing at least four times a day and trying to suppress my worries about my health and the baby's. Was diabetes affecting my ability to become pregnant? According to my endocrinologist, diabetes does not affect fertility. Then, as soon as I stopped worrying, I became pregnant.

Once pregnant, my motivation to manage my diabetes significantly increased. I was conscious of the grams of carbohydrate I was eating, monitored my blood sugar levels seven times a day and adjusted my insulin regularly. The blood sugar goal set by my endocrinologist was 3.5 to seven mmol/L, but this goal can vary depending on the doctor and your ability to recognise and treat hypoglycaemia. While I was able to achieve a healthy blood sugar level throughout most of my pregnancy, I found blood sugar control difficult during the first trimester. This was probably related to the fluctuating levels of hormones that caused my blood sugar levels to become very high during my eighth week of pregnancy. Typically, women find blood sugar levels drop too low during the first trimester, but it is not uncommon for blood sugar levels to soar into the teens. The support of the endocrinologist and diabetes educators helped to calm my fears. They adjusted my insulin dose to compensate for the 'highs.'

Although I am a diabetes educator, I found it difficult at times to be objective about my health and the baby's. I had to recognise that I couldn't treat my body like a machine and expect everything to be perfect all the time. Given the psychological impact of extra monitoring and the fear of complications, it was important to discuss my concerns with both my doctor and family in order to keep my perspective. Having the opportunity to vent during the first trimester allowed me to cope with the demands of the second and third trimester.

When the third trimester arrived, I found being pregnant and having diabetes became a full-time job. The frequency of ultrasounds and visits to the obstetrician and endocrinologist increased significantly. I was also very tired at that point in my pregnancy. Once, I was caught snoozing on the floor of my office (not recommended!). The frequency of hypoglycaemia increased because the blood sugar levels were so tightly controlled. Having a knowledgeable and supportive family and work environment was crucial to coping with the demands during this trimester.

In my view, one of the few benefits of having Type 1 diabetes was the opportunity to be induced at 38 weeks instead of 40 weeks. Early induction is often recommended because diabetes may cause the placenta to mature faster. When I was at 38 weeks, the weather was hot and humid, my sense of humour was waning and I felt I couldn't possibly get any larger. I was ready to get this pregnancy over with and start being a mum.

The induction took much longer than I had expected. Yet 31 hours of labour were much more tolerable for me with an epidural. After a year and a half of planning and perseverance, the end result was a healthy, beautiful baby girl named Lindsay. All had turned out better than I had expected; it truly was a miracle!

If you are thinking about getting pregnant, my recommendation is not only 'do it' but also 'plan it'! Talk to your endocrinologist or diabetes educator a few months in advance so that the birth of your child will be as wonderful as it should be.

(Source: Barwise 2005)

to have a normal (albeit carefully monitored) pregnancy. It is estimated that heart disease affects 1–3% of all pregnancies. It is the leading cause of indirect maternal mortality (Slaytor et al 2004) in Australia. In their most recent report on maternal deaths in Australia, Slaytor et al (2004) report that seven of the 28 indirect maternal deaths were from cardiac-related causes.

The cause of heart disease may be congenital or related to illness, usually rheumatic heart disease. Irrespective of its causation, pre-existing or de nova heart disease is seriously complicated by pregnancy.

Congenital heart disease

The majority of pregnant women with congenital heart disease are aware of their condition and are already receiving cardiologist's care. Nevertheless, not all women are aware that they have heart disease. History taking at the first antenatal contact and questions about a past history of rheumatic fever plus auscultation of abnormal heart sounds may be the woman's first inkling that she has heart disease.

Specialist, skilled care and excellent teamwork can lead to excellent outcomes for both mother and baby. Individual counselling and ongoing care requires a multidisciplinary approach and should ideally include information regarding contraception, maternal and fetal risks of pregnancy, and expected long-term outcomes. Identification of the risks associated with pregnancy and counselling the woman with heart disease are best accomplished before conception. During counselling and information sharing, the following seven areas should be considered: the underlying cardiac lesion, maternal functional status, the possibility of further palliative or corrective surgery, additional associated risk factors, maternal life expectancy, the woman's ability to care for her child, and the possibility of an increased risk of congenital heart disease in her children.

Pregnant women with 'severe' heart disease of any causation may be at particular risk for congestive heart failure, arrhythmias, thrombosis, emboli, and adverse effects of anticoagulants. Such women should be referred to a high-risk pregnancy unit in a tertiary hospital. Ideally the woman leads a team who should meet as early as possible early in the pregnancy. With the woman and her family (unless this has been done pre-pregnancy) and as early as possible, the team identifies the nature of the cardiac lesion, its anticipated effects on the pregnancy and the effects of the pregnancy on the disease, and explores potential problems. Women with heart disease in the 'low-risk' group can be managed with support in a Level II, community hospital setting.

Case study

A 27-year-old woman, para 0, had her antenatal care overseas. She had congenital aortic stenosis, which was managed with an aortic valve replacement. Her medication included warfarin prior to pregnancy, which was replaced by heparin. She developed gestational diabetes. At 31 weeks she was admitted to a tertiary hospital with provisional diagnosis of thrombosed prosthetic valve and infection. She was managed in the coronary care unit. Two days after admission, she developed dyspnoea, tachycardia and had a cardiac arrest one hour later, A caesarean section was carried out to deliver a stillborn infant followed by cardiac surgery. Her prosthetic valve was found to be mobile with a sub-valvular thrombus. The valve was replaced but she died shortly afterwards. Associate Professor Walters, the reviewer of this section of the report, commented that heparin is a relatively poor substitute for warfarin, and if used, low molecular heparin should be administered in an adequate dose and frequency, particularly with prosthetic aortic valves that are known to predispose to thrombosis.

(Source: Slaytor et al 2004, p 43)

Clinical point

Because it is often not possible for every member of a large multidisciplinary team to attend every meeting, especially in moments of crisis, it is helpful to develop and distribute widely a readily accessible, written management plan, one that is frequently updated for foreseeable contingencies.

Conservative medical measures designed to optimise intravascular volume and systemic loading conditions enable many women with congenital heart disease to have successful outcomes. Simple interventions such as maternal bed rest and avoidance of the supine position should not be overlooked. Whenever possible, symptomatic or severe valvular lesions should be addressed and rectified before conception and pregnancy. Pregnant women with mechanical valve prostheses have an obligate need for anticoagulation. Unfortunately, there remain significant problems and an impressive risk for both the mother and fetus from either haemorrhage or thrombosis with the use of either warfarin or heparin. Guidelines for the management of the pregnant woman with a mechanical prosthesis have been difficult to formulate due to the lack of adequate prospective randomised controlled trial data. Practice patterns vary widely and no consensus exists, as might be expected from the disparate results and claims of the retrospective and selective case series that have been reported to date.

Rheumatic heart disease

According to Northern Territory clinicians, Carapetis and Currie (1998), by the end of the twentieth century, the good news about rheumatic fever was that it was so rare that most Australian clinicians would never see a case. Since the 1930s, at least in affluent Australian populations and largely as a result of economic development and improved living conditions, with perhaps a small contribution from antibiotics and possibly altered virulence of circulating Group A streptococcal strains, there has been a dramatic decline in the incidence of rheumatic fever and its devastating complications. The authors (Carapetis & Currie 1998) then move to the bad news, that some socially and economically disadvantaged populations throughout the world, including indigenous and minority populations living in affluent countries such as Australia, still suffer high rates of rheumatic fever and rheumatic heart disease. Indeed, the highest *published* incidence of acute rheumatic fever in the world occurs in Aboriginal people living in the Top End of the Northern Territory (Carapetis et al 1996). Over a five-year study period, the authors discovered that the prevalence of rheumatic heart disease in the non-

Clinical point

Revision: heart function in pregnancy

On average, there is a 50% increase in circulating blood volume during pregnancy, which is accompanied by a commensurate increase in cardiac output that usually peaks in the second and third trimesters. The augmented cardiac output derives from an increase in the stroke volume, although there is also a smaller increase in heart rate, averaging 10 to 20 beats per minute. Systemic vascular resistance falls, with a disproportionately greater lowering of diastolic blood pressure and a wide pulse pressure. There is a further abrupt increase in cardiac output during labour and birth. Uterine contractions can lead to marked increases in both systolic and diastolic blood pressure. After birth there is an initial surge in preload related to the autotransfusion of uterine blood back into the systemic circulation and to caval decompression. Pregnancy is also associated with a hypercoagulable state.

Aboriginal population of the Top End was 0.014% but up to 3% of people living in remote Aboriginal communities in the Northern Territory were found to have established rheumatic heart disease. Rheumatic heart disease often leads to valvular disease such as mitral stenosis or mitral incompetence and aortic incompetence. For this reason this section is primarily focused on the effects of rheumatic heart disease, with special emphasis on the effects of valvular disease on pregnancy and its management.

Valvular heart disease

Valvular heart disease is often first recognised in pregnancy when the profound haemodynamic changes that normally occur during pregnancy put additional strain on the heart, sometimes precipitating heart failure.

Clinical presentation

Mitral stenosis is the most common rheumatic valvular lesion encountered during pregnancy. Depending on the severity and duration of the disease, pregnant women with mitral stenosis frequently present clinically with symptoms of both left-sided heart failure and right ventricular failure. However, left-sided heart failure is more common and symptoms include orthopnea, paroxysmal nocturnal dyspnoea, and dyspnoea on exertion.

Diagnostic assessment

Invasive diagnostic testing is rarely indicated in pregnant women with mitral stenosis. Echocardiography is the diagnostic test of choice because it both confirms the diagnosis and helps to determine the severity of the condition. In addition, it is used to determine pulmonary pressures, right ventricular function and mitral regurgitation.

Clinical point

Symptoms of normal pregnancy can mimic those of valvular heart disease. The presence of a loud fourth heart sound, a diastolic murmur, a grade 3/6 or greater systolic murmur, a fixed split of the second heart sound, and an opening snap should raise suspicion of cardiac abnormalities. The presence of one or more of these signs should signal the need for referral to specialist care and echocardiographic evaluation.

Management in pregnancy

In addition to the measures designed to manage symptoms, rest is encouraged and dietary advice is given to aid weight control. Iron and folic acid are prescribed to prevent anaemia, and haemoglobin estimation is undertaken frequently. To prevent bacterial endocarditis (see below) a dental referral is made early in pregnancy. If the woman presents with any signs of infection, she is commenced on antibiotics. Any deterioration in the woman's condition, such as shortness of breath and a cough, requires hospital admission for ongoing observation and assessment. Rarely, some women require mitral valvotomy during pregnancy to increase the size of the narrowed mitral valve. The cardiologist on the woman's team may restrict salt and fluid intake. However, diuretics should be used with caution to avoid hypotension and increased heart rate as well as fetal compromise. Use of beta-blocking drugs to slow the heart rate can dramatically improve the woman's symptoms.

Labour and birth

In view of the increase in cardiac output during labour and after giving birth, it is important to plan management carefully. With very few exceptions, vaginal birth is preferable and possible in most women with cardiac disease including mitral stenosis. Preterm induction is rarely indicated, but planned induction of labour and delivery in high-risk situations will ensure availability of appropriate staff and equipment. Heparin anticoagulation is discontinued at least 12 hours before induction of labour, or reversed with protamine sulfate if spontaneous labour develops, and can usually be resumed 6–12 hours post partum.

Optimal management may also require invasive haemodynamic studies in women with moderate to severe mitral stenosis. Continuous oxygen via facial mask may be helpful to reduce pulmonary pressures and fluid restriction, and use of diuretics and epidural anaesthesia with adequate volume preloading is the technique of choice.

Labour is usually conducted with the woman lying in the left lateral decubitus position to attenuate haemodynamic fluctuations associated with contractions found if she lies in the supine position. Epidural fentanyl is particularly advantageous in women with cyanotic heart disease because it does not lower peripheral vascular resistance. Instrumental

delivery with forceps or vacuum extraction will shorten the latter part of the second stage of labour and reduce the need for maternal expulsive efforts. Active management of the third stage of labour with Syntocinon—not ergometrine—can reduce the incidence of PPH and its complications.

Antibiotic prophylaxis against endocarditis

The incidence of endocarditis is no different in pregnant women with valvular heart disease than in non-pregnant women with the same condition. Streptococcal organisms (including the causative organism of rheumatic heart diseases) are the most common cause of subacute bacterial endocarditis, but acute endocarditis is usually due to more virulent organisms, such as *Staphylococcus aureus*, *Streptococcus pneumoniae* and *Neisseria gonorrhoeae*. Endocarditis prophylaxis is initiated at the onset of active labour when indicated. The American Heart Association recommendations (Bonow et al 1998) state that delivery by caesarean section and vaginal delivery in the absence of infection do not require endocarditis prophylaxis except, perhaps, in women at high risk. However, many centres with extensive experience in caring for pregnant women with heart disease use bacterial endocarditis prophylaxis routinely, as an uncomplicated birth cannot always be anticipated. However, if vaginal infection is already present, antibiotics should be started promptly. In addition, antibiotic prophylaxis seems appropriate for women in other high-risk categories. These include pregnant women who have any of the following:

- prosthetic valves
- history of bacterial endocarditis
- valvular heart disease (aortic stenosis, aortic regurgitation, mitral regurgitation or stenosis with mitral regurgitation)
- hypertrophic cardiomyopathy.

Anticoagulation therapy during pregnancy

Pregnancy involves a state of hypercoagulability caused by increased levels of various clotting factors and increased blood viscosity. Systemic anticoagulation poses major problems during pregnancy in women with prosthetic heart valves, venous or arterial thromboembolism, or atrial fibrillation with valvular heart disease. When a pregnant woman, perhaps with a mechanical heart valve, requires anticoagulation, heparin and warfarin are used but controversy continues as to which is better at different stages of pregnancy. Oral anticoagulants such as warfarin sodium cause fetal embryopathy; subcutaneous administration of heparin sodium has been reported to be ineffective in preventing thromboembolic complications (Chan et al 2000). Unfractionated heparin does not cross the placenta and has little effect on the fetus. However, long-term IV use is inconvenient and so is often unacceptable to women. Experience with low-molecular-weight heparin (LMWH) in such situations is minimal, although it appears that this drug is less effective than oral anticoagulants in preventing thromboembolism (Chan et al 2000). Moreover, LMWH is associated with low neonatal mortality and low incidences of premature delivery, spontaneous abortion, and intrauterine fetal death. However, it can cause significant osteoporosis in pregnant women. Consequently, on the basis of the data available, most authorities (Bonow et al 1998; Chan et al 2000) recommend ceasing warfarin as early as possible in pregnancy and instead using subcutaneous heparin therapy for at least the first trimester. After this, warfarin therapy can be reinstituted.

Postnatal care and follow-up

As maternal haemodynamics do not return to baseline for many days after giving birth, the following may apply for women at intermediate or high risk:

- Provide continuous monitoring for at least 72 hours post partum.
- Rest is encouraged.
- If appropriate, antibiotic cover is continued.
- Breastfeeding is not contraindicated.

Before she goes home, family planning and contraception are discussed. The woman will be followed up at the cardiology clinic, in addition to midwife and GP follow-up.

Respiratory disease

Pregnancy induces profound changes in the mother, resulting in significant alterations in normal physiology. The anatomical and functional changes of pregnancy affect the respiratory and cardiovascular systems. Management of respiratory problems in pregnancy requires an understanding of these changes for interpretation of clinical and laboratory manifestations of respiratory diseases.

Asthma

Occurring in 4% of pregnant women and complicating up to 1.5% of pregnancies, asthma represents the most common obstructive pulmonary disease of pregnancy (Blaiss 2004). Asthma does not usually worsen during pregnancy; in fact, many women, but not all, find that their asthma improves. In their systematic review of the literature, McDonald and Burdon (1996) state that although bronchial hyperresponsiveness lessens in mid-pregnancy, studies reporting changes in asthma severity during pregnancy show widely differing results. The authors (1996) state that, overall, the

Critical thinking exercise

1. How will you respond to a woman with mitral valve stenosis who asks if it is safe to take warfarin in early pregnancy?
2. Women who have had valve replacements are often on oral anticoagulation therapy. Then, as the anticipated birth date draws near, this is changed to subcutaneous heparin. Why is this change of therapy necessary and what are the evidence-based advantages and disadvantages of LMWH versus unfractionated heparin in pregnancy and the postpartum period?

data indicate that the clinical severity of asthma during pregnancy improves in about 30% of women, remains stable in about 50% and worsens in about 20%. Although the specific mechanisms involved in changing the course of asthma during pregnancy have not been determined, they are likely to be multifactorial.

Avoidance and control of asthma triggers are important because poorly controlled asthma or severe asthma not only threatens the life of the mother but also threatens the fetus because of increased maternal hypoxaemia and diminution of uterine artery blood flow secondary to hypocapnic vasoconstriction. Women with poorly controlled asthma have an increased incidence of hyperemesis gravidarum, haemorrhage and pre-eclampsia. Their babies are more likely to: be low birthweight and preterm; suffer neonatal hypoxia from complications during labour; and have increased perinatal and maternal mortality (McDonald & Burdon 1996).

Unfortunately, in pregnancy asthma can still be triggered by many factors, including allergy, upper respiratory tract infection, sinusitis, exercise, aspirin, non-steroidal anti-inflammatory agents (NSAIDS), environmental toxins (e.g. tobacco smoke, chemical fumes), humidity, anxiety and emotional distress.

Asthma medications during pregnancy

Although care providers have a natural reluctance to prescribe drug therapy in pregnancy, poorly controlled asthma is potentially more dangerous for the fetus than medication. Diagnostic testing is the same for non-pregnant women and pregnant women. However, when interpreting blood gas values, it is important to remember the normal values for pregnancy. For example, the PaO_2 is higher in pregnant women than in non-pregnant women, ranging from 102 mmHg to 116 mmHg. In addition, the normal physiological increase in minute ventilation results in a lower $PaCO_2$ range of 28 mmHg to 30 mmHg. Therefore, a low PaO_2 or a high $PaCO_2$ associated with an acute episode of asthma may represent significantly more severe respiratory compromise than similar blood gas values in a non-pregnant woman. Nevertheless, mild changes in pulmonary function are usually reversible and tolerated in healthy pregnant women. However, in some circumstances an increased basal metabolic rate, increased oxygen consumption, decreased carbon monoxide-diffusing capacity, decreased buffers and alterations in lung volumes increase the woman's susceptibility to the detrimental effects of hypoxia caused by asthma. Women should therefore be advised to continue with their pre-pregnancy medication in consultation with specialist care providers.

Management of asthma

As with non-pregnant women, beta-2 agonists are used for symptomatic benefit during acute asthma. Inhaled corticosteroids remain the mainstay of therapy for asthma control. Long-acting adrenergic agonists might be used in symptomatic patients on adequate corticosteroid therapy. Generally a stepwise approach to management is preferred, one that gradually increases the number of medications used and their doses. Occasionally corticosteroids are necessary but should be used only for short periods. An increased risk of cleft palate and placental abnormalities is reported in animals given oral steroids in first trimester, but not humans. Nonetheless, the benefits of oral steroids may outweigh the risks if they are used to manage severe asthma or during life-

BOX 33.18 Asthma management

Environmental control, pharmacological treatment and specific allergen immunotherapy are the cornerstones of asthma management for all patients. Of these, institution of environmental control measures to lessen exposure to triggers is even more vital during pregnancy, Helping women to learn how to watch for and avoid these triggers will probably improve symptom control, and may possibly result in pregnant women needing less medication. Gastroesophageal reflux is a common problem in late pregnancy and is a documented asthma trigger. Advising the woman to eat small meals and to raise the head of her bed by several centimetres may help alleviate this problem. Some women may require antacids or H_2-receptor-blocking medications.

Clinical point

Medications for asthma have been shown to be safe for both the mother and the developing baby. It is more dangerous to have untreated asthma during pregnancy than to continue with prescribed asthma therapy. Asthma reduces the amount of oxygen available to the fetus. To maintain optimum control of their asthma it is important for women to follow an individualised asthma action plan very carefully.

BOX 33.19 Asthma update

The National Heart, Lung and Blood Institute (NHBLI) website (see below) has updates on the *Report of the Working Group on Asthma and Pregnancy*, published by the National Asthma Education and Prevention Program (NAEPP): *Managing Asthma During Pregnancy: Recommendations for Pharmacologic Treatment—Update 2004*. It also has the *Expert Panel Report: Guidelines for the Diagnosis and Management of Asthma* (1997) available for download. The new guidelines offer recommendations regarding the use of allergy medications in pregnancy based on recent studies of these medications. Information about the expert panel and its financial disclosures are included in the full report.

National Heart, Lung and Blood Institute (NHLBI) http://www.nhlbi.nih.gov/health/prof/lung/asthma/astpreg.htm

threatening exacerbations because the steroidoral cleft palate relationship is irrelevant after the first trimester.

Breastfeeding

Breastfeeding should be encouraged in women with asthma, as breast milk confers some immunity to infection to the baby, especially to respiratory and gastrointestinal infections. Breast milk contains very small amounts of the usual medications used to prevent and treat asthma, but there is no evidence that this is harmful to the infant. However, the manufacturers of budesonide have recommended discontinuation of this drug during lactation because of an absence of information regarding its transmission into breast milk. The decision to alter a successful medication regimen that is controlling the mother's asthma must be weighed against any potential detrimental effects to the infant from continuation of the drug.

Consequently, women should be reassured that although asthma medications do enter breast milk, their concentrations are extremely small and do not have any adverse effects on their babies.

Acute asthma exacerbation

Acute exacerbations that necessitate emergency department visits typically require a course of systemic corticosteroids. In addition, oxygen therapy is used to maintain oxygen saturation levels at or above 95% to ensure both maternal and fetal wellbeing. There is no evidence of teratogenic effects associated with bronchospasm relaxants such as the beta-2 agonists (category A)—salbutamol, terbutaline and fenoterol. Although IV salbutamol is used to delay the onset of preterm labour, these affects do not occur with bronchodilators administered by metered-dose inhaler or wet nebulisation.

Tuberculosis

Tuberculosis (TB) is an infection caused by *Mycobactrium tuberculosis*. Its inflammatory process causes destruction of lung tissue, increased production of sputum and coughing. If a woman receiving medication for active TB becomes pregnant, she continues with her medications. If the disease is diagnosed for the first time during pregnancy, anti-tuberculoid medication is still commenced and this protects the fetus from the disease. Labour is managed normally and, in the presence of active disease, an elective vacuum extraction or forceps delivery may be recommended to shorten the second stage of labour.

The disease may reactivate in the postnatal period. Breastfeeding is contraindicated if the woman has active TB while treatment is established. However, anti-tuberculoid medications cross into the breast milk. Vaccination is always recommended in high-risk groups, such as people from Asian or Pacific backgrounds and Indigenous Australians, or if other members of the household have or have had a history of pulmonary TB or if they are likely to come in contact with people at high risk of infection. In Australia and New Zealand, parents are encouraged to immunise their babies with BCG (bacille Calmette-Guerin) vaccine.

Renal disease

The renal system undergoes monumental physiological and anatomical changes during a normal pregnancy. An understanding of these changes is necessary in order to understand how they may lead to or worsen pre-existing or new renal disease. Only the most common conditions are dealt with in this section. Others such as glomerular nephritis, chronic renal disease and renal transplantation are not included here and the reader should refer to the appropriate specialist texts.

Urinary tract infection

Urinary tract infections (UTIs), especially asymptomatic bacteriuria and cystitis, are common pregnancy complications. Pyelonephritis is less common but has the potential to cause significant morbidity and adverse outcomes. Early identification and treatment of UTIs in pregnancy and post partum are crucial because of their close association with maternal hypertension, anaemia and preterm labour, making the fetus at risk of all the complications associated with low birthweight. The fetus is also at risk of IUGR. It seems that the bacterium that causes the UTI has the potential to infect fetal membranes, leading to chorioamnionitis. Finally, inadequately treated UTIs and upper tract infections such as pyelonephritis have a high incidence of later chronic renal pathology.

Traditionally, screening pregnant women's urine for glucose, ketones and protein at every antenatal visit has been a common practice. The gold standard for screening for asymptomatic bacteriuria is growing bacterial cultures of urine samples from women in early pregnancy. Contrary to popular belief, non-culture methods such as dipsticks are not generally reliable for the identification of bacteriuria in asymptomatic

Revision

Normal anatomical and physiological changes in pregnancy

The normal anatomical and physiological changes in pregnancy predispose the pregnant woman to UTIs and the reader may need to refresh their pre-existing knowledge by revising an appropriate textbook. In brief, starting in the first weeks of pregnancy, most pregnant women develop hydronephrosis of pregnancy. Under the influence of pregnancy hormones, increased bladder volume and decreased bladder tone, along with decreased ureteral tone, contribute to increased urinary stasis and ureterovesical reflux. This urine becomes a good growth medium for bacteria. Also, an increase in the plasma volume during pregnancy decreases urine concentration. More than two-thirds of pregnant women develop glycosuria, which encourages bacterial growth in the urine. Increases in urinary progestins and oestrogens reduce the ability of the lower urinary tract to resist pathogens.

populations, including pregnant women. Routine urinalysis is imprecise for identification of pyuria. Pyuria-based methods, particularly leucocyte-esterase dipstick, are subject to false negatives in bacteriuria without pyuria and false-positives with contamination from vaginal secretions. Nevertheless, many maternity centres require urinalysis at every antenatal consultation. If this is the case, women may prefer to test and interpret their own urine specimens for the presence of protein and nitrites or other evidence of infection. In addition to laboratory screening tests, it is important that the midwife gathers data about the woman's history of infections and existing renal pathology, renal function studies and family or personal history of renal disease, hypertension or connective tissue disorders.

Asymptomatic bacteriuria and cystitis

As many as 11% of pregnant women will develop asymptomatic bacteriuria and, as the name suggests, have no symptoms of a UTI. The prevalence is higher among women from lower socio-economic backgrounds and those with a history of asymptomatic urinary infection. Increased frequency of screening during pregnancy identifies more cases. Approximately 1–2% of women who are not bacteriuric at initial screening early in pregnancy will develop bacteriuria later in the pregnancy. Asymptomatic bacteriuria is significant if there are 10^5 organisms per mL of cultured urine. The usual organism responsible is *Escherichia coli* (over 90%). Other possible organisms include *Proteus mirabilis*, *Klebsiella pneumoniae*, *Staphylococcus saprophyticus*, *Pseudomonas aeruginosa* and the alpha-haemolytic or beta-haemolytic *Streptococcus*.

The choice of antibiotic should address the most common infecting organisms (i.e. Gram-negative gastrointestinal organisms such as *E. coli*). Historically, ampicillin has been the drug of choice, but in recent years *E. coli* has become increasingly resistant to ampicillin. Other antibiotics include nitrofurantoin, the cephalosporins, cefaclor or amoxicillin-clavulanate. Fosfomycin (Monurol) is taken as a single dose. Sulfonamides can be taken during the first and second trimesters, but during the third trimester their use carries a risk of kernicterus of the newborn, especially preterm infants. Tetracyclines are contraindicated for use in pregnancy because of rare maternal acute fatty liver necrosis. In addition, they cause permanent staining of the fetal dentition. A five- to 10-day course of antibiotic treatment is usually sufficient to eradicate the infecting organism(s). Some authorities have advocated shorter courses of treatment—even single-day therapy.

Symptomatic cystitis

A woman with symptomatic cystitis often complains of urgency and frequency of micturition and dysuria. She may have some lower abdominal discomfort and a slightly raised temperature and pulse rate. In general, treatment is initiated before the results of the culture are available. A midstream urine sample (MSU) is sent to the laboratory for a bacterial count, the leucocyte (pus) cell count and the identification of the organisms present and their sensitivity to several antibiotics. If the bacterial count is over 10^5 organisms per mL of urine, the woman is commenced on a broad-spectrum antibiotic (see above). Usually the infection is due to *E. coli*. Antibiotic choice, as in asymptomatic bacteriuria, should focus on coverage of the common pathogens and can be changed after the organism is identified and sensitivities are determined.

An increased intake (3000 mL) of oral fluids is encouraged. The woman is observed for any signs of the onset of labour, and fetal wellbeing assessed through CTG recording of the fetal heart rate. A repeat MSU should be obtained one to two weeks later and a further course of antibiotics prescribed if infection is still present. Women who present with more than

Research

A study of various tests to detect asymptomatic urinary tract infections in an obstetric population (Bachman et al 1993)

Bachman and colleagues compared the efficacy of faster, and usually less expensive, screening methods (e.g. dipstick, nitrite dipstick, urinalysis and urine Gram staining) with urine culture and found that although it was quicker and more cost-effective to screen for bacteriuria with dipsticks, less than half of the women with bacteriuria were identified compared with screening by urine culture. Further, the increased rate of false-negatives and the relatively poor predictive value of positive tests made the faster, albeit cheaper, methods less efficacious. The authors recommended that a urine culture be routinely used to screen for bacteriuria at the first antenatal visit and again in the third trimester.

BOX 33.20 Preventing UTIs

Midwives are ideally placed to work with women to prevent the initial occurrence of UTIs and ongoing problems. Measures include the following:

- Drink 6–8 glasses of water each day, to flush out bacteria. Unsweetened cranberry juice may prevent UTIs.
- Avoid refined foods, fruit juices, caffeine, alcohol and sugar.
- Develop a habit of urinating as soon as the need is felt, emptying the bladder completely.
- Wipe the perineum from front to back after voiding or defecation.
- Avoid using strong soaps, douches, antiseptic creams, feminine hygiene sprays and powder.
- Urinate before and after intercourse.
- Wear cotton underwear and avoid tight-fitting pants.
- Use lubricating jelly if needed during sexual intercourse.
- Report early signs of UTI or genital infection.
- Always complete a course of antibiotics.

three UTIs in the antenatal period require a renal physician consult and further investigation, and may be commenced on an antibiotic such as nitrofurantoin for the remainder of the pregnancy in addition to regular assessment.

Pyelonephritis

Acute pyelonephritis during pregnancy is a serious systemic illness that can progress to maternal sepsis, preterm labour and birth. It is defined as inflammation of one or both kidneys. Pyelonephritis occurs in 2% of pregnant women; almost a quarter of these have another episode of the disease in the same pregnancy. Infected urine is forced up through the ureters and infects the renal pelves and the kidney substance, causing pyleonephritis. The diagnosis is made when the presence of bacteriuria is accompanied by systemic symptoms or signs such as fever, chills, nausea, and vomiting and flank pain. The woman feels most unwell, has a high temperature, rapid pulse and shivering, and rigors may occur. Headaches, nausea and vomiting may also be present. Symptoms of lower tract infection (i.e. frequency and dysuria) may or may not be present.

Collaborative management

Early, aggressive treatment is important in preventing complications from pyelonephritis. Hospitalisation is not always necessary, although it is indicated for women who are exhibiting signs of sepsis, who are vomiting, perhaps dehydrated and who may be having uterine contractions. Intravenous antibiotic therapy (and IV fluids, if hospitalisation is required) may be initiated before obtaining the results of urine culture and sensitivity. Several antibiotic regimens may be used. The woman's vital signs are recorded four-hourly and she is observed for signs of the onset of labour. Fetal wellbeing is assessed through CTG recording of the fetal heart rate. Follow-up and repeat MSUs are undertaken to ensure the infection has been adequately treated. Other diagnostic tests may include renal ultrasonography or, if indicated, an abbreviated IV pyelogram. Even the low-dose radiation involved in an IV pyelogram may be dangerous to the fetus and therefore such tests should be avoided during pregnancy whenever possible. However, in the presence of recurrent pyelonephritis, an IV pyelogram may be necessary.

There are a number of non-pharmacological, 'natural' remedies for the prevention and treatment of UTIs:

- Urinary antiseptics are antimicrobial: uva ursi (*Arctostaphylos uva ursi*), buchu (*Agathosma betulina*), thyme leaf (*Thymus vulgaris*), pipissewa (*Chimaphila umbellata*).
- Urinary astringents tone and heal the urinary tract: horsetail (*Equisetum arvense*), plantain (*Plantago major*).
- Urinary demulcents soothe the inflamed urinary tract: corn silk (*Zea mays*), couch grass (*Agropyron repens*).

Clinical point

The most common reason for treatment failure in pyelonephritis is antibiotic resistance.

There has been little research and no well-controlled studies examining the effectiveness of homeopathic remedies in the treatment of UTIs. Qualified homeopaths, however, may recommend a range of treatments for UTI, based on their expertise and clinical experience. Before prescribing a remedy, homeopaths take into account the woman's constitutional type—physical, emotional, and intellectual make-up—before deciding on the most appropriate remedy for a particular individual.

- *Apis mellifica* or *Berberis*—for dysuria
- *Aconitum*—for early symptoms of UTI
- *Cantharis*—this is the most common and considered the most effective homeopathic remedy for UTI.
- *Mercurius* and *Nux vomica*—urgency and dysuria
- *Pulsatilla*—for bladder inflammation
- *Staphysagria*—for UTIs usually associated with sexual intercourse or sexual abuse.

Obstetric cholestasis (intrahepatic cholestasis)

Obstetric cholestasis is a rare liver disease characterised by itching and abnormal liver function tests (Coombes 2000). The itching initially is in the palms of the hands and the soles of the feet and there is no rash. It commences in the last 12 weeks of pregnancy and increases in severity, spreading and becoming more centralised and more distressing as the pregnancy progresses, especially at night (Coombes 2000). Other symptoms may be dark urine, pale stools and/or jaundice. The term 'cholestasis' refers to the diminished secretion of bile formed by the liver to the intestines. Bile accumulates in the bloodstream and may cause itching. The cause is unknown but it is thought that the high levels of circulating oestrogen in pregnancy may cause the reduction in the flow of bile (Turner 2000). Fat-soluble vitamins such as vitamin K are not absorbed, resulting in increased risk of PPH and fetal intracranial haemorrhage. In addition the fetus of a woman with cholestasis is at risk of premature birth, meconium aspiration, intrauterine death, stillbirth and non-reassuring fetal heart tracings.

Diagnosis is made by a history of itching in the presence of abnormal bile acid (salts) test results. Liver function tests may be normal. The woman with obstetric cholestasis requires close monitoring of herself and her fetus. This includes regular CTG recordings, fortnightly ultrasound assessment for growth, weekly liquor and Doppler placental function scans and weekly blood tests. Rest and a good diet are encouraged. Associated UTIs are common. For her comfort the woman is advised to have frequent cool baths, to use skin lotions to soothe the itch and to wear loose-fitting cotton clothing. Ursodeoxycholic acid (Urso) improves the itching and normalises biochemistry. Dexamethasone and vitamin K administration are also helpful. Labour is induced at about 37 weeks to avoid an increased risk of stillbirth (Kenyon et al 2002). Itching resolves during in the first two postnatal weeks (Turner 2000). The woman should be warned that oral contraceptives can cause a similar condition and

that obstetric cholestasis is likely to recur in subsequent pregnancies.

Epilepsy

While most women with seizure disorders find that pregnancy has no effect on their disease, about one-third will have an increase in seizure activity. Epilepsy is a disease of the central nervous system resulting in convulsive seizures accompanied by paroxysmal cerebral dysrhythmia, followed by a period of unconsciousness. Women of childbearing age who have epilepsy have many concerns about how their epilepsy will affect their chances of having a baby. They want to know how anti-convulsive medications will affect them in pregnancy and their unborn child. Epilepsy imposes special risks for pregnancy and the woman and the clinicians who support her should be aware of these. Ideally, planning for a baby begins well before conception, so the woman and her clinical team can work together to keep the mother healthy and give her a very good chance of delivering a normal, healthy baby.

Risks to pregnancy

During pregnancy, the number of seizures may increase or decrease or remain unchanged. About 50% of pregnant women have no change in the number of seizures during pregnancy. Many women experience an increase in seizure frequency because they have changed or reduced the amount of anti-convulsive medication they take. Therefore, whenever possible, the anticonvulsant medication the woman has been prescribed prior to becoming pregnant should be maintained, though the dosage may require adjusting later in the pregnancy. Nevertheless, anti-epileptic medications pose significant risks for the fetus.

Risks to the mother and fetus

Reports of congenital malformations associated with anti-epileptic drugs (AEDs) are well documented. Unique malformations are associated with many of the commonly prescribed AEDs: phenytoin, phenobarbitone, primidone, valproate, carbamazepine and trimethadione. Children born to women with epilepsy are, on average, smaller in size and weight than those children born to women who do not have epilepsy. The reasons for this discrepancy are not clear. However, there is some evidence that the increased incidence of growth disparities and congenital malformations in babies of mothers with epilepsy occurs even without AED use.

Types of fetal malformation when the mother has epilepsy include microcephaly, slowed growth and impaired intellect. Certain other abnormalities, such as cleft lip, cleft palate, heart abnormalities and spina bifida, are seen more frequently in children born to mothers on AEDs. Less serious fetal abnormalities include ptosis, decreased muscle tone, hernias and talipes.

The mother's seizures represent the single largest risk to the fetus because it is deprived of oxygen during the seizure. Rarely, the fetus may be injured if the mother falls, is involved in a motor vehicle accident or injures herself during a seizure. Therefore the goal during pregnancy should be to prevent all seizures. There is still considerable controversy about the use of AEDs in pregnancy, which drugs to use and the associated risks to the fetus. In general, since the risk from the drugs is very small, having a seizure during pregnancy is much more dangerous to the fetus than the dangers associated with anti-epileptic medications. Therefore, if the risk for recurrent seizures is high then medication should still be used. However, in women at low risk of seizure, before becoming pregnant it may be possible for the woman to decrease pharmacotherapy or to taper the dosages of AEDs. Though it might appear that the ideal situation would be to stop AEDs, for most women this is not a realistic option. In the twenty-first century, the potential disruption of the woman's lifestyle by seizures, such as the risk of loss of driver's licence, makes elimination of AEDs impractical. Just as importantly, maternal seizures increase the risk of injury, miscarriage, epilepsy in the offspring and children's developmental delay.

Collaborative management

All women diagnosed with epilepsy or other neurological disorders causing seizures and wanting to have a baby require an expert, multidisciplinary team who work collaboratively with the woman to provide her and the baby with quality care.

Preconceptual care

The woman should be supported in ways that ensure that her pregnancies are planned, and so it is crucial that she has access to and uses effective contraception. Combined pill regimens are required by women on enzyme-inducing anticonvulsants (carbamazepine, phenytoin, primidone, phenobartitone) because these drugs reduce the effectiveness of oral contraceptives. All women should be offered genetic counselling. Pre-pregnancy discussions should include information about the risks to mother and fetus as well as the need for modification of her AED regimen to reduce the number of drugs and total dose. Anticonvulsant drugs may result in folic acid deficiency, so the woman is advised to take oral folic acid 5 mg daily for the first three months of pregnancy.

The following is a checklist for preconceptual discussion:

- Find out what the woman knows and fill in the gaps.
- Discuss the diagnosis and its implications for childbearing.
- Review seizure frequency and severity.

Clinical point

More than 95% of pregnant women with epilepsy give birth to normal, healthy babies. Women should be reassured that the risk of fetal malformations associated with epilepsy and associated medications is very small. Other serious diseases represent a much higher risk for fetal deformity than epilepsy. For example, diabetic women deliver, on average, 92 healthy babies out of 100.

- Consider use of a seizure diary.
- Discuss drugs—benefits, disadvantages, modifications and side-effects.
- Discuss the impact of pregnancy on the woman and her family's lifestyle.
- Provide addresses of support organisations.
- Discuss contraception and pregnancy with the woman.
- Agree on a timetable for follow-up support.

Pregnancy

The woman is offered serum screening at 16 weeks and at least one detailed ultrasound (by an appropriately skilled sonographer) at 11–13 weeks and then again between 18 and 22 weeks. It may be necessary to adjust the anticonvulsant regimen. For women on enzyme-inducing anticonvulsants, the risk to the baby of haemorrhagic disease of the newborn is increased, so vitamin K 10–20 mg daily may be administered to the woman from 36 weeks until delivery. Excessive weight gain due to fluid retention during pregnancy may exacerbate seizure activity and so the woman will need advice about how to manage her weight gain.

Intrapartum care

The usual anticonvulsant regimen is maintained during labour. The same range of analgesia (including epidural) available to other mothers should be available. Early recourse to caesarean section under general anaesthesia may be necessary if it is not possible to control seizures, which often occur during labour. Where possible, a paediatrician should review the baby to exclude the possibility of rare congenital malformations secondary to the teratogenic effects of anticonvulsants.

Postpartum care

Anticonvulsant drugs also cross the placenta and the neonate may develop withdrawal symptoms. As the risk to the baby of haemorrhagic disease of the newborn is increased, vitamin K is administered to the infant immediately after birth. Midwives should support and encourage breastfeeding, and provide advice about safe and suitable settings for feeding, bathing, and so on. Before discharge it is important to review AEDs and contraceptive regimens and to reiterate the need for pre-conceptual care for future pregnancies.

Management of seizures

In the community or in hospital, for patients with generalised tonic-clonic seizures, the following general guidelines should be followed:

- Secure the airway.
- Call for help—midwives, anaesthesiologists, obstetrician, physician and paediatrician.
- Give oxygen.
- Assess cardiac and respiratory function.
- Secure IV access in large veins.
- Manage seizures acutely with IV benzodiazepines (10 mg of diazepam or lorazepam 4 mg IV), then load phenytoin (1 g loaded over one hour). If there is a delay in gaining IV access, give diazepam 10–20 mg rectally.
- Assess the fetal heart rate or fetal status.
- Rule out eclampsia.

On admission to hospital, care may include the following:

- Collect blood for full blood count, urea and electrolyte, liver function tests, calcium, glucose, clotting, AED levels and storage for later analysis.
- Check fetal status. A non-reassuring heart rate trace may indicate an emergency caesarean section.
- Measure blood gases to assess extent of acidosis.
- Establish aetiology. Give 50 mL 50% glucose IV if there is any suggestion of hypoglycaemia and IV thiamine (given as Pabrinex two pairs of ampoules) if there is any suggestion of alcohol abuse or impaired nutritional status.

If the seizures persist (status epilepticus), the woman is:

- admitted to an intensive care unit (ICU) and administered general anaesthesia
- monitored using EEG to assess seizure control
- referred for specialist advice.

Thromboembolic disease

Venous thromboembolic (VTE) disease causing deep vein thrombosis and pulmonary embolism is a major cause of maternal mortality in Australia, the United Kingdom and the United States, occurring at a rate of approximately one death per 100 000 maternities (Obstetric Medicine Group of Australasia 2001). The rate is much higher in older women. In the United Kingdom, women aged over 39 years had a mortality rate of one death per 3300 pregnancies (Obstetric Medicine Group of Australasia 2001). Pulmonary thromboembolism (PTE) is also a leading cause of maternal mortality in Australia (Slaytor et al 2004). There were six deaths out of a total of 90 mortalities in the 1997–1999 triumvirate in which PTE was judged to be the principal cause of death. All six were classified as Direct Maternal Deaths. In their report, Slaytor et al (2004, p 26) comment that based on a preliminary analysis of hospital discharge data from 1997–1999 it is likely that there were 500–600 cases of pulmonary embolism associated with pregnancy and the post partum.

Pathology

The development of venous thromboembolism (VTE) requires the compounding effect of three factors, often referred to as Virchow's triad, after the scientist who first described these aetiological associations in relation to VTE 150 years ago. The basis of the triad is stasis, vessel trauma, and hypercoagulability. Progesterone-mediated changes in the blood vessels causes stasis of the venous blood flow, resulting in pooling of blood. Compression of the pelvic blood vessels compounds this physiological change. Damaged endothelium may be caused by direct trauma, such as during birth via caesarean section, infections of surrounding soft tissue, IV catheters or prolonged use of them. The trauma releases platelet-activating factors, initiating the coagulation cascade, which results in platelet adhesion to the blood vessel wall and the beginning of thrombus formation. Thirdly, clotting

WOMAN'S STORY

From *Living with Epilepsy*, by Julie Dennison

Here is one of the many talks I have given on my personal experiences with epilepsy. This was to the staff at the Epilepsy Centre of the National Society for Epilepsy.

So you want children! What a wonderful way to seal a relationship. Is it always possible to do this? Not in all cases. There are many illnesses where pregnancy is thought to be too dangerous and very unwise. So what about epilepsy?

Is it possible to give birth? And do you pass on the gene that says: 'You will have epilepsy and have the same problems as your parents'? Perhaps, perhaps not. No-one can be sure. Epilepsy is not always hereditary. Just in some cases. I was lucky.

Despite family members trying to get me to adopt children, I went ahead and had children of my own. As there was no history of epilepsy in my family—I was just unlucky to be born with it—the doctors seemed to think that all would be well. So we went ahead.

All medication had to be stopped on the doctor's advice. I put on a lot of weight. . . . The seizures were occurring so frequently that everything became difficult. I was lucky, though, as friends and local children were a great help. The local shop was only just down the road, a mere few minutes away, but that walk became a major trip. People would walk with one on either side of me.

. . . So let's get to the practical side of things. Before cooking, I prepared most of the food in the dining room, rather than the kitchen. If I did have a fall, it would be onto a carpet rather than a concrete floor. This would be safer for me as well as my unborn child.

Getting upstairs? Well, I would walk upstairs sideways and slide downstairs, step by step, on my bottom. This was the safest way to travel.

The side door of the house was always left open in the summer. This was so that my neighbours could hear the noise I would make when a seizure took place. . . . I was even having seizures in my sleep. There seemed to be no escape. Most of my life was lived indoors whilst I was pregnant. . . .

The next stage was the birth. Once again it was hard work. . . . Then an eight pound, twelve ounce baby boy was born, measuring twenty-three and a half inches long. He was beautiful, and within less than a few months he had been declared free of epilepsy. All that stuff I had been told about my children being less than perfect was just sheer and utter rubbish. My baby was fine: No illness, no disease no nothing.

[At home] the rules, regulations and just simple common sense had to apply. I had a life in my hands. So how did I cope? When the babies (we had another boy 18 months later) were small, night feeds were always done by my husband. He knew that to get through the day safely I had to have rest, so he had a day job then had to come home to a not very restful night! One thing about a relationship is that it's a partnership. . . .

We had an electric bottle warmer . . . so I didn't have to go near a gas stove. [We bought a microwave to heat the baby feeds.] . . . Feeding time was difficult. It was too dangerous to put my baby in my arms and feed him. I had no warning of my seizures so anything could happen. So I used to feed my son in his buggy. I would kneel beside the buggy and lean backwards with my arm outstretched as far as possible. If I did have a fall I would fall backwards, and not on my young child. . . .

Bathing my baby could only be done with someone else in the house. . . . I always took part in the little things, and these meant so much to me. Changing my baby was very similar to feeding; kneeling down on the floor beside my baby, and if possible leaning away from him. . . .

As the babies got older they wanted to crawl. But I couldn't let them crawl freely. I used to put them in a playpen with their favourite toys. My absences were occurring at a rate of about 20 to 30 every day. They didn't last long, but each was long enough to cause a tragedy. . . . I regret I could never take my boys to playschool or primary school. It was too dangerous, so someone would take them for me and I would watch from the window. Every detail of our lives had to be discussed and thought out very carefully.

The children were told at a very young age about their Mum's problems. They had to be, so they would be prepared. I think we told them in simple terms that Mum would fall down from time to time, or she would blank out and may not hear what they were saying. It was difficult to explain to them without putting them in a panic, but the best way is simple honesty. Children accept things far easier than many people think.

From a very early age, they were able to get help. They were too small to do first aid, but by getting help they were on the right track. . . . Once I burnt myself with an iron. I have had many falls on concrete floors resulting in broken and cracked ribs, cuts, bruising and sprains. . . .

My children, who are now 16 and 18 respectively, still care and each is there like a coiled spring every time I make an involuntary movement. They tell their friends, and none of them seem to worry. They take me for what I am and, like myself, they raise a smile when a blackout occurs. It is the only way to cope.

(Source: Dennison 2004)

factors alter during pregnancy. There are increased levels of Factor V and VIII and fibrinogen, acquired resistance to activated protein C (an endogenous anticoagulant) and a reduction of its co-factor, protein S. Increased inhibitors of plasminogen activator result in impaired fibrinolysis. In addition, hypercoagulability of blood may be caused by other

haematological conditions such as anaemia or infectious disease (pneumonia) or as a secondary complication to renal disease, hypercoagulable medications and oral contraceptives. Drife (2003) makes the very important point that compared to the non-pregnant population, there is a twelve-fold increased risk of thromboembolism in pregnant women. In contrast, oral contraceptives increase the risk of thromboembolism three-fold. However, the risk of thromboembolism associated with the Pill is better known than the risks associated with pregnancy. Drife (2003) argues that it is regrettable that such misconceptions are helping to restrict the availability of oral contraceptives to women in developing countries, where deaths from repeated unplanned childbirths are a more significant cause of maternal mortality.

Risks for venous thromboembolism

Pregnancy is a risk factor for VTE and has a ten-fold increase in risk in comparison to non-pregnant women (RCOG 2004). The risk is even higher if delivery is by caesarean section, especially if it is an emergency procedure. Although it is associated with high degrees of morbidity and mortality, VTE during pregnancy and the immediate postnatal period is rare. A Cochrane Review identified the best estimate of incidence as 0.13%; however, other estimates varying from 0.06% to 0.11% have been published. Women particularly at risk of thromboembolic disease include those over 35 years of age, women who have undergone an operative delivery including unplanned caesarean section, immobility, maternal weight over 80 kg, women with significant medical disorders such as heart disease or previous thromboembolic disorders, women with infection, high parity and women with a diagnosis of pre-eclampsia. Recently a number of congenital thrombophilias have been discovered; the most common abnormality underlying VTE is Factor V Leiden (activated protein C resistance) and thrombophilias also associated with deficiencies in protein C and protein S. Antithrombin III deficiency is the rarest but carries the highest thrombogenic risk. Pregnant women with these thrombophilias are at significant risk of VTE.

Diagnosis

Diagnosis depends first and foremost on an awareness of the condition. Successive reports for the United Kingdom (*Ministry of Health Confidential Enquiries: Why Mothers Die*) have included case studies of women whose care providers failed to recognise the classic symptoms even when risk factors such as obesity or a family history of VTE are present.

Prophylaxis

The Obstetric Medicine Group of Australasia (2001) stresses that VTE can occur at any time during pregnancy; its prevalence is approximately equally distributed between the three trimesters. Although two-thirds occur during pregnancy, the day-by-day risk is greatest in the first weeks after birth. Major known risk factors for VTE in pregnancy have been identified. These risk factors often coexist and reinforce each other (Obstetric Medicine Group of Australasia 2001). The Royal College of Obstetricians and Gynaecologists (2004) recommends that although the efficacy or benefit of the following recommendations is unknown, no high-grade evidence is available:

- all 'at-risk' women should be monitored for symptoms and signs of VTE during the first week post partum

Research

Prophylaxis for venous thromboembolic disease in pregnancy and the early postnatal period (Cochrane Review) (Gates et al 2005)

Background: Venous thromboembolic disease, although very rare, is a major cause of maternal mortality and morbidity, hence methods of prophylaxis are often used for women at risk. This may include women delivered by caesarean section, those with a personal or family history of VTE and women with inherited or acquired thrombophilias. Many methods of prophylaxis carry a risk of side-effects, and as the risk of thromboembolic disease is low, it is possible that the benefits of thromboprophylaxis may be outweighed by harm. Current guidelines for clinical practice are based on expert opinion only, rather than high-quality evidence from randomised trials.

Objectives: To determine the effects of thromboprophylaxis in association with pregnancy in women who are pregnant or have recently delivered on the incidence of venous thromboembolic disease and side-effects.

Main results: Eight trials involving 649 women were included in the review. Four compared methods of antenatal prophylaxis; low molecular weight versus unfractionated heparin (two studies), aspirin plus heparin versus aspirin alone (one study), and unfractionated heparin versus no treatment (one study). Four studies assessed postnatal prophylaxis after caesarean section; one compared hydroxyethyl starch with unfractionated heparin, two compared heparin with placebo (one low molecular weight heparin, one unfractionated heparin) and the other compared unfractionated heparin with low molecular weight heparin. It was not possible to assess the effects of any of these interventions on most outcomes, especially rare outcomes such as death, thromboembolic disease and osteoporosis, because of small sample sizes and the small number of trials making the same comparisons.

Authors' conclusions: There is not enough evidence to show which are the best ways to prevent DVT around pregnancy, after a caesarean or in the early postnatal period. Large-scale randomised trials of currently used interventions should be conducted.

- hydration should be maintained and early mobilisation encouraged
- graduated compression stockings with or without calf stimulation should be used during and after Caesarean section in women at moderate risk (one or two risk factors)
- in women at high risk (three or more risk factors), LMWH or unfractionated heparin prophylaxis should be used and continued for at least five days.

Deep vein thrombosis

Deep vein thrombosis (DVT) or thrombophlebitis/phlebothrombosis is seen more frequently in women with a history of venous thrombosis. In more than 70% of cases the thrombosis is in the iliofemoral veins, which are more likely to embolise (Greer 1999). There is clot formation in the deep veins of the leg, typically the calf or femoral veins, or occasionally the iliac veins. With a DVT the woman usually complains of pain or swelling (usually the left leg). Features such as immobilisation, asymmetric calf swelling (> 3 cm difference in calf circumference measured 10 cm below the tibial tuberosity) or swelling of the entire leg are the most reliable signs. At worst, the entire affected leg may be white, cold and oedematous. This rare condition is known as *phlegmasia alba dolens*. DVT can occur at any time during pregnancy. Diagnosis can be difficult. A positive Homans' sign (pain on dorsiflexion of the foot) is not a reliable diagnostic sign.

The gold standard for diagnosis of DVT has been contrast venography but this is invasive. Doppler ultrasonography is now the most widely used modality for evaluating patients with suspected DVT. When used in combination with a clinical prediction 'rule', ultrasound examination is accurate in predicting the need for anticoagulation therapy. However, a normal ultrasound study in a 'high-risk' woman requires additional investigation before DVT can be ruled out. Colour duplex ultrasonography allows direct visualisation of the deep veins and detection of venous flow. It is non-invasive, safe and readily repeatable. Ultrasound assessment has several limitations: its accuracy depends on the operator; it cannot distinguish between old and new thrombi; and it is not accurate in detecting DVT in the pelvic veins or the small vessels of the calf, or in the presence of morbid obesity or significant oedema. Diagnosis of DVT is based on:

- failure of the vein to compress
- presence of a thrombus
- absence of venous flow augmentation during compression of the calf.
- non-compressibility of the vein—this is the most sensitive and specific feature of proximal DVT (> 95%).

Magnetic resonance venography (MRI) is a relatively new technique with a sensitivity and specificity > 90% for DVT. It is not a routine test, as it is expensive and not widely available. Nevertheless, it is potentially useful in diagnosing DVT involving the pelvis, abdomen and upper extremities. MRI appears to be at least as sensitive as ultrasonography in detecting calf and pelvic DVTs because these thromboses are so difficult to compress with ultrasonography and hard to visualise with venography.

Management

Once a diagnosis is made, the woman is commenced on heparin to prevent further clotting. During labour, heparin should be given in a thromboprophylactic dose, returning to a therapeutic dose after the birth. Heparin dosage is based on estimations of the APTT, international normalised ratio (INR) and prothrombin times (Jilma et al 2003). LMWH is

Clinical point

Midwives are well placed to support women requiring management of DVT at home. All aspects of the management plan must be clearly defined for the woman, her family, and her caregivers, including the family's GP. Ideally, the plan should be individualised from a standardised protocol and written in consultation with the woman and her team of medical and midwifery professionals experienced in the treatment of DVT. Each medical facility will need a protocol that fits its own practice patterns as well as the unique needs of the woman, who may be pregnant or have a newborn baby to care for as well. It is important that hospital-based and community-based team members (including the woman) work together to adopt the management plan so that it ensures consistent, seamless transition from acute care to the home-care setting. The guidelines should include criteria for anticoagulant therapy, patient and caregiver education, and type and frequency of monitoring.

Multidisciplinary teamwork is essential and follow-up care is crucial. Monitoring community-based treatment of DVT should include tracking for compliance, subcutaneous injection technique, local adverse effects from the injections, signs of bleeding, signs of recurrent thrombosis, and initiation and monitoring of warfarin therapy. Much of this can be done on an outpatient basis by midwives or nurses specialised in anticoagulation therapy. Initially they will need to visit the woman daily for the first weeks of treatment.

Critical thinking exercise

Barbara (G4P3), aged 40 years, had an emergency caesarean section for prolonged labour two days ago. As she walks to the nursery to see her baby for the first time, you notice that she is limping. Barbara laughs and tells you she is sore all over but her left leg is really sore.

What will you do? And what will you say to Barbara?

preferred because it is simpler to administer and the woman can be taught how to self-inject. Warfarin may be commenced after birth in combination for about three months. The woman wears anti-embolic stockings and is usually on bed rest until the swelling has reduced and the anticoagulant therapy is beginning to take effect. She often requires analgesics and will need physiotherapy.

Pulmonary thromboembolism

Pulmonary thromboembolism (PTE) is more common in the postnatal period than in pregnancy. The signs and symptoms of PTE are non-specific and so the clinical recognition of PTE is notoriously inaccurate. The lack of sensitivity of the clinical diagnosis of PTE is evident from postmortem studies demonstrating that most cases of PTE detected post mortem were not diagnosed (or treated) prior to death. Shortness of breath and rapid respirations accompanied by leg or chest pain with cyanosis are the most common symptoms, although a cardiac arrest may also be the first indication. Frothy, bloodstained sputum may also be apparent. To confirm the diagnosis, the woman requires blood gases, a chest X-ray, electrocardiogram and a ventilation-perfusion (V/Q) scan of the lungs. If the V/Q scan shows low or intermediate probability of a PTE, a pulmonary angiography is indicated.

Any woman with a suspected PTE requires hospitalisation, anticoagulation and supportive care in consultation with an obstetrician and a physician. Supplemental oxygen should be provided to reverse hypoxia and maintain a PaO_2 of more than 60 mmHg. Intubation may be required to maintain adequate fetal oxygenation (i.e. PaO_2 of < 60 mmHg) or for uncontrolled rising maternal $PaCO_2$. Fluid resuscitation and pressors such as dopamine may be used to maintain adequate blood pressure (systolic pressure > 80 mmHg), but there is a significant risk that uterine blood flow may be compromised. Narcotic analgesics should not be withheld. Only women with life-threatening manifestations of PTE should be treated with a fibrinolytic agent such as tissue plasminogen activator, since as yet there are currently no data on the risk of placental abruption or potential injury to the fetus. These agents are contraindicated post partum. Emergency thoracotomy and embolectomy may be beneficial as a last-ditch effort for critically ill patients.

Case study

Pulmonary embolism with bilateral DVT

A 29-year-old woman (para 0) weighing 79 kg had a spontaneous onset of labour at 41 weeks gestation. An emergency Caesarean was performed for non-progression of labour, despite oxytocin augmentation and an epidural. There were no operative difficulties. On day two, she suddenly collapsed with dyspnoea and rapidly deteriorated. Resuscitation was not successful. There were no other apparent risk factors for thromboembolism.

(Source: Slaytor et al 2004, pp 25–26)

Once the woman's condition has been stabilised, anticoagulation treatment to prevent further clot formation is commenced with heparin (Jilma et al 2003). Dosage is based on regular estimation of APTT, INR and prothrombin times. Medication is later changed to warfarin with regular prothrombin times taken, and continued for at least three months (Jilma et al 2003).

Infections

Like every other person in society, pregnant women are at risk of viral and bacterial infections. Infections are a particular concern during pregnancy because some infections increase the chance that problems will occur in the fetus or newborn, or are more severe in pregnant women. Of specific interest in this chapter are genital infections that complicate pregnancy. Other common infections are described briefly in the following sections but we place most of our focus on the diseases caused by Group B Streptococcus (GBS) in part because of its potentially catastrophic effects on the fetus but also because of the controversies surrounding the issue of screening for GBS infection.

Listeriosis

Listeriosis is a notifiable disease and a form of food poisoning caused by the bacterium *Listeria monocytogenes*, a Gram-positive, aerobic, motile bacillus with aerobic and facultative anaerobic characteristics. The organism is found in soil and water and can be carried by animals that do not appear ill, leading to contamination of food of animal origin such as meat and dairy products. Unpasteurised raw milks or foods are also sources of *Listeria* organisms.

Pregnant women are about 20 times more likely than other healthy adults to get listeriosis. The real incidence is not known, as listeriosis is an uncommonly diagnosed infection (FSANZ 1999). In Australia the number of cases of listeriosis reported averages about 50 to 70 per year (FSANZ 1999). While there have been many reported outbreaks of this disease overseas, there have been few reported in Australia and New Zealand. In Western Australia in 1990 there were six stillbirths reported in a cluster of nine cases. The implicated food was a particular brand of pâté. In New Zealand in 1992, the perinatal death of twins was linked to the mother consuming contaminated smoked mussels during her pregnancy (FSANZ 1999).

Listeriosis is difficult to diagnose. Pregnant women with listeriosis are often asymptomatic, or they may have a febrile illness similar to influenza with symptoms of fever, muscle aches and, sometimes, nausea or diarrhoea during the

Critical thinking exercise

How would you answer the following question? 'Should I get a flu shot now that I am pregnant, or should I wait until the pregnancy is a bit more advanced?'

bacteraemic phase of the disease. Although the symptoms may be mild, listeriosis can still lead to preterm birth, neonatal sepsis or even stillbirth. In neonates, the mortality rate is approximately 50%.

Prevention

According to the FSANZ (1999), it is not possible to prevent raw food from becoming contaminated with *Listeria*. However, it is easy to make food safe to eat. Freshly prepared food is safe, as the bacteria have not had a chance to grow in the food. However, raw fruit and vegetables should be washed thoroughly before eating. Listeria is also destroyed during normal cooking, so freshly cooked food is safe. If it has been more than 12 hours since a perishable food such as salad or meat has been prepared, it should not be eaten, as *Listeria* can grow on these foods, even in the refrigerator.

It is vital that pregnant women eat healthily during pregnancy, choosing from a wide variety of foods including vegetables, fruit, dairy foods, bread, cereals, pasta, lean meat, fish, eggs and nuts. To guard against listeriosis, pregnant women should avoid eating:

- certain refrigerated ready-to-eat food that has not been freshly cooked or prepared. This includes cold meats, salads, soft cheeses and pâté.
- raw meats, raw seafood and unpasteurised milk.

Treatment

Treatment is usually with antibiotics—penicillin or amoxyl/ampicillin either alone or in combination with trimethoprim and sulfamethoxazole. For penicillin-sensitive women, trimethoprim and sulfamethoxazole may be used alone.

Sexually transmitted infections

There are more than 50 sexually transmitted infections (STIs) and numerous other genitourinary infections that have the potential to affect the health and wellbeing of the woman, her partner and the unborn baby. Some STIs, such as genital herpes, chlamydia and bacterial vaginosis, are quite common in pregnant women. In Australia and New Zealand, other STIs, notably HIV and syphilis, are much less common. However, in some areas such as the Kimberley of northern Australia, syphilis is increasingly common. Early diagnosis and treatment are extremely important for preventing the effects of the disease on pregnant women and their infants.

Clinical point

Listeria infection is usually asymptomatic. Accurate clinical diagnosis is difficult in most cases. Minor illnesses in pregnancy do not warrant speculative treatment with antibiotics because of concern over listeriosis. The main protection against *Listeria* infection is through careful attention to food preparation and storage and to personal hygiene.

Genital herpes

Infection with genital herpes simplex virus Type 2 (HSV-2) is a major reproductive health problem. Transmission occurs through direct, intimate, oral–genital or genital–genital contact. The first episode is called the initial or primary infection, and it is at this stage that some virus retreats to the nerve ganglia. Subsequent episodes, known as recurrences, occur if and when the virus replicates in the ganglion, releasing virus particles that travel along the nerve back to the site of the initial infection. Typically, lesions appear 2–14 days after exposure. Without antiviral therapy, the lesions usually last for 20 days. For most people, the first indication of infection starts 2–12 days after exposure to the virus. The development of symptoms may take longer or be less severe in some people, especially those who have previously developed partial immunity to the virus, perhaps having a Type-1 infection (e.g. cold sores). Antibody response occurs three to four weeks after the infection and is lifelong. However, unlike protective antibodies to other viruses, antibodies to HSV-2 do not prevent local recurrence(s) and so HSV-2 becomes a chronic infection characterised by periods of remission and exacerbation. The symptoms associated with local recurrences tend to be milder than those occurring with the primary disease.

Symptoms associated with primary infections are both local and systemic, although more than 75% of people with a primary HSV-2 infection are asymptomatic and these are responsible for many neonatal HSV infections. Local symptoms include intense pain, dysuria, occasional itching, vaginal discharge and, commonly, lymphadenopathy. Systemic

symptoms are due to viraemia and include fever, headache, nausea, malaise and myalgia. Women particularly often experience pain on urinating, and when this happens, it is important to avoid problems of urinary retention by drinking plenty of fluids to dilute the urine and thereby reduce pain and stinging. Some women may also notice vaginal discharge. Not everyone experiences symptomatic recurrences but of those that do, recurrences are usually shorter and less severe than the initial episode.

Diagnosis

In order to confirm a diagnosis of genital herpes simplex virus (HSV) infection, it is necessary to prove the presence of HSV. Detection of HSV antibodies in the bloodstream is not sufficient because this cannot define the site of HSV infection. Laboratory analysis is usually made either by virus culture (where the virus is grown in material known as a culture medium) or by antigen detection, where components of the virus are specifically identified.

Pregnancy and HSV-2

Women with HSV-2 can experience a safe pregnancy and normal vaginal childbirth. This is especially so when the diagnosis is made prior to becoming pregnant. If she already has a history of genital herpes, the woman's antibodies will protect the fetus from an infection during pregnancy and the neonatal period. Recurrent genital herpes presents only a minimal risk in pregnancy, though it may interfere with the woman's enjoyment of pregnancy. However, the fetus may be at risk when the woman has:

- a severe primary infective episode during the first trimester, which can lead to miscarriage. This is a very uncommon complication and it is important to reassure the woman that this hazard is also present with a number of other viral infections, including the flu.
- a primary episode of HSV-2 in the last trimester of pregnancy, because there are large amounts of circulating virus present and insufficient time for the mother to produce enough antibodies to protect the fetus. Transmission of virus to the fetus causes neonatal herpes, a potentially fatal but rare condition. Careful monitoring, judicious use of antiviral therapy and/or caesarean delivery in the presence of an active lesion can reduce the risk to the baby.

Care during pregnancy

It is important that a pregnant woman informs her lead carer if either she or her partner has genital herpes. In the third trimester, regular checks should be made and the woman and her caregiver can discuss the best option for giving birth, including a caesarean section or the use of antiviral drugs. Other than this, the pregnant woman should simply observe the normal guidelines for healthy pregnancy as closely as possible. Good nutrition and rest are even more important at this time.

Acyclovir treatment of HSV-2 can significantly reduce morbidity in the mother and potentially in the infant. It is, however, not recommended in pregnancy, although there is no evidence of adverse fetal effects. Its use should be considered when it is judged that its benefits outweigh the risks. After birth, specimens for viral culture should be collected from the baby for early identification of infection. If cultures are positive, acyclovir treatment of the neonate is advised. Parents should be advised to report early signs of perinatal HSV-2 infection (lethargy, fever, poor feeding or lesions). Breastfeeding is recommended unless the mother has lesions around the nipples. Acyclovir is excreted in breast milk but its use is not contraindicated as it does not appear to harm the infant.

Chlamydia

Chlamydia is the most common STI in Australia and New Zealand, especially among young people. In Australia, chlamydial notifications have increased four-fold over the past decade (Chen et al 2003). However, as most infections are asymptomatic, the 26,000 cases reported in 2002 probably represent only a fraction of the true incidence and prevalence (Chen et al 2003). Infection with *Chlamydia trachomatis* has become a major public health problem because of the long-term consequences of infection experienced predominantly by women. These include chronic pelvic pain, ectopic pregnancy and infertility. Rarely, males may also become infertile.

Chlamydia trachomatis is an obligate intracellular parasite. Once considered a virus, it is now classified as a bacterium, based on its sensitivity to antibiotics and its reproduction cycle. According to Chen et al (2003), although chlamydia can easily be treated and cured, it can have dire consequences if left untreated: 40% will develop pelvic inflammatory disease (PID). Of these women, 20% will become infertile; 18% will develop chronic pelvic pain, and 9% will have potentially life-threatening tubal pregnancy. More than two-thirds of women with chlamydia are asymptomatic.

Screening

Consensus has not been reached on the optimal time for screening for chlamydia or even whether it should be a 'routine' screening test. Screening early in pregnancy increases the opportunity to improve the pregnancy outcome, whereas screening in the third trimester prevents transmission to the infant. Testing women at high risk of chlamydial infection is, however, recommended. High-risk individuals include those with a clinical presentation suggestive of chlamydial infection, individuals attending GPs for testing of STI, those attending STI and family planning clinics, gay men's health centres and the partners of those already diagnosed with an STI.

Laboratory investigations currently available are:

- cell culture (only in specialised laboratories)
- antigen assays, including direct immunofluorescence or enzyme immunoassay
- hybridisation assays such as the DNA probe
- amplification assays including polymerase chain reaction (PCR) and ligase chain reaction (LCR).

Treatment

In asymptomatic women with positive culture findings and in symptomatic women, erythromycin, amoxicillin, clindamycin and azithromycin are all used to treat chlamydia.

Clinical point

Treatment of male sex partners of women with bacterial vaginosis has not resulted in improved cure rates or a reduced rate of recurrence.

Bacterial vaginosis

With bacterial vaginosis, the population of normal lactobacilli is decreased, with resultant overgrowth of other organisms, including *Gardnerella vaginalis*, *Mobiluncus* and anaerobes. The dominant commensal found in the vagina is *Lactobacillus*, and the constitution of vaginal flora is altered by the pH of the vagina. Bacterial vaginosis is associated with an increased risk of several pathological conditions, including postoperative infection and PID.

In pregnant women, bacterial vaginosis is associated with preterm rupture of the membranes and preterm labour and birth. The microbes found in bacterial vaginosis are also often found in the amniotic fluid of women with chorioamnionitis. The presence of atypical cells on Papanicolaou smear is also more common in women with bacterial vaginosis.

Diagnosis

Bacterial vaginosis is diagnosed by the presence of clinical and microscopic findings. Women with bacterial vaginosis report an abnormal vaginal discharge and may complain of an unpleasant, fishlike vaginal odour, especially after sexual intercourse. The discharge is generally white or grey, and women may have burning during urination or itching around the vagina, although the colour and amount of discharge varies greatly from woman to woman. The normal pH of vaginal secretions is less than 4.5. In women with bacterial vaginosis, the pH is usually greater than 4.5. The organisms responsible for causing bacterial vaginosis depend mainly on the pH of the vagina. With a pH of more than 4.5, *Gardnerella vaginalis* and anaerobes become the most likely causative organism.

Laboratory tests include:

- *wet mount*—a sample of vaginal discharge is examined to identify the bacteria present, to look for white blood cells that indicate an infection, and to look for unusual cells called clue cells. The presence of 'clue cells' is the most reliable indicator of bacterial vaginosis.
- *culture*—a culture of vaginal discharge may show heavy growth of microbes associated with bacterial vaginosis
- Gram stain
- *oligonucleotide probes*—to detect the genetic material (DNA) of the bacteria causing the infection.

Treatment

The drugs of choice for bacterial vaginosis are metronidazole (Flagyl™), which reports a cure rate of 84–96%, or oral clindamycin (Cleocin™) with a cure rate of 94%. When prescribing metronidazole, the lead carer should stress the importance of abstaining from all forms of alcohol, as a disulfiram-type reaction can occur. In addition, metronidazole may interfere with the metabolism of warfarin (Coumadin™) and anticonvulsants; consequently, dosages of these medications may need to be altered. Women taking barbiturates may require a higher dosage of metronidazole. In contrast, although clindamycin is also an effective treatment for bacterial vaginosis it is much more expensive and is associated with gastrointestinal irritation such as diarrhoea and, rarely, colitis.

Research

A systematic review, published in 2005, investigating 'Antibiotics for bacterial vaginosis or *Trichomonas vaginalis* in pregnancy' concluded that there was no evidence that treatment of bacterial vaginosis reduced perinatal or serious bacterial morbidity.

Okun N, Gronau KA, Hannah ME 2005 Antibiotics for bacterial vaginosis or *Trichomonas vaginalis* in pregnancy: a systematic review. American College of Obstetrics and Gynecology 105(4):857–867

Syphilis

In some parts of Australia such as the Northern Territory and certain locations in New Zealand, syphilis has again become a major cause of stillbirth, and babies with congenital syphilis are increasingly common. In other locations the prevalence of syphilis is so low that clinicians are now questioning the benefits of screening for the disease (Public Health Laboratory Service Syphilis Working Group 1998).

Early diagnosis and treatment are extremely important if the effects that syphilis has on pregnant women and their infants are to be prevented. Untreated primary or secondary syphilis in pregnant women can lead to congenital syphilis in 40–50% of cases. A lack of or inadequate antenatal care and failure to properly diagnose and treat maternal syphilis are the most important factors leading to congenital syphilis, and so adequate screening of high-risk populations and treatment should be the focus of widespread public health strategies aimed at prevention, early diagnosis and treatment. Syphilis, a notifiable disease, is caused by *Treponema pallidum*, a helical, tightly coiled, motile spirochete. The disease is characterised by: a primary lesion; a secondary eruption involving skin and mucous membranes; and long periods of latency culminating with late lesions of skin, bone, viscera, cardiovascular and central nervous systems. The stage of maternal disease during which the fetus is exposed to infection determines the degree and type of morbidity; the earlier the disease stage, the higher the morbidity. Untreated primary or secondary syphilis in pregnancy causes almost a 100% rate of infection in the fetus. The disease can cause stillbirth, neonatal death or congenital syphilis.

Screening

Even when syphilis is considered unlikely, routine antenatal screening is probably warranted for prevention and surveillance, especially since the tests are relatively easy to administer and inexpensive. The earlier in pregnancy the treatment, the more efficacious it is. Therefore, serological

Critical thinking exercise

What are the differences between screening for syphilis and diagnosing the condition?

Clinical point

For excellent education resources, visit eMedicine's Sexually Transmitted Diseases Center. Also, see eMedicine's patient education article (http://www.emedicine.com/med/topic2224.htm).

tests should be performed at the initial prenatal visit. If the woman is considered to be at high risk, it may be necessary to perform a re-test at about 28 weeks gestation and again after birth.

Diagnosis

Diagnosis of syphilis is made in the same manner as for a non-pregnant woman. In primary syphilis, the diagnosis is confirmed by identifying *T. pallidum* in dark-field examination of material taken from a lesion. However, because most pregnant women do not have visible lesions, serological screening is the primary means of establishing the diagnosis. Traditionally, screening strategies used an initial non-treponemal test (e.g. rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL)). Because these tests are highly sensitive but non-specific, pregnancy often causes false-positive results; therefore, positive findings are followed up with specific anti-treponemal antibody tests such as the microhaemagglutination assay-T pallidum and the fluorescent treponemal antibody absorption test. However, many laboratories now screen with an automated enzyme immunoassay (EIA) test for anti-treponemal IgG. Unless treatment is instituted in the very early stages of infection, the EIA usually remains positive for life, unlike the non-treponemal tests, which show falling levels (or may become non-reactive) after treatment or occur spontaneously over time.

Treatment

Treatment is the same as for non-pregnant women, with a single dose of 2.4 million units of benzathine penicillin for both primary and secondary syphilis, although some experts recommend another dose a week after the initial one, especially in the third trimester or in the case of secondary syphilis. For latent syphilis, treatment consists of three doses of benzathine penicillin. In pregnancy, penicillin is the only drug that can be used to treat syphilis because the accepted alternatives to treatment are erythromycin and tetracycline and both of these are teratogenic; in any case, erythromycin may not prevent congenital syphilis.

Gonorrhoea

Gonorrhoea is caused by *Neisseria gonorrhoeae*, a Gram-negative diplococcus, and is transmitted by close sexual contact. Although many women are asymptomatic there are some reports of women presenting with endocervicitis, premature rupture of membranes, chorioamnionitis, septic miscarriage, IUGR, prematurity, and postpartum sepsis leading to PID. Proctitis is diagnosed in up to 50% of women with gonorrhoea and may be the only site colonised with *N. gonorrhoeae* thus warranting testing of rectal specimens for the disease. Similarly, individuals with gonococcal pharyngitis are frequently asymptomatic, and again the pharynx may be the only site colonised. Gonorrhoea is transmitted vertically during the birth process but there is no evidence to suggest placental transmission. Therefore newborns are exposed to the disease only during vaginal birth. The babies are at risk of an acute conjunctivitis known as ophthalmia neonatorum.

Screening

Gonococcal infections cause no symptoms in approximately 50% of women and therefore testing for gonorrhoea is one of the recommended routine, universal screening tests in pregnancy. However, some centres recommend screening only high-risk pregnant women at the first antenatal visit and again in the third trimester.

Diagnosis

The laboratory diagnosis of gonorrhoea depends on the demonstration of *N. gonorrhoeae*, or detection of its DNA in samples from the endocervix, pharynx, rectum and urethra.

Treatment

The treatment of choice is an antibiotic such as ciprofloxacin or ofloxacin, but ciprofloxacin is contraindicated in pregnancy. Unfortunately there is increasing evidence that some strains of *N. gonorrhoeae* are resistant to antibiotics. All patients treated for gonococcal infection should also be empirically treated for chlamydial infection.

Group B Streptococcus

Group B Streptococcus (GBS) is a naturally occurring Gram-positive bacterium found in the rectovaginal flora of up to 30% of healthy women. GBS colonisation is rarely life-threatening but it has the potential to cause infection and ongoing complications for the pregnant woman, the fetus and baby during pregnancy, labour and the postpartum period.

Intra-amniotic infections are often polymicrobial and occur more frequently in women with marked GBS colonisation. The time-honoured clinical signs and symptoms of chorioamnionitis include the following:

- pyrexia (an intrapartum temperature > 37.8°C)
- significant maternal tachycardia (> 120 bpm)
- occasional chills, malaise
- fetal tachycardia (> 160 bpm)
- purulent or offensive amniotic fluid or vaginal discharge
- varying levels of uterine tenderness
- maternal leucocytosis (total blood leucocyte count 15,000–18,000 cells/mm^3).

Of the criteria listed in above, intrapartum maternal pyrexia appears to be the most frequent, and other findings, such as fetal tachycardia, may be less important in the absence of

maternal fever. While GBS may cause clinical urinary tract infections in pregnant women, many will have no symptoms of genital tract colonisation. UTIs caused by GBS complicate up to 4% of pregnancies. Women can contract amnionitis, endometritis, sepsis or meningitis antenatally from GBS, but associated maternal mortality is rare (Schrag et al 2002). Fetal and neonatal GBS infection is mostly preventable, provided it is identified early and managed appropriately. Antibiotics such as penicillin or ampicillin are used prophylactically or in the treatment of maternal infection and to prevent fetal infection or early-onset neonatal disease associated with maternal urogenital colonisation by GBS. Penicillin is the agent of choice for intrapartum antibiotic prophylaxis. Ampicillin is an acceptable alternative, but penicillin is preferred because of its narrower spectrum of antimicrobial activity. Intravenous administration is the only route of administration recommended for preventing GBS disease in the intrapartum period because of the higher intra-amniotic concentrations achieved with this method.

James (2001) warns of the potential adverse and unintended effects of using antibiotics prophylactically or to treat active GBS infections such as: allergic or anaphylactic reactions to the drugs used for intrapartum antibiotic prophylaxis, the emergence of strains of GBS resistant to standard therapies and, increasingly, serious antibiotic-resistant neonatal infections caused by agents other than GBS. Nevertheless, when it is transmitted to the fetus or the neonate, GBS is a common and significant cause of neonatal mortality and morbidity (Gilbert et al 2002). While only a small proportion of the babies of women known to be carriers of GBS are actually infected, up to 80% of the mothers of infected babies have one or more identifiable risk factors in labour (Gilbert et al 2002).

Before the onset of labour, ascending infection spread from the maternal gastrointestinal tract or vagina may cause fetal infection in utero. Grimwood and colleagues (2001) comment that after the introduction of intrapartum IV antibiotic therapy, the incidence of GBS infection in New Zealand fell to 0.5 per 1000 live births. Moreover, the fetus may become infected with GBS if it aspirates infected amniotic fluid. Nevertheless, GBS infections frequently result in stillbirth, neonatal pneumonia or sepsis. If the fetus does not contract the infection until it begins its passage through the birth canal, despite becoming colonised it will probably remain asymptomatic (Schrag et al 2002). Babies with late-onset GBS (after one week of age) usually present with meningitis.

Screening for GBS

(For additional information, see Ch 32.) Because of the potentially catastrophic outcomes following perinatal GBS infection, most centres advocate screening all pregnant women for GBS. Currently there are two schools of thought. In the culture-based screening method (Schrag et al 2002), universal antenatal screening for vaginal and rectal GBS colonisation of all pregnant women is performed at 35–37 weeks gestation to identify GBS carriers. These women are offered IV antibiotic cover in labour. In addition, women diagnosed with GBS bacteriuria during their current pregnancy and those who have previously given birth to a baby with early-onset GBS infection are also offered intrapartum antibiotics. Proponents of the risk-based method screen only those deemed to be at risk of a GBS infection once they are in labour. Critics of this approach argue that although attempts have been made to identify risk factors that influence GBS infections, such as ethnicity, smoking, maternal age, and number of partners, colonisation rates are so inconsistent that targeting only high-risk women for selective screening is not an effective strategy.

Women whose culture results are unknown at the onset of labour are managed according to a risk-based approach. These risk factors include labour < 37 weeks gestation, ruptured membranes for over 18 hours, and/or maternal pyrexia of 38.0°C or above. Women with negative vaginal and rectal GBS screening cultures within five weeks of delivery do not require intrapartum antibiotic cover even if they later develop these risk factors (Schrag et al 2002).

The recommended intrapartum regimen is five million units of penicillin G intravenously followed by 2.5 million units every four hours until birth. Penicillin G is preferred because of its narrow spectrum profile, although ampicillin,

Research

Group B streptococcal disease in the era of intrapartum antibiotic prophylaxis (Schrag et al 2000)

A comparison between the risk-based and culture-based approaches to screening for GBS colonisation in 5144 births demonstrated that the culture-based screening approach was 50% more effective than the risk-based strategy in preventing neonatal GBS disease. Although the risk-factor approach was the least expensive option, universal screening at 35 to 37 weeks of gestation followed by treatment of all colonised women during labour was the most effective option.

Clinical point

Effective and timely reporting of results to the primary carer is important in the prevention of GBS infection.

cefazolin, clindamycin, erythromycin and amoxycillin are acceptable alternatives if penicillin G is unavailable or if the woman is allergic to penicillin.

Early-onset neonatal GBS infection

Unless neonatal GBS infections are diagnosed early and treated with antibiotics and supportive therapy, morbidity and mortality are high. Symptoms of early-onset GBS in newborn babies often begin before the baby leaves the birthing room (Gomella et al 1999). They include: respiratory grunting, lethargy, irritability, poor feeding, tachycardia or bradycardia, pyrexia or low temperature, rapid or slowed respirations and hypotension. There are raised white cell count and cell-reactive protein (CRP) levels. Blood, urine or cerebral spinal fluid cultures confirm that the baby has a GBS infection.

Hypertension in pregnancy

Hypertension is the most common medical problem encountered during pregnancy, complicating 2–3% of pregnancies. This chapter uses the classificatory system used by the Australasian Society for the Study of Hypertension in Pregnancy (ASSHP). The ASSHP define the following types of hypertension in pregnancy:

- *hypertension*—systolic blood pressure (BP) greater than or equal to 140 mmHg, or diastolic BP greater than or equal to 90 mmHg when repeated over several hours (Korotkoff V)
- *chronic (pre-existing) hypertension*—hypertension diagnosed before pregnancy or in the first 20 weeks of gestation in the absence of any underlying cause. Hypertension that is diagnosed for the first time during pregnancy and does not resolve post partum is also classified as chronic hypertension. There may be proteinuria. In contrast, chronic hypertension that is primary or secondary to an underlying condition, such as renal disease, renovascular disease, pheochromocytoma or Cushing syndrome, is known as essential hypertension.
- *gestational hypertension* (pregnancy-induced hypertension (PIH))—hypertension detected for the first time after 20 weeks gestation without proteinuria. It usually resolves by three months post partum without any other signs of pre-eclampsia.
- *pre-eclampsia (PE)*—a multisystem disorder associated with hypertension and proteinuria, which rarely presents before 20 weeks gestation. The pathological changes are primarily ischaemic, affecting the placenta, kidney, liver, brain and other organs. The exact cause of pre-eclampsia is unknown, although abnormal placental implantation, endothelial dysfunction, and/or abnormal immune responses have all been suggested as possible factors.
- *pre-eclampsia superimposed upon chronic hypertension*—pre-eclampsia that occurs in women who are already hypertensive; in such cases, the outlook is much worse than for either condition alone.
- *eclampsia*—one or more seizures that occur in association with pre-eclampsia. Eclampsia is an obstetric emergency (see Ch 36).

Chronic (pre-existing) and gestational hypertension

The incidence of chronic hypertension in pregnancy is 1–5%. Management aims to achieve a diastolic blood pressure of less than 90 mmHg. In contrast to chronic hypertension, gestational hypertension is a provisional diagnosis: some women may go on to develop proteinuria (pre-eclampsia), whilst others may have pre-existing hypertension that has been masked by the physiological drop in blood pressure in the early part of pregnancy. A diagnosis of gestational hypertension is confirmed if pre-eclampsia does not develop and the blood pressure returns to normal by 12 weeks post partum.

Appropriate baseline assessment in women with chronic hypertension includes an evaluation of pre-existing target organ damage including cardiomegaly, renal insufficiency and retinopathy, preferably made prior to pregnancy. These are important for diagnosis and ongoing management. Renal function is assessed with a 24-hour urine protein and creatinine excretion, and/or a serum creatinine or a spot urine protein/creatinine ratio. An electrocardiogram will detect left ventricular hypertrophy. Baseline ultrasounds for dating the pregnancy are useful, as are follow-up scans, to detect fetal growth restriction—these usually begin at 28 weeks gestation and are repeated every four weeks until birth.

Women with chronic hypertension often continue taking their antihypertensive medication, although it may be necessary to switch to a different medication during pregnancy (Magee et al 1999). There is, however, no evidence that anti-hypertensive therapy improves perinatal outcomes, and some studies show an increase in fetal growth restriction in women taking these medications (Magee et al 1999). This is especially true for the beta-blockers, with the exception of labetalol. Methyldopa and hydralazine have the best 'track records' and are the preferred agents. However, the ACE inhibitors have been implicated in fetal renal damage and are therefore contraindicated in the first trimester. There is little data on calcium channel blockers such as nifedipine, but what does exist shows neither deleterious nor advantageous effects.

There is no evidence to demonstrate that bed rest is an effective therapy. Similarly, weekly non-stress tests (NSTs)

Clinical point

All pregnant women should be screened for pre-eclampsia at the first antenatal clinic visit and periodically for the remainder of the pregnancy.

after 32 weeks gestation may be prudent, but there is little objective evidence of benefit. If fetal growth restriction, oligohydramnios or superimposed pre-eclampsia are diagnosed, twice-weekly NSTs beginning at 32 weeks gestation are commenced. Doppler flow studies and biophysical profiles are useful adjuncts to NSTs and ultrasounds in assessing fetal wellbeing. Complications of chronic hypertension are: an exacerbation of maternal hypertension, superimposed pre-eclampsia and uteroplacental insufficiency, IUGR and placental abruption. Provided these complications do not arise and hypertension does not worsen, the woman can be delivered at term.

Pre-eclampsia

Pre-eclampsia (PE) complicates about 8% of pregnancies and is a multiorgan disease associated with abnormalities of the coagulation system, disturbed liver function, renal failure, cerebral ischaemia and fetal growth restriction. PE is always characterised by hypertension and proteinuria with or without oedema (Brown et al 2000). The exact mechanisms that lead to PE are still unclear. What is known is that some women have predisposing factors and are more at risk of the disease than others. PE is more common in: primigravidas, those aged over 40, women with a new partner, women with a previous history or family history of PE, multiple pregnancies, hydrops fetalis, women with other medical conditions such as diabetes or renal disease, obesity and women who have used some reproductive technologies (Brown et al 2000). In addition, PE is more common in women with large placentas, those whose sisters or mothers had PE and in women with auto-immune (collagen vascular) diseases.

Pathophysiology

Postulated mechanisms underlying the pathophysiology of PE are complex and beyond the brief of this text, and the reader should combine this account of PE with an appropriate anatomy and physiology text as well as literature from journals. It is likely that the primary trigger in PE is poor placental perfusion due to abnormal placental trophoblastic infiltration of the uterine spiral arteries (Lew & Klonis 2003), a process that occurs many weeks before the signs of PE become apparent, resulting in a high impedance circulation instead of a low-pressure system necesary if the fetus is to be adequately oxygenated.

The secondary pathology in PE is probably related to reduced blood flow to the woman's major organs, which causes endothelial damage. This causes a cyclic pathological process. Decreased blood flow to the placenta causes inadequate placental perfusion. In response, vasoactive substances are released by the hypo-perfused placenta, which in turn leads to further widespread endothelial damage and profound vasospasm, with a consequent reduction in plasma volume. Endothelial damage activates the coagulation cascade; platelets adhere to the sites of endothelial damage. Prostaglandin metabolism is also altered, with an increase in thromboxane and a decrease in prostacyclin concentration contributing to further platelet dysfunction and vasoconstriction. Because these pathological changes occur so near the beginning of pregnancy, the fetus is compromised very early in the pregnancy. Table 33.2 lists the effects of PE and the primary body systems affected.

Critical thinking exercise

You find that a woman who books into your antenatal clinic for the first time at 25 weeks pregnant has a blood pressure of 150/95. There is no proteinuria. What is the most likely cause of her hypertension and what are you going to do about it?

Diagnosis

According to the ASSHP (Brown et al 2000), for PE to be diagnosed there must be:

- hypertension after the 20th week of gestation, and rarely earlier, perhaps when there are extensive hydatidiform changes in the chorionic villi
- a diastolic blood pressure of at least 90 mmHg and a systolic blood pressure of at least 140 mmHg. These blood pressures must be manifested on at least two occasions six hours or more apart.
- proteinuria (presence of 300 mg or more of protein in a 24-hour urine collection or a protein concentration of 1 g/L or more. This level of proteinuria should produce a 2+ reaction on a standard urine dipstick in at least two random urine specimens collected six hours or more apart; and possibly evidence of:
  - renal insufficiency
  - liver disease
  - neurological problems
  - haematological disturbances
  - fetal growth restriction.
- oedema is now considered to be of little clinical importance as it occurs equally in women experiencing normal pregnancy and in PE. However, the rapid onset of oedema is usually abnormal (Brown et al 2000). Pathological oedema is defined as a generalised accumulation of fluid of greater than 1+, pitting oedema after 12 hours of bed rest or weight gain of 2 kg or more in 1 week, or both.

In addition, many women with PE will have abnormal liver function tests:

- aspartate aminotransferase (SGOT) level higher than 72 IU/L, and LDH levels > 600 IU/L
- alanine transaminase (ALT) levels > 40 IU/L
- alkaline phosphatase levels > 60 IU/L in first trimester, > 80 IU/L second trimester and > 140 IU/L in third trimester
- total albumin level 34 g/L decreases to 28 g/L at term. There is a strong relationship between low serum albumin levels and adverse maternal and fetal outcomes.
- total bilirubin levels > 17 μmol/L.

Although transaminase levels rise as a result of hepatocellular necrosis, prothrombin time remains within the

TABLE 33.2 Effects of pre-eclampsia

System	Effects

(Source: Hart & Coley 2003, p 39)

reference range. As PE worsens there may be evidence of haematological abnormalities: haemolysis (haemoglobin < 110 g/L, with reticulocytosis) or thrombocytopaenia (< 150×10^9 g/L platelets).

Renal function tests (plasma creatinine, creatinine clearance, blood urea and total urea protein and uric acid) are often abnormal. However, a total urinary protein of > 500 mg/L in 24 hours is associated with severe PE . A serum creatinine level ≥ 0.10 mmol/L also indicates significant renal impairment. In women with PE, serum uric acid levels are slightly increased but levels > 0.35 mmol/L are associated with poor fetal outcomes, although women with normal serum uric acid levels and clinical signs of PE may still develop complications.

Classification

The ASSHP classifies PE as mild or severe (Brown et al 2000).

Criteria for mild pre-eclampsia:

- hypertension as defined above but not meeting the criteria for severe pre-eclampsia (below).
- proteinuria > 300 mg/24 hours.
- urine output > 500 mL/24 hours.

Criteria for severe pre-eclampsia:

- BP of > 160/110 on two occasions at least six hours apart.
- The presence of an elevated blood pressure and any of the systemic symptoms noted below categorises the patient as having severe PE regardless of the blood pressure:
  - proteinuria > 500 mg/24 hours or 3+ or 4+ on urine dipstick
  - massive oedema
  - oliguria < 400 mL/24 hours
  - systemic symptoms including pulmonary oedema, headaches, visual changes, right upper quadrant pain, elevated liver enzymes, or thrombocytopaenia
  - signs and symptoms of imminent eclampsia; at least two of hyperreflexia with clonus, visual disturbances and severe headaches.
  - intrauterine growth restriction.

Severe PE and eclampsia are dealt with in Chapter 36.

Management

Because PE is a multiorgan disease that compromises maternal and fetal health, any woman with hypertension must be referred to a medical practitioner, and will need to birth in hospital. Management of PE depends on several factors:

- gestational age of the pregnancy
- severity of the disease
- presence of complicating factors
- evidence of maternal or fetal compromise.

The definitive treatment for PE is delivery of the fetus and placenta. This is a reasonable choice for viable fetuses or when the mother's health is significantly compromised. Examples of these risks include signs of: impending eclampsia, pulmonary oedema, compromised renal function, placental abruption, a platelet count < 100,000/μL, a ratio of serum alanine aminotransferase to serum aspartate aminotransferase that is twice the reference range with concomitant epigastric and right upper quadrant tenderness, persistent severe headache or visual changes, and uncontrolled severe hypertension.

Expectant management

In the past, pregnant women with hypertension were admitted to hospital. Admission to hospital is always stressful and, for many women, emotionally and financially costly. In many

Research

Prevention of PE

Currently there are no well-established therapies to prevent PE (Duley 2003). However, it seems that low-dose aspirin therapy (100 mg per day or less) probably reduces the incidence of PE and eclampsia in women who have an abnormal uterine artery function on Doppler ultrasound examination performed in the second trimester. The results of studies supporting its use should be discussed with women known to be at risk of PE.

Small trials have studied the efficacy of daily calcium supplementation as a preventive measure (Atallah et al 2004). As with aspirin therapy, calcium supplementation may produce modest blood pressure reductions in pregnant women who are at above-average risk for PE and in pregnant women with existing low dietary calcium intake, but the optimum calcium dosage has not been established (Atallah et al 2004).

For decades, women have been advised to make a range of changes to their lifestyles and implement numerous dietary modifications in an effort to prevent or manage PE (Brown et al 2000). None of these have been shown to be effective. Research on the use of antioxidants (high doses of vitamins C and E) in the prevention of PE is promising (Duley 2003). However, further large studies are needed to confirm these early findings, and so as yet antioxidant therapy is not recommended.

cases, hospitals are not restful places. This intervention would be justified if there were clear benefits but as yet there is no evidence that hospitalisation for mild PE improves maternal and fetal outcomes (Duley 2003). Women with mild PE without significant proteinuria often prefer to be an 'outpatient' and remain at home or be admitted as a 'day case' for assessment and evaluation. Expectant management at home (or in hospital) requires reduced activity and careful checking and daily recording of:

- fetal activity
- blood pressure
- urine protein.

A daily log of symptoms and assessments is combined with frequent (at least twice-weekly) checks by the lead carer. The woman may be advised to stop employment, reduce her activity level and, if possible, spend a considerable amount of time in bed. However, although bed rest is considered a reasonable and logical treatment for PE, its ability to improve outcomes has not been proved—in fact, it may be harmful (Duley 2003). Strict bed rest for three days or more significantly increases the risk of thromboembolic disease in either the legs or lungs (from 1 in 1000 to 16 in 1000) when it is used to prevent preterm labour (Kovacevich et al 2000).

Collaborative management

The goals of management are twofold: first, to recognise PE early; and second, to monitor the mother for evidence of disease progression that would mandate either delivery or more intensive fetal surveillance. Baseline laboratory evaluations should be performed early in pregnancy for all women known to be at high risk of PE. All women should have their blood pressure recorded at each antenatal consultation and more frequently in women at high risk of PE. Although increases above the baseline (> 30 mmHg systolic or > 15 mmHg diastolic) are no longer considered a criterion for the diagnosis of PE, rapid increases warrant closer observation. Fundal height should be measured at each visit because a fundal height less than expected for the estimated gestation may indicate IUGR or oligohydramnios, both of which are associated with PE. In addition, evidence suggestive of IUGR and/or oliguria may be apparent long before the diagnostic criteria for PE are apparent. Further assessment of rapidly increasing, generalised oedema or maternal facial and periorbital oedema combined with rapid weight gain is warranted because marked fluid retention may be associated with the onset of severe PE.

Once hypertension is documented during the second half of pregnancy or if the onset of PE is suspected, laboratory tests to confirm the diagnosis and to track its progression include hepatic enzyme levels, platelet counts, serum creatinine levels and a 12- to 24-hour urine collection (or spot creatinine tests) for total protein measurement. Blood tests include a full blood count, urea and electrolytes and coagulation profiles (APTT, PT, fibrinogen). Antepartum surveillance (NSTs) two or three times a week and/or biophysical profiles and/or Doppler flow studies are used to monitor fetal growth and to ascertain the most appropriate and safest time for delivery.

Education for the family begins as soon as the diagnosis is confirmed and should include information about the disease process, signs and symptoms of worsening disease, proposed course of treatment, including physical and laboratory assessment, medications, potential complications for the woman and her baby and the plan for birthing.

Hospital management

Hospital admission may become necessary if the woman feels 'safer' in hospital, if her hypertension worsens, in the presence of proteinuria, if there are signs of end organ involvement, or if there are concerns about fetal wellbeing. The laboratory tests and assessments described above are used to monitor the progress of the disease. It is crucial that an accurate fluid balance chart is maintained and reviewed daily to ensure that renal impairment is detected quickly. Table 33.3 lists the systemic complications of mild and severe PE.

Antihypertensive therapy

Antihypertensive therapy for PE is indicated once the BP is persistently > 160/100 mmHg, with the aim of achieving a diastolic BP of 90 to 100 mmHg. This is to avoid 'overcorrection' and the risk of exacerbating placental hypoperfusion. Antihypertensive drugs used to control hypertension include methyldopa, atenolol and labetalol. Angiotensin-converting enzyme (ACE) inhibitors are contraindicated in pregnancy.

TABLE 33.3 Systemic complications of eclampsia/pre-eclampsia

System	Complication
Cardiovascular	Cardiogenic and non-cardiogenic pulmonary oedema
Neurological	Cerebral oedema Cerebral haemorrhage, a direct consequence of hypertension Convulsions, coma
Hepatic	Subcapsular haematoma (epigastric or right upper quadrant pain) Hepatic rupture
Renal	Renal failure Proteinuria
Haematological	Thrombocytopaenia Disseminated intravascular coagulopathy (DIC) Haemolysis
Fetal	Fetal growth restriction Placental abruption

(Source: Lew & Klonis 2003, p 362)

Timing of delivery

Delivery is the only 'cure' for clinically diagnosed PE and should be accomplished as soon as the fetus is mature, or earlier if the mother's condition deteriorates or if there is evidence of significant fetal compromise. The timing and management of delivery requires close collaboration between the woman and her obstetric, midwifery, paediatric and anaesthetic team members. If the fetus is between 24 and 34 weeks gestation and urgent delivery is required, corticosteroids are administered to the mother to stimulate fetal lung maturation and the production of surfactant. Vaginal birth is preferable and epidural analgesia is the preferred choice of analgesia for labour. Epidurals reduce the maternal stress response and release of catecholamines, which occur in labour when pain cannot be controlled. Epidural analgesia and anaesthesia are contradicted if there is evidence of coagulopathy (platelet count $< 50\,000 \times 10^9$/L).

Indications for immediate delivery

Fetal indications:

- IUGR
- non-reassuring NST
- oligohydramnios.

Maternal indications:

- progressive deterioration of liver function
- progressive deterioration of renal function
- suspected placental abruption
- persistent severe headache or visual changes
- persistent severe epigastric pain, nausea or vomiting.

Pre-eclampsia superimposed on chronic hypertension

PE superimposed on chronic hypertension is characterised by new-onset proteinuria (or by a sudden increase in the protein level if proteinuria is already present), a rapid increase in blood pressure (assuming hypertension already exists), or development of the HELLP (haemolysis, elevated liver enzymes, low platelet count) syndrome. Recognising PE superimposed on chronic hypertension can be very challenging. The condition should be suspected when any one of the following is present: BP > 160/110 mmHg; heavy proteinuria (more than 2 g per day), or existing proteinuria that abruptly worsens; BP suddenly increases after a period of good control; or serum creatinine levels rise to more than 110 mmol/L. Immediate management is similar to that described for PE. Once the baby is born, further assessment and treatment of ongoing hypertension is required.

Postpartum management of hypertensive disease

Although birth is the only 'cure' for PE, the condition often deteriorates immediately after delivery, and up to 30% of cases of PE are only diagnosed post partum when the mother develops eclamptic seizures. Most maternal deaths occur after delivery. It is therefore important that in the first 72 hours after birth, clinicians continue to monitor the mother's blood pressure, continue therapy and ensure that she is not 'overloaded' with fluid. If she has been diagnosed with severe PE it is crucial that a meticulous fluid balance chart is still maintained and carefully reviewed. Good analgesia cover is also important after operative delivery to reduce the stress response associated with uncontrolled pain. In women with PE, antihypertensive medication may be required post partum for three or four weeks. Little information is available on the effects of antihypertensive medication during lactation, although as yet there is no evidence that antihypertensive drugs have a detrimental effect on the baby. Hypertension and other signs of PE should remit by six to 12 weeks post partum. At a follow-up consultation, the woman should be informed of her risk of PE and its consequences in subsequent pregnancies. Women with PE do not appear to have an increased risk of future hypertension or cardiovascular disease, although women with transient hypertension or chronic hypertension do.

Critical thinking exercise

Why are ACE inhibitors contraindicated in pregnancy?

Clinical point

Up to 40% of eclamptic seizures occur before delivery; approximately 16% occur more than 48 hours after birth.

Multiple pregnancy

Twin birth occurs in approximately 1 in 80 pregnancies and triplets once in 80 × 80 (6400) pregnancies. Multiple gestations have a higher incidence of complications than singletons from conception until the birth of the second twin. The complications associated with multiple pregnancies have resulted in a significant increase in the proportion of preterm births and the number of babies admitted to neonatal intensive care units.

Incidence of multiple births

According to the Australian Bureau of Statistics' *Year Book Australia* (ABS 2002), birth registrations over the past 20 years indicate that while the number of pregnancies (births) resulting in a live birth has been declining, the number of multiple births has increased (see Fig 33.4). This is primarily attributed to the increased use of assisted conception technologies and the increasing number of births to older women. While the actual number of multiple births remains relatively low, there has been a steady increase in Australia and New Zealand since the 1970s.

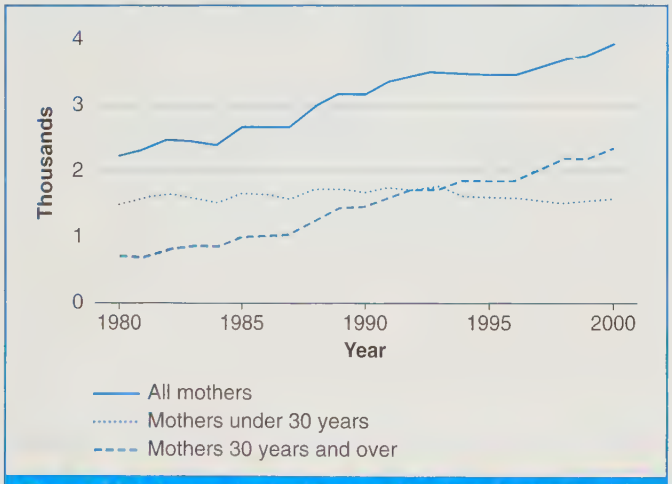

Figure 33.4 Increasing incidence of multiple births in Australia (based on ABS 2002)

Classification

There are two major types of twin gestations: dizygotic (DZ) and monozygotic (MZ). MZ twins (uniovular and identical) occur sporadically. In contrast, the incidence of DZ (binovular and fraternal) increases with advancing maternal age and parity. In some families, DZ twinning is probably inherited. DZ twins are more common than MZ twins (see Fig 33.5). In Caucasians about 30% of twin pregnancies are MZ and about 70% DZ.

DZ twins develop from two ova fertilised by different spermatozoa. They have separate gestational sacs with separate placentas, chorion, amnion and umbilical cords. The developing fetuses may be of the same or different sex and are no more alike than siblings. In contrast, MZ twins develop from a single ovum, which splits within a few days of embryogenesis into two identical halves, each developing into one twin with a separate amnion and umbilical cord but usually sharing one placenta and chorion. These babies are of the same sex, have the same blood group and share very similar physical and psychological characteristics.

Chorionicity

Zygosity refers to the type of conception, whereas chorionicity refers to the type of placentation. Twin placentas are classified into two categories according to the number of layers in the septum between the two amniotic sacs. Depending on the stage of embryogenesis at which the zygote splits, four different types of twins may result. All dizygotic twins have DC (dichorionic/diamniotic) placentas. The placentas may be fused or separate, but when examined after birth blood vessel anastamoses between the two vascular beds are seldom discovered.

In MZ twins, if the zygote splits early (within 72 hours after fertilisation) each twin will lie in its own sac and the placentas have separate chorions and amnions (dichorionic/diamniotic). However, in about 70% of MZ twins, division does not occur until the blastocyst stage between four and eight days after conception. In this case each twin will have its own amniotic sac but the placenta will only have one chorion but two amnions. An even smaller number (< 1%) of MZ twins will have monochorionic-monoamniotic placentas, so the twins share the same amniotic sac. There is no intervening membrane and so the fetuses and their umbilical cords can freely intermingle and entwine. Monoamniotic placentation

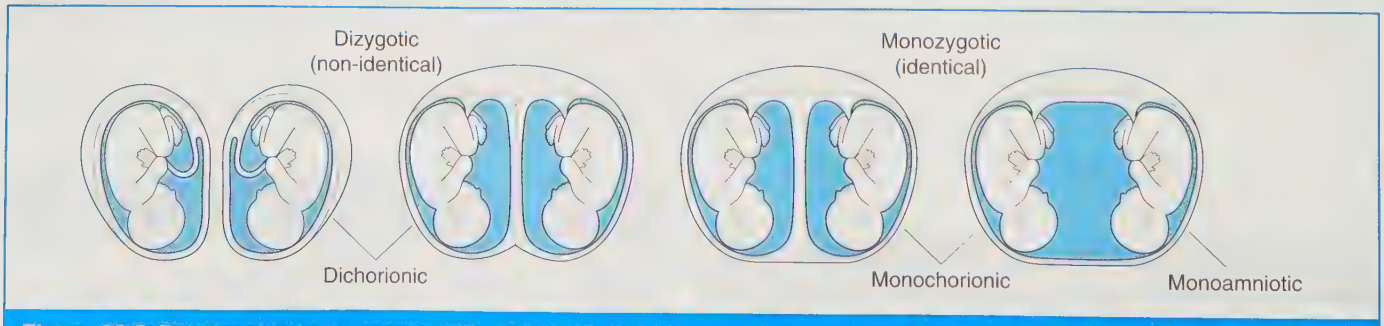

Figure 33.5 Relationship between zygosity and chorionicity (based on Henderson & Macdonald 2004)

occurs when division takes place between days 7 and 11—that is, after the amnion has differentiated. Conjoined twins are an even rarer subtype of monozygotic twinning and occur because splitting of the embryo does not take place until after the primitive streak has differentiated. Triplets can be MZ, DZ or trizygotic.

Mortality/morbidity

Multiple pregnancies are considered to be 'high risk' because the mortality rate is about four times that for singletons. Evidence suggests that about 75% of one or both twins are miscarried (Sebire et al 2000; Sutcliffe et al 2001). In many cases this is due to congenital abnormalities, which are more common in MZ and monochorionic twins. In the so-called 'vanishing twin' syndrome, the 'lost' twin is reabsorbed into the mother's body or miscarried with few or no symptoms. Occasionally one fetus dies early in the pregnancy and is retained in the uterus until term, becoming flattened and mummified. This is known as a *fetus papyraceus* ('paper-like'). Depending on local regulations, the fetus may require birth and death certificates.

Higher-order multiple births have even higher mortality and morbidity rates compared to twins and singletons. This is mostly due to the increased proportion of infants with low birthweight and preterm delivery and the complications associated with these. Several authors dispute this, however, arguing that regular fetal surveillance and appropriate steroid administration is necessary for good perinatal outcomes in monoamniotic twin gestations (Allen et al 2001; Sebire et al 2000; Sutcliffe et al 2001). Twin-to-twin transfusion syndrome, in which blood from one twin is transfused to the other twin via blood vessels in their shared placenta, is a rare but serious and potentially life-threatening condition affecting 15% of MC twins (Sutcliffe et al 2001).

Other complications include:

- preterm labour and birth
- low birthweight
- placenta praevia
- placental abruption
- intrauterine growth restriction
- pre-eclampsia
- increased frequency of birth asphyxia
- malpresentation
- pre-labour and preterm rupture of the membranes and GBS infection
- umbilical cord accidents
- operative delivery
- postpartum haemorrhage.

Goals of management

Care of the woman and her muti-fetal pregnancy should be designed to prevent and/or treat the complications that may occur in order to optimise physical and psychosocial outcomes for the mother, baby and family. Supporting the parents of twins is not just about obstetric management of the pregnancy; it is also about helping the woman and her family to adapt to a rapid increase in their family, to prepare for parenting multiples and supporting them to make informed decisions about the management of their 'high-risk' pregnancy. Maternal adaptations to pregnancy are exaggerated with twins. Plasma volume increases an additional 10–20% in twin over singleton pregnancies. Nutritional requirements rise, carbohydrate metabolism may differ, but the most marked changes arise because of the increase in maternal blood volume and consequently maternal cardiac output. Red blood cell mass increases to a lesser degree than plasma volume and so there is a relative anaemia because of this haemodilution. Both iron and folate requirements are higher in twin pregnancies. Because of the complications associated with multiple pregnancy, most women are referred to a medical practitioner and prepare for hospital births and, increasingly often, an operative birth. However, many of the complications associated with multiple pregnancy occur irrespective of the place of birth and, indeed, hospitalisation cannot prevent their occurrence.

Diagnosis of multiple pregnancy

Generally, the diagnosis of twins is not difficult for the astute midwife. By the end of the first trimester, uterine size is larger than expected for gestational age by last menstrual period and/or earlier examinations. The woman may report excessive nausea and vomiting or that she 'feels as if she is having twins'. In the second trimester, abdominal palpation of multiple fetal parts may suggest the presence of more than a single fetus, and occasionally, two sets of fetal heart rates may be detected. Ultrasound early in the first trimester usually confirms any suspicion the woman has that she is having twins. During abdominal ultrasonography, two gestational sacs can be visualised after six weeks gestation; vaginal ultrasound allows for an even earlier diagnosis. If the initial diagnosis is made very early in pregnancy, a repeat ultrasound several weeks later will confirm the presence of twins, rule out anomalies and determine chorionicity. Because of the increased rate of congenital abnormalities, women should be offered both biochemical genetic and nuchal translucency tests. Many practitioners recommend serial scans every four to six weeks to evaluate fetal growth and for concordance, especially if the twins are MZ. Non-stress tests, Doppler flow studies and biophysical profiles all play an important role in the ongoing assessment of fetal wellbeing, especially IUGR and growth discrepancies. The NST is reasonably reliable in assessing fetal wellbeing in multiple gestations. A problem arises when the NST results are discordant for the two fetuses. If only one NST is non-reactive, another test such as the biophysical profile should be performed on both fetuses. If this suggests fetal compromise, delivery or hospitalisation may be indicated. These decisions are based on gestational age, degree of compromise, and assessment of fetal maturity.

Sometimes one of the twins dies. Grieving for the dead baby while at the same time celebrating the life of the second child is very difficult for the parents.

WOMAN'S STORY

We were thrilled to find that at last I was having twins, after so many unsuccessful cycles of IVF. And then one day they told me one of my precious babies had died. Knowing that I was carrying a dead baby and a live one was very strange. Every time I went for a scan I was terrified that they would tell me that the second baby was going to die. I used to wonder if the one who was left knew that her sister was dead. I wanted to grieve for my dead baby and I felt guilty if I felt happy for the one who was still alive, but I was. When Linda was born, so beautiful and so healthy, we were so grateful and wanted to celebrate her birth, but I mourned for my second baby girl all over again. I wasn't sure what I was supposed to feel and I alternated between relief, guilt, sorrow and intense joy. Linda is too young to talk about it yet but I often wonder if she misses her identical sister. One day we will talk about it, but not today.

Collaborative management in pregnancy

Care of the woman with a twin pregnancy is designed to support the parents as they prepare for parenting and to prevent, identify and treat the complications that may arise. These have been dealt with earlier in the chapter. Consequently, many clinicians recommend: more frequent consultations with the obstetric team; more ultrasounds and tests for fetal wellbeing and to predict preterm labour; iron and calcium supplements; and sometimes restrictions and limitations on the woman's activities.

Preparation for birth

The mechanisms involved in vaginal birth of the first twin are similar to those for singleton pregnancies; however, malpresentation, fetal compromise, maternal and placental bleeding and the need for abdominal delivery are increased in twin pregnancies. Therefore, intensive and continuous monitoring of maternal and fetal wellbeing and the progress of labour are essential. Induction of labour and augmentation with Syntocinon and artificial rupture of membranes for one or both babies are used if necessary. Blood is cross-matched and IV access obtained because of the increased risk of PPH. Epidural analgesia is recommended if there is hypertension or if the labour is preterm or complicated by the possibility that there will be malpresentation of the second twin.

Equipment is prepared for the births of two babies, keeping in mind that the babies may be small for dates or preterm and that the birth of the second twin may be complicated. Each twin is monitored simultaneously. Immediate availability of two paediatricians and an anaesthetist is recommended.

Once Twin A is born and the umbilical cord is clamped, blood should not be collected until after delivery of the second twin. There are two reasons for this:

- There may be vascular connections between the placentas, such that blood from Twin B escapes from the cord of Twin A.
- Removal of blood from the placenta may hasten its separation from the uterine wall, leading to placental abruption.

A section of umbilical cord can safely be ligated and removed for blood gases if this is hospital protocol.

BOX 33.22 Symptoms of preterm labour

- All women should be aware of the symptoms of preterm labour, primarily after 20 weeks gestation. These include cramps, contractions, menstrual pains, increasing pelvic or vaginal pressure, increasing low back pain, heavy vaginal discharge, vaginal spotting or bleeding, rectal pressure.
- There is no evidence that bed rest improves fetal outcomes but it may improve the woman's sense of wellbeing
- Adequate hydration, 6–8 glasses of liquid per day, is helpful.
- Recognise whenever an activity is associated with the above symptoms, and then stop or reduce that particular activity.
- For any pattern of symptoms suggestive of preterm labour that does not resolve within one hour of bed rest, contact the lead carer.

Delivery of the second twin

Route of delivery of the second twin engenders significant controversy in the intrapartum management of twins. There is general agreement that vaginal delivery is safe in twins who both present as vertex, and caesarean delivery is indicated only in the presence of the usual obstetric and fetal indications. Management of vertex–nonvertex twins is perhaps the most controversial. The options are caesarean delivery, external cephalic version (ECV), and assisted vaginal breech delivery or breech extraction. An important factor in this decision is the skill and experience of the personnel available. If the decision is made to proceed with a vaginal birth, as long as the fetal heartbeat of the second twin is reassuring, the time interval until the baby's birth is not critical. What is critical, however, is that the labour is progressing. As soon as the first baby is born, the second baby's heart tones are monitored continuously, and the baby's position, lie and presentation determined by palpation and vaginal examination or, as is increasingly common, with real-time ultrasound. If the lie is longitudinal, whether the vertex or the breech is presenting, the membranes are artificially ruptured and a short period of time left to elapse to see if contractions establish. If they do not, augmentation with oxytocin is warranted. The delivery of the second twin usually occurs quite quickly as the cervix has already been fully dilated. Because of the risk of PPH, the third stage is managed actively. Syntocinon® is given only after the birth of the second baby and after confirming that there is not a third baby waiting to be born. Many clinicians recommend that an IV infusion of Hartmann's solution or normal saline containing 40 mIU of Syntocinon® is commenced

to ensure the uterus remains well-contracted in the immediate postnatal period, thereby avoiding a PPH. The placenta and membranes are examined to determine that they are complete and whether the twins are MZ or DZ, although this is confirmed by placental histology.

Care of the woman in the puerperium proceeds as for a singleton pregnancy, though the woman may require extra practical support and assistance to establish feeding and organise the care of two babies. Contact with local support groups such as the local multiple birth association is encouraged from early in pregnancy.

Conclusion

For the woman experiencing a complicated pregnancy, many associated issues arise. The woman's level of anxiety increases as the pregnancy progresses. The woman needs assistance and support if she is to be away from her normal place of residence for a period of time, including possible transfer to a regional tertiary unit and the associated dislocation from her close family and friendship network. Adequate childcare for other children may need to be organised. The cost in time and dollars of attending specialist appointments needs to be addressed. The emotional toll of a complicated pregnancy is ongoing and may not necessarily be resolved with delivery of the baby. The compromised fetus often results in the birth of a baby requiring specialist paediatric services for a period of time. At the same time, the new mother needs time to recover both physically and emotionally from a complicated pregnancy. The midwife's involvement in each woman's pregnancy is fundamental to ensuring that the woman receives appropriate care that is not compromised by exposure to unnecessary risk.

Review questions

1. At 10 weeks pregnant, Neve is unable to eat any food without vomiting and feels nauseated all day. What actions will you take?
2. Beth is eight weeks pregnant and rings you to say she has had some fresh vaginal bleeding. What advice will you give her?
3. Lydia is 32 weeks pregnant. She tells you as she has had some fresh vaginal bleeding. What are possible causes for the bleeding? What information will you need to help you make a diagnosis? Describe the advice you will give Lydia.
4. Victoria is 22 weeks pregnant. She comes to your clinic complaining of feeling unwell and with lower abdominal crampy pain. What other information do you require? What will you do?
6. Isabella's first pregnancy has progressed normally. However at her 36 week antenatal check, Isabella has a blood pressure recording of 140/98 mmHg and + protein on dipstick. What actions do you take?
7. At 32 weeks pregnant, Joanna rings you, saying that her skin feels very itchy, especially on her palms. She tells you that she has no rash. What do you advise?
8. RE results of Kelly's 28-week gestational diabetes challenge test (50 g glucose polymer load) at one hour post glucose dose is 9 mmol/L. The normal range is < 7.9 mmol/L. What are your obligations as the midwife providing Kelly's care?
9. Portia has a fundal height of 15 weeks at her 12-week antenatal visit. A subsequent USS confirms a twin pregnancy. Portia is very keen for you to continue to provide midwifery care for the remainder of her pregnancy. Under what conditions could this be provided? What plan for care and ongoing management will you negotiate with Portia?
10. Rae is 37 weeks pregnant with her first baby. She rings you at 2 am and says she has heartburn, can't stop vomiting and 'feels most unwell'. Her pregnancy has proceeded normally so far. What will you suggest?

CHAPTER 34

Disturbances in the rhythm of labour

Carol Thorogood and Catherine Donaldson

Key terms

cephalo-pelvic disproportion, dystocia, Friedman's curve, hypertonic uterine action, hypotonic uterine action, incoordinate uterine action, malposition, malpresentation, partogram, prolonged labour, 'trial' of caesarean scar, 'trial' of labour, VBAC

Chapter overview

Maternity care in most developed countries including Australia and, until recently, New Zealand is dominated by a medicalised, technologically orientated, interventionist model of maternity service provision. Soaring intervention rates suggest two things: that Western women's bodies are no longer able to cope with labour and birth without medical intervention; and that intervention is occurring in many 'normal' labours and births. Whatever the cause, increased intervention in birth, including inductions of labour, caesarean sections, the use of regional anaesthesia and analgesia, and operative deliveries, has not made substantial differences in improving maternal and neonatal outcomes for women living in resource-rich nations.

Despite the very best of care and support, not all labours proceed as planned and an exploration of the causes, associations and management of these deviations from the usual birthing journey is the overall aim of this chapter. First, however, the authors reconsider what a 'normal' journey is and what it is not. The chapter then describes the factors that disturb the rhythms of labour, leading to what is commonly called dystocia (difficult labour), such as prolonged labour, malpresentations and positions, and preterm labour, as well as the interventions used to manage these, such as augmentation and induction of labour, and operative delivery (caesarean section, forceps and Ventouse extractions). The authors draw on woman-focused and empowering language—disturbance in the rhythms of birth—to describe some of the causes of dystocia, rather than mechanistic and disempowering idiom, such as the oft-used but ill-defined 'failure to progress' or 'trial of labour' and 'trial of scar', because the former is more women-centred and does not ascribe notions of failure and inadequacy or blame to the birthing woman. However, because the latter terms are part of the everyday language found in the literature and in most delivery wards, they are included here as well.

The anatomical structures, physiology and biosciences underpinning disturbances in the rhythms of labour are covered only briefly in this chapter. Therefore it is important that students who may be unfamiliar with these concepts refer to a specialised text to enable them to apply this material to the content of this chapter.

Learning outcomes

Learning outcomes for this chapter are:

1. To analyse the causes, identification, effects and management of disturbances in the rhythms of labour and birth
2. To critically discuss the evidence that supports common medical interventions in birth
3. To describe the ways in which midwives work to keep birth culturally, emotionally and physically safe when disturbances in the rhythms of labour occur.

Introduction

Many midwives do not subscribe to an interventionist model of care for all women. For example, in New Zealand, the Midwifery Council's (2004) Scope of Practice clearly places emphasis on the midwife supporting the physiological processes of normal birthing, and this is evident throughout the Council's Competencies for Registration as a midwife. As Powell-Kennedy and Shannon (2004) discovered in a qualitative study, the support of normalcy is fundamental to a midwifery model of care, one that is prefaced by a view that birth for most women should be a normal process even though some labours are more difficult than others. Participants in the study commented that women's bodies are physiologically prepared for labour and birth (Powell-Kennedy & Shannon 2004). The midwives described how they reassured birthing women that even though their labour might be long and painful, it was still normal (ibid). Moreover, they 'embraced a tolerance for wide variations in normal labour and for sustaining as much normalcy as possible, even when pathology had been identified' (Powell-Kennedy & Shannon 2004, p 256). These midwives believe, as does the WHO (1997), that there should always be a valid reason for intervention in the natural process of birth.

A review of the literature concerned with labour and birth reveals that since the seventeenth century, clinicians have endeavoured to differentiate between a 'normal' and an 'abnormal' labour and birth. Certainly, the history of midwifery and obstetrics suggests that across time and place, clinicians have created, eliminated and re-worked descriptions of 'normal' labour. Many of these are still in use, although they are not supported by scientific or research-based evidence, and more often than not have been created according to the authors' hunches, opinions, cultural beliefs or convenience rather than evidence. Gross and colleagues (2005) comment on the difficulties associated with determining the precise onset of labour and the duration of each of its phases and stages. There are still large gaps in our knowledge and understandings about birth. As yet there is no consensus about the appropriate length of each stage of labour or how to differentiate between a 'normal' and an 'abnormal' labour and the risk factors associated with it. For instance, despite a paucity of evidence, an unengaged fetal head in a nullipara at the beginning of labour has long been held to be a risk factor for cephalo-pelvic disproportion (CPD) and therefore is cited as an indication for a 'trial' of labour or caesarean section. This is despite research by authors such as Takahashi and Suzuki (1982), and Diegmann et al (1995), who found no significant differences in labour outcomes between nulliparas with an engaged fetal head at the beginning of labour and those with an unengaged fetal head. Similarly, medical and midwifery students are often introduced to notions of specific time intervals expected from each phase of labour, and this knowledge is reinforced by what they see in the hospital environment even though these are arbitrarily timed.

The Greek word for 'difficult' or abnormal labour is 'dystocia' and this topic is the focus of this chapter. Every midwife will at some time be confronted with complications in labour or deviations from a normal labour. The midwife must know how to recognise these variations and take appropriate action until they are resolved, or make a referral and transfer care to a specialist lead carer. Irrespective of the place of birth, the composition of the healthcare team or planned interventions, midwives always work in partnership with each woman to create a space for birth that is culturally, emotionally and physically safe (Powell-Kennedy & Shannon 2004).

Midwives who are evidence-informed and reflective practitioners often find that obstetric interventions such as the induction of labour, especially if there are no accepted medical indications for the procedure, pose ethical and professional dilemmas that need to be addressed. The benefits of a clearly defined midwifery philosophy (Clarke 2002) along with the relevant Standards for Practice and Codes of Ethics, enable midwives to determine their own boundaries in regards to decision-making about their participation in interventions in the labour and birth processes.

Reflective exercise

If they are to provide quality midwifery care, midwives need to consider how knowledge is generated, where it comes from and how their own value and belief systems affect their understanding of 'normal' birth, its duration, the role of pain in labour and complications such as cephalo-pelvic disproportion. As you work through this chapter, reflect on the 'facts', especially those taken for granted, by asking the kinds of questions posed by Walsh (2003):

- Whose purpose does knowledge serve?
- Where does knowledge come from?
- Who created it and why?
- Who benefits?
- How has knowledge of birth been influenced by a technological-mechanistic view of birth that is readily apparent in twenty-first century popular and medical culture?

Rhythms of labour

Midwives' and women's perceptions of the expected length of labour have been seriously undermined by dominant medical hegemony (Bates 2004). This has culminated in the overuse of protocols such as the 'active management of labour'. According to Thornton (1996) there is scant evidence to support this practice but it is still used in many maternity units.

Understanding the physiology and the mechanisms or cardinal movements of labour, including how the shape of the maternal pelvis influences the passage of the fetus through the birth canal, aids recognition of deviations from the usual pattern and rhythm of labour.

BOX 34.1 Active management of labour

In the late 1970s and early 1980s, two Irish clinicians, O'Driscoll and Meagher (1980), introduced to maternity units in Dublin a 'package' of care that they termed 'active management', which, they argued, resulted in a reduced incidence of prolonged labour and a caesarean section rate of less than 7%. The package included: antenatal education; one-to-one midwifery care; precise criteria for the diagnosis of the onset of labour; two-hourly timed vaginal examinations, and early use of high doses of Syntocinon that achieved a rate of cervical dilatation of at least 1 cm/hr. Across the world this model of care was welcomed and widely accepted. Even today, few randomised studies have evaluated the efficacy of 'the active management of labour package'. Frigoletto and colleagues (1995) found no significant differences between the 'active management' group and a 'usual-care' control group in the rate of caesarean section. However, the median duration of labour was shorter in the 'active management' group by 2.7 hours. Nevertheless, the authors concluded that there was no justification for the universal recommendation of 'active management of labour'. Moreover, beginning in the mid-1980s, research confirmed what midwives intuitively knew—that constant social support during labour is associated with shorter labours, higher rates of vaginal births, and a reduction in the amount of pharmaceutical analgesia used in labour (Klaus et al 1986; Hodnett 2003). In other words, the same outcomes may have been achieved by midwifery one-to-one support without the other arms of the 'package'.

Slower than expected progress in labour and midwifery support

The first clinician to provide a definitive instrument for the assessment of individual labours was a US obstetrician, Emanuel Friedman (1954). It remains the standard for defining the normal progress of labour. Friedman's initial predictions about the normal progress of labour were based on the evaluation of the labour progress of 100 women. The rate of cervical dilatation was determined by frequent rectal examinations. No exclusions were made for malpresentations, malpositions or multiple pregnancies. Work by Albers (1999) and Zhang et al (2001) have challenged Friedman's work on the duration of labour. Friedman set the normal progress of labour as a cervical dilatation rate of 1.2 cm/hr for primigravidas and 1.5 cm/hr for multigravidas (Friedman 1954). He depicted labour as a sigmoid curve, with the first stage of labour divided two distinct phases: *latent* and *active* (Fig 34.1). The active stage begins at 3–4 cm of cervical dilatation and can be further subdivided into three sequential phases: acceleration, maximum slope and deceleration.

In an attempt to improve maternity services in Rhodesia, Philpott and Castle (1972) refined Friedman's work. They described the active phase of labour as progressing in a straight line and at a cervical dilatation rate of 1 cm/hr, with no distinction for parity. In an 'advance' of Friedman's work, they placed an alert line on the cervicograph (Fig 34.2). The alert line, unlike the sigmoid curve described by Friedman, was a straight line and calculated on a rate of cervical dilatation of 1 cm/hr irrespective of parity. A second parallel line, known as the action line, was later drawn on the cervicograph (partogram), four hours to the right of the alert line. The latter was an arbitrarily chosen time that was considered to allow sufficient time for a woman to be transferred from a local maternity unit in Rhodesia (now Zimbabwe) to a tertiary hospital in Harare (then Salisbury).

Critical thinking exercise

The following list identifies the assessments a midwife makes and records in every labour:

- *fetal heart rate*—by intermittent auscultation, or continuous electronic fetal heart rate monitoring
- *cervicogram*—rate of cervical dilatation and descent of the fetus through the pelvis
- *uterine contractions*—quantification of frequency, duration and strength
- *amniotic fluid* (if the membranes have broken)—state of fluid; presence of meconium
- *maternal urine production*—assessed for the presence of ketones and protein
- *maternal adaptation to labour*—blood pressure, pulse rate and temperature
- *hydration and nutrition*—fluid and dietary intake and output
- *maternal wellbeing*—behaviour and response to labour, levels of fatigue, pain and coping ability
- *family support*—level, type and effect.

Using the above headings as a guide, determine how frequently various clinicians (medical practitioners, midwives working in the community, birth centres or in tertiary hospitals) assess these variables and the range they use to establish whether labour is progressing normally.

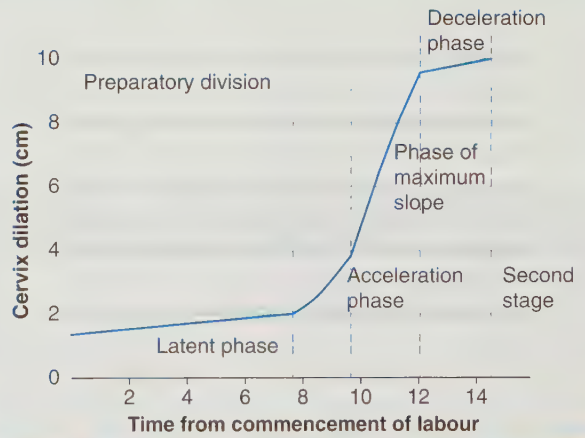

Figure 34.1 The Friedman curve (based on Friedman 1954)

Cervicographs with warning and action lines are now in general use in many Western countries, and clinicians are expected to plot the rate of cervical dilatation and descent of the fetal head on a cervicograph, an important component of intrapartum assessment. Many clinicians intervene in labours as soon as they extend beyond predetermined intervals, even if there are no indications that maternal or fetal wellbeing is jeopardised.

The majority of trials testing the efficacy of the partogram have taken place in hospital settings. To date no trial has demonstrated that the partograph has lowered the rate of maternal mortality. Moreover, work by Albers et al (1996; Albers 1999) shows clearly that normal labour can and does last much longer than is commonly believed. These labours are not inevitably associated with increased morbidity in mothers or infants. Indeed, the complications often linked to prolonged labours may be caused as much by interventions (repeated vaginal examinations, augmentation of labour, epidural analgesia, operative delivery) than a lengthy labour itself.

Slow progress in the latent phase of labour

During the latent phase, the contractions become more regular and increase in intensity; there is slow but gradual cervical dilatation. Its precise duration is difficult to determine and probably the best option is to ask the woman when her labour began, and believe her. Women empowered to take control of their birth experience will alert the midwife of changes in their labour and are best placed to determine whether they are 'in' or 'not in' labour. Walsh (2003) makes the point that in a partnership of reciprocal respect and trust, women's fear of intervention during the usual ebb-and-flow patterns of labour can be minimised. According to current medical thinking, a prolonged latent phase of labour (from beginning of labour to the onset of active labour and cervical dilatation of 3–4 cm) is defined as one lasting more than 20 hours, with a mean of 8.6 hours.

Slow progress in this phase of labour is not necessarily indicative of dystocia or CPD. Further, active interventions to accelerate labour in the latent phase are not always associated with improvements in outcomes and may actually be harmful because of the increased risk of intrauterine infection and umbilical cord prolapse. The treatment of choice for a lengthy early labour is rest and sleep.

Slow progress in the active phase of labour

According to medical dictum, the active phase of labour is characterised by increasing frequency and intensity of contractions, progressive descent of the presenting part and dilatation of the cervix of 1 cm/hr. It covers the period from the end of the latent phase (3–4 cm of cervical dilatation) to complete dilatation of the cervix (10 cm of cervical dilatation). Figure 34.2 uses a partogram to plot the expected progress of labour and the typical pattern of prolonged labour based on Friedman's 'ideal' of normal labour. Alternatively, using Alber's work (1999) as a guide, the usual rate of cervical dilatation

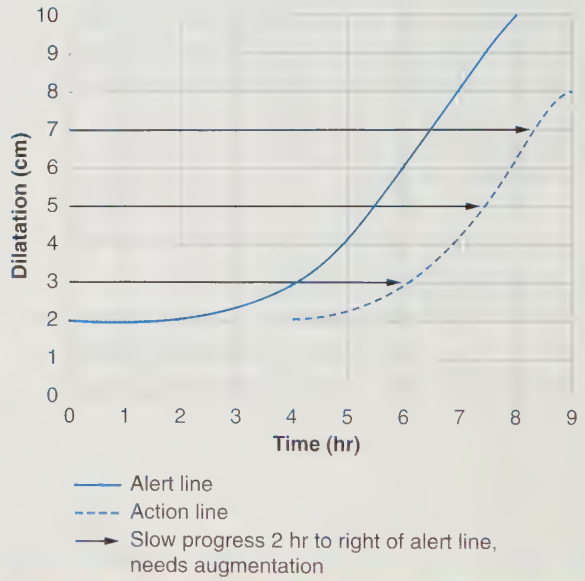

Figure 34.2 Partogram plotting the alert and action lines (based on Stables & Rankin 2004)

Research

In the United States, Cesario (2004) conducted a cross-sectional survey aimed at reassessing the average length of each phase of labour associated with a good outcome. The goal was to learn whether there was a consensus among nurse (sic) managers about whether to revise Friedman's labour curve. It aimed at reassessing the average length of each phase of labour associated with a good outcome. Nearly two-thirds of the 89 respondents reported not using the labour curve, and more than three-quarters stated that Friedman's curve was not suitable for assessing women in labour. More than 85% believed that the curve should be revised. The results suggest that the time limits used to determine whether labour is proceeding satisfactorily may need to be expanded. There should be more emphasis on the methods that nurses (sic) use to assess labour and on the interventions that may affect the length of each stage of labour.

Critical thinking exercise

Friedman described three stages in the active phase of labour: acceleration, maximal slope and deceleration. Make your own partogram and draw the typical curve. As you support women in labour, plot their labours on a 'personal' partogram. Later, reflect on how many 'normal' labours actually fitted this pattern but still had positive outcomes.

Reflective exercise

Ask colleagues with differing levels of clinical expertise and backgrounds how they determine whether labour is progressing in the active phase, without performing frequent vaginal examinations. Just as importantly, ask women (probably multiparas) how they know that their labours are progressing normally and that the baby is beginning to travel through the birth canal.

in this stage for nulliparas is 0.5 cm/hr in the absence of complicating factors, and the mean duration of active labour is 7.7 hours. For the duration of labour, the upper limit (mean + 2 standard deviations, i.e. the variance around the average) is 17.5 hours. In multiparas the mean duration is 5.6 hours and the upper duration 13.8 hours. Thus there are wide variations in the duration of women's labours, and these do not fit the expected Friedman pattern.

A misdiagnosis of slower than expected labour in the active phase can lead to unnecessary obstetric intervention, such as augmentation of labour using oxytocic drugs and artificial rupture of the membranes (ARM). Empowered, knowledgeable women will alert the midwife to an apparent slowing down in the pattern of contractions once labour has established. Non-invasive evaluation of contraction patterns occurs by gentle abdominal palpation, which tracks the descent of the fetus through the birth passage, and by careful assessment of the strength, regularity and duration of contractions. This assessment is subjective and should always be considered along with the patterns of the woman's behaviour and reactions to each contraction. Findings are confirmed by vaginal examination. A change in an established pattern of labour may indicate that there are potential complications that require investigation and possible intervention (Enkin et al 2000). The pattern of contractions can be altered by other factors including fear and anxiety. Transfer to hospital will often slow labour down. Similarly, labour often slows just before the second stage of labour begins, probably to give the mother a much needed rest before the work of second stage begins.

Although a longer than expected, albeit normal, duration of labour is not uncommon in primigravidas, there are other potentially problematic reasons for observed changes in contraction rhythms and these are now explored. They are:

- maternal dehydration or ketosis
- anxiety and fear
- ineffective pattern of contractions
- malposition (an occipitoposterior position)
- malpresentation
- cephalo-pelvic disproportion.

Maternal dehydration, ketosis and the progress of labour

Labour is hard work, and the body needs energy to work effectively. However, in industrialised countries, the effect of restricting fluids and food in labour is controversial. Restricting women's intake to fluids or ice chips during labour is a widely accepted obstetric tradition, which began about 50 years ago, when women frequently gave birth under general anaesthesia and were therefore at risk of aspiration pneumonia. However, modern anaesthesia techniques have improved, and in any case general anaesthesia is rare in modern obstetrics. Moreover, no period of fasting guarantees an empty stomach, and clear liquids leave the stomach almost immediately. Other clinicians have argued, with scant evidence to support this hypothesis, that fasting causes ketosis and dehydration, which leads to more painful contractions, slower labour and fatigue. Moreover, according to Enkin et al (2000), withholding food and drink from women in labour is unlikely to be beneficial. For these reasons, many healthcare providers no longer restrict eating and drinking during a normal labour.

Anxiety and fear

The relationships between continuous support in labour, fear, anxiety and the progress of labour are described elsewhere in this text. In brief, anxiety, excessive pain and fear are known to increase the amount of catecholamines ('fight-or-

Research

The effect of unrestricted oral carbohydrate intake on labour progress (Tranmer et al 2005)

In 2005, Tranmer and colleagues examined whether giving women the option of eating what they wanted during early labour decreased the incidence of dystocia. They randomised more than 300 nulliparous women before the onset of labour to receive either usual care, consisting of ice chips, popsicles or sips of fluid while in the hospital, or an intervention, consisting of a 'booklet containing easy-to-read guidelines on suggested nutrient and fluid intake during labour based on nutritional guidelines for individuals who participate in prolonged, moderate, aerobic exercise'.

The study data and patient questionnaires did not in fact support the authors' hypothesis that women encouraged to eat early in labour would fare better. But neither did the results reveal a sound basis for preventing them from doing so. There was no difference between the two groups in the rate of dystocia, nor were there differences in the rates of nausea or vomiting, both oft-cited reasons for restricting oral intake. In addition, there were no instances of gastric aspiration or death in either group.

Although the authors don't call for a change in current practice, they do recommend more research on this topic and telling women about the study so that they can decide whether to bring food to the hospital to eat and drink in labour.

flight' hormones) released into the maternal circulation, and these influence the effectiveness of uterine contractions. For centuries, midwives and women have known that uncontrollable anxiety and fear increase the pain of labour and inhibit its progress. There is now qualitative and quantitative evidence to support this ancient knowledge. Moreover, we now know that women who feel in control of their bodies, their labour and what is happening to them are less likely to experience uncontrollable pain (Hunter 2002). Women who experienced sexual abuse in childhood or have had prior traumatic birth experiences, or have strong 'control' issues, may sometimes have difficulty surrendering to the power of their labour (Hofberg & Brockington 2000; Sjogren & Thomassen 1997). Indeed, maternal fear of childbirth is the most common reason for nulliparous women's request for caesarean delivery (Hildingson et al 2002). Women with extreme fear of labour (tocophobia) may develop post-traumatic stress disorder if they feel 'forced' to go through vaginal birth, but may benefit from counselling or psychiatric consultation (Hofberg & Brockington 2000).

Ineffective contraction patterns

Dystocia encompasses various complications in labour, the most common being incoordinate uterine contractions that result in an extremely painful and prolonged labour. Other contraction patterns include coordinate hypotonic and hypertonic uterine activity.

Incoordinate uterine action

Incoordinate uterine action is characterised by asynchronous, hypotonic or hypertonic uterine contractions, which, because they do not begin in the uterine fundus and do not pass in a wave downwards to the cervix, result in ineffective contractions. It is associated with frequent, painful contractions often combined with constant backache and pain that persists well after the contraction has finished. There is a loss of fundal polarity, and in hypertonic incoordinate uterine action there is an increased uterine resting tone. Consequently, placental blood flow is reduced and fetal compromise may occur (Liu et al 2003). Two variations of hypertonic incoordinate uterine activity are the so-called 'colicky uterus' and 'constriction ring dystocia'. In the former, various parts of the uterus contract independently and this is combined with generalised and severe pain. An extreme form of incoordinate uterine action occurs with a localised spasm of one part of the uterus. However, constriction ring dystocia is rarely seen in developed countries. In association with ineffectual uterine contractions it occurs when an annular spasm arises at the junction between the upper and lower uterine segment, usually in late first stage or early in the second stage of labour. Unlike Bandl's pathological retraction ring, constriction rings are not associated with obstructed labour and cannot be palpated abdominally. Often, constriction rings arise from injudicious use of oxytocin or during intrauterine manipulation such as an internal podalic version. Relaxants including inhalation of amyl nitrate, or deep anaesthesia with a drug such as halothane, may eliminate the localised myometrial spasms, but as a last resort caesarean section with a vertical incision may be required.

Clinical point

Strategies to prevent, or support women in dealing with, anxiety and fear in labour are:

- one-to-one midwifery care in which a trusting relationship has been established
- eating and drinking to avoid fatigue and dehydration, which may slow labour
- massage, acupressure and warm tub baths or showers to ease pain and induce relaxation, which may enhance progress
- warm water immersion, which has been called the 'midwives' epidural'
- talk, which provides comfort, reassurance and encouragement, and aims to relieve anxiety and explore the psychological or emotional issues or adverse environmental elements that might be causing the 'slow' labour.

Hypotonic uterine contractions

Ineffective contractions are commonly associated with a poorly fitting presenting part on the cervix. Hypotonic uterine action (contractions are short in duration and of weak intensity) result in a slower than expected rate of cervical dilatation and prolonged labour. The pattern may occur in early labour (primary) or later after a normal contraction pattern has been established (secondary). Typically this pattern is observed after the administration of epidural or narcotic analgesia but is frequently associated with some degree of cephalo-pelvic disproportion. There is also evidence that women are genetically predisposed to hypotonic uterine action (Dizon-Townson & Ward 1997). Once the presence of factors that preclude the use of oxytocics are eliminated, many clinicians advocate augmentation of labour with an artificial rupture of membranes (ARM) and Syntocinon infusion. However, studies of the effectiveness of amniotomy have not demonstrated that it significantly improves outcomes, although the duration of labour is shortened slightly.

Hypertonic uterine contractions

A precipitated labour is defined as one with total duration of less than two hours. For some women this may be their normal pattern, but the most common cause of hypertonic uterine action is the injudicious use of oxytocic drugs. Fetal welfare may be compromised when the intensity of uterine contractions is increased, resting intervals are shortened and duration of the contraction is increased. Hypertonic contractions may also cause maternal trauma—including uterine rupture or perineal damage. A combination of excessively forceful uterine contractions and minimal soft tissue resistance can give rise to precipitate labour, fetal anoxia and cerebral trauma, maternal lacerations, and postpartum haemorrhage caused by uterine atony. Early recognition of the problem, timely preparation for

birth under controlled conditions, and properly administered analgesia or anaesthesia may minimise these risks.

Working with women experiencing ineffective contraction patterns

The woman and her support people should be active participants in all decision-making. Encouragement from the midwife and support persons in labour often improves outcomes in slower labours, reducing the need for augmentation of labour (Enkin et al 2000). A longer than expected labour can affect the woman's ability to cope, leading to an increased release of catecholamines (stress hormones), which cause the labour to slow down. The midwife will need to use all her skills in supporting women in a long labour, in particular taking care to avoid maternal dehydration and ketosis, which is best determined by measuring urine output and urinalysis. It is important to avoid a full bladder because this may inhibit descent of the presenting part in the pelvis and delay the second stage of labour. Regular assessment of and documenting maternal and fetal wellbeing as well as the progress of labour are useful to detect the onset of complications and guide the selection of strategies to treat them. According to Enkin et al (2000), research suggests that simple measures such as encouraging the woman to ambulate assists the birth process, as gravity facilitates the descent of the presenting part. Research by authors such as Cluett et al (2004) indicates that labouring in water may alleviate the effects of dystocia. Indeed, Enkin et al (2000) state that ambulation and ensuring women eat and drink as they wish may be as effective as augmentation of labour with oxytocin for a significant number of women. However, because of the hypothetical risk of aspiration of gastric contents during general anaesthesia, many hospitals have a policy of 'fluids only' in labour for *all* women. Indeed, restriction of all food in labour, ketosis and dehydration may exacerbate ineffective contraction patterns and dysfunctional labour (Newton & Raynor 2000). Moreover, fasting, enforced bed rest, intravenous therapy and continuous electronic fetal monitoring imply notions of loss of control, sickness and helplessness, which may also interfere with the progress of labour and necessitate intervention such as augmentation of labour, epidural analgesia and operative delivery (Broach & Newton 1988).

Women experiencing ineffective contraction patterns and prolonged labour are more at risk of postpartum haemorrhage (PPH). Therefore, a discussion of the management of the third stage of labour should occur early enough for the woman to be able to make informed decisions about the need for an active management of the third stage of labour.

Collaborative interventions

The primary goal of all clinicians working with women as they labour is to provide the safest outcome for both mother and infant. It is crucial that midwives have the skills and knowledge required to detect labour and contraction patterns that pose risks for the mother and fetus. Once dystocia is recognised, it is important to identify its cause and, if possible, correct it or minimise the harmful effects it may have on the mother and her baby and treat the causes of the dystocia. Frequently this can be relieved by simple measures such as alleviating intolerable pain or fear. In most cases this will include transferring primary care to a multidisciplinary team. The lead midwife should avail herself of support from her back-up midwife in primary settings or support from the midwifery staff in secondary/tertiary hospitals so that the lead carer can take regular breaks and have adequate rest while continuing to provide continuity of care in partnership with the woman (NZCOM 2005).

Reflective exercise

How will you, as the midwife, support a woman's choice to refuse medical advice that she have her labour augmented or other interventions such as an operative delivery?

Augmentation of labour with an amniotomy (ARM)

There is no need to artificially rupture membranes with an amniotomy if labour progresses normally. Nevertheless, early amniotomy has been advocated as a component of the active management of labour, especially if there is slower than expected progress in the active phase of labour (Fraser et al 1999). It is often used to accelerate the progress of labour by increasing the frequency and quality of contractions, and performed prior to inducing or augmenting the labour. It may also be performed to obtain access to the fetus for a scalp pH assessment, to attach a fetal scalp electrode or to assess the liquor.

An ARM requires the woman's consent. According to a Cochrane Review (Fraser et al 2000), amniotomy is associated with risks as well as benefits and should only be performed in the presence of abnormal labour progress. Benefits include a reduction in labour duration and a possible reduction in abnormal five-minute Apgar scores. The reviewers (Fraser et al 1999) found no support for the hypothesis that routine early amniotomy reduces the risk of caesarean delivery. Indeed, there was a trend (non-significant) toward an increase in caesarean section. An association between early amniotomy and caesarean delivery for fetal distress was observed in one large trial. As soon as the membranes are ruptured there is an increased risk of umbilical cord prolapse, fetal compromise and chorioamnionitis. Once an ARM has been performed, birth should occur within 24 hours. Many Australian clinicians now advocate the administration of intravenous antibiotics if the membranes are ruptured for more than 12 hours; this is not yet common practice in New Zealand hospitals. Nevertheless, if the baby is at risk of infection from Group B Streptococcus (NZCOM 2004), intravenous antibiotics are recommended after rupture of membranes for more than 18 hours.

The amniotic sac and its liquor protect the fetal head; once the membranes break, this effect is removed. Compression of the fetal head leads to increased moulding and changes in the

fetal heart rate—variable decelerations are often apparent on the electronic fetal heart rate trace because the fetal head is no longer cushioned by the amniotic fluid. Below are listed some of the potential consequences of an amniotomy that may require emergency intervention:

- maternal risk factors:
  - prolapse of the umbilical cord
  - chorioamnionitis
  - sepsis
  - significant umbilical cord compression
  - rupture of a vasa previa
- fetal risk factors:
  - preterm birth
  - infection
  - cord prolapse
  - malpresentation.

Indications for amniotomy

- to augment or stimulate labour
- to look for the presence of meconium in the liquor
- placement of a fetal spiral electrode (Boston 2004).

Contraindications for amniotomy

- presentation unknown or unstable
- cervix dilated less than 3 cm
- fetal head not engaged
- non-vertex position of the fetal head
- woman refuses the procedure
- HIV-positive
- active genital herpes simplex virus.

Clinical point

Before performing an ARM, the midwife:

- ensures the woman has consented to the procedure
- ensures that there is indication for the intervention and no contraindications
- performs an abdominal palpation and vaginal examination to determine the stage of labour, presentation, position, cervical dilatation and position of the fetal head relative to the ischial spines
- during a vaginal examination, assesses the progress of labour by cervical dilatation. Unless the fetal head is well engaged in the pelvis, ARM is not advocated.
- introduces the amniohook through the cervix and makes a small tear in the membranes lying in front of the fetal head

After the procedure, the midwife:

- checks and records the colour, odour and quantity of the liquor and the fetal heart rate
- ensures that the woman is dry and comfortable, and informs her of findings.

Critical thinking exercise

You are the midwife for Maria, a primigravida who has been in labour for 15 hours. Maria's mother Henrietta asks you to 'break the waters—my midwife broke mine'. What will you say and do?

BOX 34.2 ARM terminology

ARM = amniotomy or artificial rupture of membranes
SROM = spontaneous rupture of membranes
PROM = prelabour or premature rupture of membranes
PPROM = preterm, prelabour rupture of membranes

Augmentation of labour with Syntocinon

Before intravenous oxytocics are administered, cephalo-pelvic disproportion needs to be excluded by careful abdominal palpation and vaginal examination. The most frequent complications of oxytocin-augmented labours are uterine hyperstimulation causing excessive maternal pain, fetal compromise, cord compression and, more rarely, uterine rupture. Consequently, most hospitals have a policy of continuous electronic fetal monitoring once augmentation or induction of labour with oxytocin begins. After birth, PPH from uterine atony is a significant risk.

Malposition

There is only one malposition—an occipitoposterior (OP) position of the fetus (Fig 34.3). In about 10% to 25% of pregnancies, the fetal head enters the maternal pelvis with the occiput lying in the posterior segments of the pelvis. In most cases the architecture of the pelvis is normal, but in others the pelvic diameters may be reduced. OP positions are more common in the presence of long, narrow pelvic walls (oval-shaped pelvis) or with convergent pelvic side walls and prominent ischial spines. For the baby lying in a right occipitoposterior (ROP) position to rotate to a right occipitoanterior (ROA), the head must rotate 135° from an ROP to a right occipitolateral (ROL), to ROA and then, as the head begins to birth, a direct OA (DOA). Thus, prolonged labour is a frequent complication associated with an OP position. In more than two-thirds of cases, the fetal head achieves this rotation. However, in about 15% of cases the fetal attitude is one of deflexion, and the sinciput becomes the denominator. If this happens, the sinciput, not the occiput, rotates to the front of the pelvis so that the fetal head completes a short rotation of 45° and the head is born 'face-to-pubes'. With a deflexed fetal head, the presenting diameter is 12.5 cm—much larger than the 9.5 cm of the suboccipitobregmatic diameter of the well-flexed head, and so as the head births there is a much higher chance of perineal lacerations. In 20% of cases the fetal head attempts the 'long rotation' but

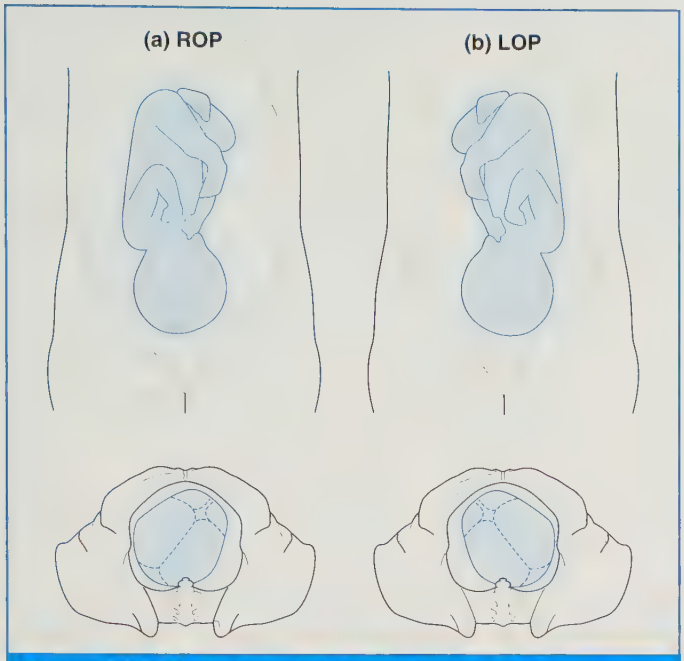

Figure 34.3 Occipitoposterior position (based on Henderson & Macdonald 2004)

arrests at the level of the ischial spines—known as deep transverse arrest.

Working with a woman experiencing an OP labour

The woman usually experiences a long, discouraging and trying labour with intense pain in the small of her back. Others will have an uncontrollable urge to push before the cervix is completely dilated. Many require pharmaceutical analgesia, including epidurals, to cope with intolerable pain and exhaustion. However, encouraging the woman to ambulate, assume positions such as the all-fours position and squatting in the first and second stage, as well as offering massage or labouring in water helps the pain and may aid the fetus to rotate anteriorly. Although there is no evidence that assuming an all-fours position and pelvic rocking (Kariminia et al 2004) achieves fetal rotation in the last weeks of pregnancy, anecdotal evidence indicates that once they are in labour many women find this activity and positioning more comfortable than assuming a supine or semi-recumbent position in bed.

Diagnosis

On abdominal palpation, the fetal back is often felt on the mother's flanks, there is a sensation of 'limbs everywhere', and the fetal head (Fig 34.3) is deflexed and slow to engage in the pelvis. A saucer-shaped depression is often seen at or just below the umbilicus because the shoulder is lying posteriorly. On vaginal examination, the anterior fontanelle can be felt in the anterior quadrant of the mother's pelvis and the posterior fontanelle at the back. Deep transverse arrest must always be considered if, during second stage on vaginal examination:

- the sagittal suture remains in the transverse diameter of the pelvis
- in a primigravida the uterine contractions become hypotonic
- there is increasing and extensive moulding of the fetal head
- there is increasing caput succedaneum
- the fetal head does not descend past the ischial spines.

It is possible to manually rotate the fetal head to an OA position once the cervix is completely dilated. As in all instances of dystocia with an OP position there is a higher incidence of early rupture of membranes, chorioamnionitis, fetal infection, fetal compromise and asphyxia. Infection occurs because the membranes are ruptured for a longer period of time and from multiple vaginal examinations. Operative intervention—episiotomy, ventouse, forceps or caesarean section—is more common in OP positions. Operative delivery carries with it the inherent risks of major surgery: infection, haemorrhage, wound infection, urinary retention and infection, pulmonary embolism and anaesthesia-related complications.

Malpresentations

Malpresentations are defined in the tenth edition of *Baillière's Midwives' Dictionary* (Tiran 2003) as 'any presentation of the fetus other than vertex. It may be a breech, face, brow, or shoulder presentation'. Many medical texts assert that failure to recognise malpresentations and manage them appropriately—that is, with immediate medical intervention—often leads to catastrophic complications, including uterine rupture, obstructed labour, and maternal and fetal death. Such language sets 'high-risk' alarm bells ringing. All midwives must be competent to recognise and deal with emergencies as they arise (Midwifery Council of New Zealand 2004). Operative intervention is not always the best way to deal with malpresentations, and skilled practitioners can often achieve good outcomes with a less interventionist approach. However, in an era of 'defensive medicine' this mode of care is becoming increasingly difficult to support because of the pressure to resort to immediate obstetric intervention as the first line of management.

A good example of how some research fails to support a non-interventionist model of care is the Canadian Term Breech Trial. Since its publication (Hannah et al 2000), debate has raged about how best to safely birth a baby presenting by the breech. Despite its findings and recommendations, a few clinicians still argue that the recommended practice of delivering breech babies by elective caesarean section has more to do with clinicians' personal fears and prejudices, often caused by lack of personal experience and competence, conflicting research evidence, policies and guidelines for both midwives and women, than evidence (Crabtree 2004; Hall & Taylor 2004). Nevertheless, the Term Breech Trial (TBT), a large multi-centre randomised controlled trial (Hannah et al 2000), supports earlier and well-substantiated findings that all babies presenting by the breech, regardless of the mode of birth, are significantly more at risk of perinatal mortality and morbidity even if these babies are at term and have

no congenital anomalies. Secondly, during the TBT, which involved 2088 women with a singleton fetus in a breech presentation at term where women were allocated to either planned caesarean or a planned vaginal birth group, the authors discovered that the risk of perinatal or neonatal death or serious neonatal morbidity was significantly lower in the planned caesarean group, without a significant increase in the risk of maternal death or serious maternal morbidity (Hannah et al 2000). There have been several published critiques of the trial, for example by Halmesmäki (2001), which have argued that factors other than the mode of delivery confounded the findings. There is no doubt, however, that since the publication of the results of the TBT, at least in industrialised countries, few babies presenting by the breech are born vaginally. This means that midwifery and medical practitioners do not have the opportunity to birth breech babies, yet some women still want vaginal breech births. Despite modern technology some breech babies are undiagnosed and if women labour quickly, clinicians have little option but to assist in the vaginal birth of a breech baby.

The New Zealand Guidelines Group (October 2004), a multidisciplinary team, has produced clinical guidelines for clinicians that, while recognising the potential complications of vaginal breech birth in terms of fetal mortality and morbidity, recommends that women be given evidence-based information about the risks and benefits of both vaginal breech birth and caesarean section *prior to* (our emphasis) birth so that they can make informed decisions and choices about their care. This gives rise to the debate over what actually constitutes the provision of informed choice and the use of evidence-based information. As research by Stapleton et al (2004) into the culture of informed choice demonstrated, fear of litigation was a major factor influencing the way in which choices were presented to or withheld from women. Such fears prevent the development of a trusting relationship between the woman and her midwife.

The New Zealand Guidelines group authors stress that maintaining skills for facilitating vaginal breech birth remains important for all clinicians. While these guidelines have been developed specifically for the care of women undergoing a breech birth, they hold true for all women with a malpresentation, or indeed any complication in labour.

Breech presentation

Midwives sharing practice stories will often relate tales of how they diagnosed breech babies in labour and that these women went on to have successful uncomplicated vaginal births. Others talk about the detrimental effects of obstetric interventions such as epidurals, unnecessary ARM or making women birth in bed in the lithotomy position. Anecdotes from midwives experienced in vaginal breech birth show how they defend maternal choice for a standing vaginal breech birth, and how they coped with coercive behaviour from midwife colleagues and obstetricians who insist on a caesarean delivery rather than adopting a watching, observing and supportive approach to breech birthing.

Authors such as Crabtree (2004) maintain that women with a breech baby are now opting to birth at home or arrive in advanced labour at the hospital to avoid an operative delivery. As this chapter has already pointed out, babies presenting by the breech are at greater risk of complications than babies presenting by the vertex (Hofmeyr & Hannah 2002). Consequently, most hospitals bound by strict protocols and guidelines (Stapleton et al 2004) insist that all babies presenting as a breech be delivered by caesarean.

In most developed countries, less than 1% of all breech babies are born vaginally. Emphasis is now being placed on testing the efficacy of external cephalic version (ECV) in late pregnancy to reduce the incidence of breech presentation at the onset of labour (Hofmeyr 2002; Hofmeyr & Hannah 2002; New Zealand Guidelines Group 2004).

Sometimes a breech presentation is diagnosed late in labour. The lead midwife who finds a breech presentation should inform the woman of her findings and, as far as possible given the stage of labour, provide an evidence-informed, objective description of all possible outcomes, and follow guidelines/protocols concerned with consultation and referral. A breech presentation in labour presents a challenge for all midwives, especially those unfamiliar with vaginal breech birth. An emergency vaginal breech birth should not result from lack of care or expertise in diagnosis of the presentation in pregnancy and in labour.

Diagnosis

In late pregnancy or during labour, the breech baby may often be well 'engaged' in the pelvis and the fetal head positioned 'under the diaphragm' so that it is very difficult to identify on abdominal palpation. Real-time ultrasonography confirms the diagnosis and rules out hyper-extension of the head, hydrocephalus or footling or kneeling breech, all of which pose unacceptably high risks for a vaginal breech birth.

Types of breech presentation

There are three types of breech: legs extended at the knee (frank), 65%; both legs flexed at the hips and knees (complete), 10%; and a single or double footling breech—one or both feet are tucked underneath the buttocks, 25% (Fig 34.4).

Mechanisms of labour

The mechanisms of a right sacroanterior (RSA) position are as follows:

- The lie is longitudinal.
- The attitude is complete flexion.
- The presentation is breech.
- The position is RSA.
- The denominator is the sacrum.
- The presenting part is the right buttock.
- The bitrochanteric diameter of 10 cm enters the pelvis in the right oblique diameter of the pelvic brim.
- The sacrum points to the right iliopectineal eminence.

Descent occurs with increasing impaction of the buttocks. The right buttock reaches the pelvic floor and rotates forward into the pelvis one-eighth of a circle; internal rotation of

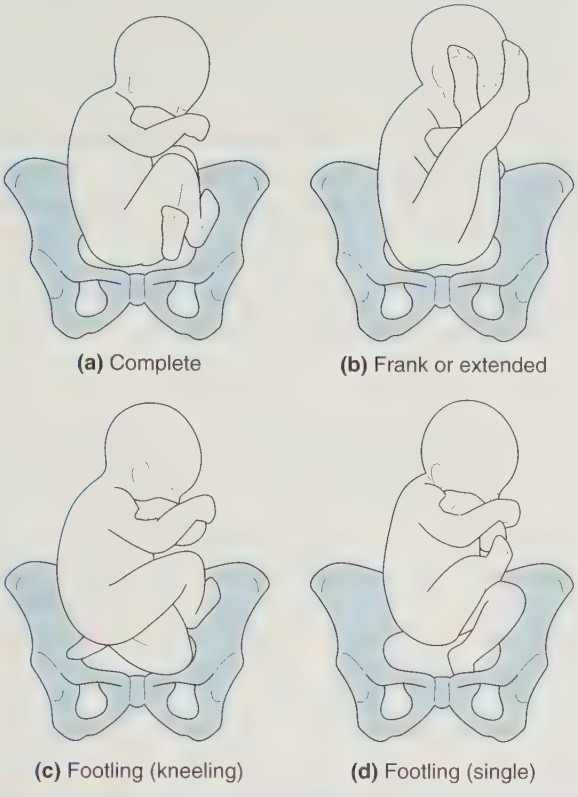

Figure 34.4 Breech presentations (based on Henderson & Macdonald 2004)

the buttocks occurs. The leading buttock escapes under the symphysis pubis; the posterior buttock sweeps the perineum and the buttocks are born by lateral flexion. Restitution of the buttocks now takes place. The anterior shoulder enters the pelvis in the same oblique diameter as the buttocks and rotates forwards one-eighth of a circle, escaping under the symphysis pubis. The posterior shoulder now sweeps the perineum and the shoulders are born. The head enters the pelvic brim in the transverse diameter; the occiput rotates forwards along the right side of the pelvis; at the same time external rotation of the body occurs so the back remains uppermost. The chin, face and sinciput sweep the perineum and the head is born in a flexed attitude.

Birthing a breech baby

Breech presentation is the most common malpresentation, occurring in about 4% of all births. The incidence is directly related to the gestational age of the fetus. Prematurity is the most common cause of breech presentation. At about 25 weeks gestation, more than 25% of babies present by the breech. By 34 weeks the incidence has decreased to 6% and by term to 3%. Other causes include: chance, parity, multiple births, uterine anomalies, placenta praevia; fetal anomalies (polyhydramnios, hydrocephalus, fetal neuromuscular disorders, macrosomia). The main causes of perinatal morbidity and mortality are: cord prolapse, intracranial haemorrhage, low Apgar scores, asphyxia, cervical spine injury, fractures of the long bones (humerus and femur), and fracture of the clavicle. Of note is that in the seventh *CESDI Report* (CESDI 2000), the single most important and avoidable factor in causing stillbirth and death in breech births was suboptimal care in labour. While it is true that a few babies presenting by the breech are born at home, it is generally accepted that because a breech is a malpresentation and therefore birthing a breech baby is outside the scope of midwifery practice except in an emergency situation, all babies diagnosed as a breech should be referred to a medical consultant for collaborative care in a hospital with facilities for caesarean section and ready access to a team of midwives, obstetrician, paediatrician and anaesthetist.

According to Varney (2004), before birthing a breech baby vaginally, nine criteria should be met:

- careful abdominal examination or sonography to rule out hyperextension of the fetal head, hydrocephalus or a footling breech
- complete cervical dilatation
- elimination of any doubts about the adequacy of the size of the pelvis
- emptying of the bladder
- consideration of whether or not to cut an episiotomy
- determination of effective pushing efforts
- preparation in place for a full-scale newborn resuscitation
- positioning of the woman so that there is plenty of room for lateral flexion and downward traction of the body, shoulders and finally the head
- consultation with an obstetrician, who should either be present or immediately available.

Labour and breech birth

Vaginal examination must be performed when a breech presentation is suspected, not only to establish that labour has commenced but to exclude a cord presentation, cord prolapse once the membranes rupture, as well as a foot, knee or compound presentation. When labour is well established, asking the woman to remain upright and mobile will greatly aid descent of the buttocks and dilatation of the cervix. Midwifery support and care during labour is no different from that for a cephalic presentation. Intermittent fetal monitoring is important and usually adequate, although many hospital institutions have protocols in place for continuous fetal monitoring. The membranes should be left intact; if they spontaneously rupture, then meconium is often seen and should not be considered a sign of fetal distress but a positive sign of descent of the buttocks. A vaginal examination is recommended before maternal pushing commences, as the buttocks may descend without the cervix being completely dilated, especially if the baby is small. Banks (1998), a midwife experienced in breech births, writes that 'the premature urge to push before full dilatation that is often mentioned to women as being problematic in breech births is unlikely to be noticeable in a term infant who will have a hip size in a flexed or extended legs position equal to head size' (p 70).

An upright position will aid descent of the baby once pushing begins in second stage but this should not commence until the buttocks distend the vulva. At this time the membranes should be ruptured if this has not already occurred, to reduce contact of meconium with the baby's after-coming head. As the buttocks are born it is possible to see the buttocks move 'up and down' just before crowning—this is known as 'rumping'.

Physiological birth of a breech baby

The midwifery adage, 'hands off the breech' and 'keep the back uppermost', holds true today. This is easier to achieve if the woman is in an upright position. If the baby's legs are extended they will not be released until the chest is born. Watchful patience will usually see the extended legs birth on their own but the midwife can bring the leg down if necessary by placing a thumb on the popliteal fossa with two fingers of the same hand over the baby's shin to bring down the leg. When the baby's head enters the pelvis, the fetal heart rate may drop as the umbilical cord is compressed between the mother's bony pelvis and the baby's head. Once this happens the baby needs to be birthed within six minutes and continuous pushing may be required to facilitate a timely birth. As the cord is now visible, the baby's heart rate can be checked by gently feeling its pulsations or the chest felt once that appears. The baby's head should be born slowly to avoid a tentorial tear. Wrapping a warm towel around the baby's bottom and gently supporting the body helps to stop the head from extending. Once the nape of the baby's neck is visible, the woman is asked to lean forward from the waist and this tilts her pelvis to aid clearance of the baby's nose and mouth from the perineum while the rest of the head is born slowly.

Various techniques can be used to deal with assisting the breech baby birth should this be necessary. These are rarely required if the woman maintains an upright standing or squatting position with patient birth supporters. Practising these manoeuvres using a doll and pelvis or mannequin can reduce fear of having to perform them in an emergency. For example, a flexed fetal arm can be bought down across the chest by use of the index and middle fingers splinting the baby's arm and bringing the arm down across its face 'like a cat washing its face' Banks (1998, p 88).

Delivering the after-coming head of a breech baby

Most vaginal birth breech babies born in hospital take place with the mother lying in a semi-recumbent position, often with an epidural in situ. According to the Canadian Consensus Statement (Society of Obstetricians and Gynaecologists of Canada (SOGC) 1994), there is no evidence that epidural analgesia is an essential component of vaginal breech birth. Induction or augmentation of labour are also justified (SOGC 1994). However, because of the increased risk of prolapsed umbilical cord if the membranes rupture and the presenting part does not fit snugly in the pelvis, so that the cord prolapses, hospital protocols often state that the woman should be encouraged to remain in bed, frequently with an electronic fetal monitor attached to her body. Similarly, because of the increased risks associated with breech births, the woman is often fasted and prepared for an immediate operative delivery.

As the baby begins to birth, it is crucial not to apply traction on the baby because this may deflex or extend the head, causing entrapment. The baby is allowed to 'hang'—hands off the breech! If the baby's back starts to rotate so that it is facing up, it can be gently rotated by two hands around the pelvic girdle so that the back remains uppermost (Fig 34.5). At this point the baby is again left to hang. When the scapulae deliver, the arms can be optionally swept across the chest and out of the birth canal, or they will birth spontaneously.

Mauriceau-Smellie-Veit

Delivery of the head should be by flexion, which ensures the same favourable diameters to delivery as with a cephalic presentation. A modified Mauriceau-Smellie-Veit (MSV, Fig 34.6) manoeuvre is used to flex the head. It is best to do this from a position below the baby, probably kneeling. One hand and forearm supports the baby's body, which straddles the arm, with the ring and index finger on the maxillae, the middle finger under the chin (not the mouth). An assistant may apply suprapubic pressure to maintain flexion of the occiput. The other hand is placed on the baby's back with a finger pushing down on the occiput to keep the head flexed. The head is delivered by drawing the baby downwards. Some traction on the shoulders by the upper hand may be required. As the head is delivered very slowly, the baby's body is kept in a neutral position in respect to the head and then gently raised in a large arc so that the child rests on the mother's abdomen.

Lovset manoeuvre

The Lovset manoeuvre (Fig 34.7) is particularly useful in the delivery of shoulders when the arms are extended, or in the presence of a nuchal arm. It involves a series of rotations combined with downward traction. Lateral flexion of the fetus is exaggerated to enable descent of the posterior shoulder below the sacral promontory. The midwife or obstetrician rotates the body 180°, always keeping the back uppermost—the posterior shoulder rotates anteriorly, and then lies beneath the symphysis pubis. The midwife then

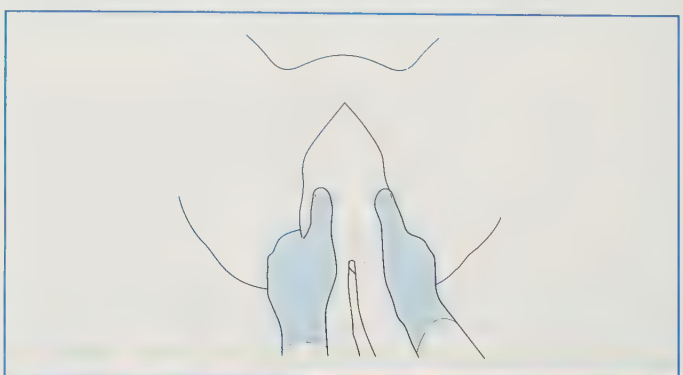

Figure 34.5 Breech birth

brings the arm downwards, then rotates the body back 180° in the opposite direction to deliver the second shoulder anteriorly once it too rotates to below the symphysis pubis. The other arm can now be delivered in the same way.

Complications of a breech birth

Complications of a breech birth are identified as cord prolapse, premature separation of the placenta, fetal hypoxia and an impacted breech when the baby is too large for the pelvis (Coates 2004). The breech baby is at risk of complications from mismanagement by the operator, such as Erb's palsy from damage to the brachial plexus when the neck is twisted, fractures of the clavicle, humerus or femur, or dislocation of hips or shoulders. Internal trauma can occur to the adrenal glands or rupture of the spleen or liver, again by grasping the baby's abdomen tightly. Some degree of bruising is to be expected, especially of the male genitalia, and so the parents should be reassured about this before the birth.

External cephalic version

Version or turning of the breech is a technique used to change a fetal presentation by abdominal or intrauterine manipulation. The latter, usually an 'internal podalic version', is rarely performed. It is used to convert the second twin from a transverse lie to a cephalic or breech presentation. In contrast, the procedure of external cephalic version (ECV) is becoming increasingly common. This section focuses on the use of ECV to turn a breech presentation to cephalic. Spontaneous version of a breech presentation occurs in about 20% of cases. In the remainder, an ECV is a useful technique to 'turn a breech', and has been practised since the time of Hippocrates. The efficacy of ECV has been rigorously appraised in six randomised controlled trials. There is a significant reduction in caesarean section in women where there is an intention to undertake ECV (Hofmeyr and Kulier 2000). Consequently, it is recommended that all women with an uncomplicated breech presentation be offered an ECV between 37 and 42 weeks of pregnancy (New

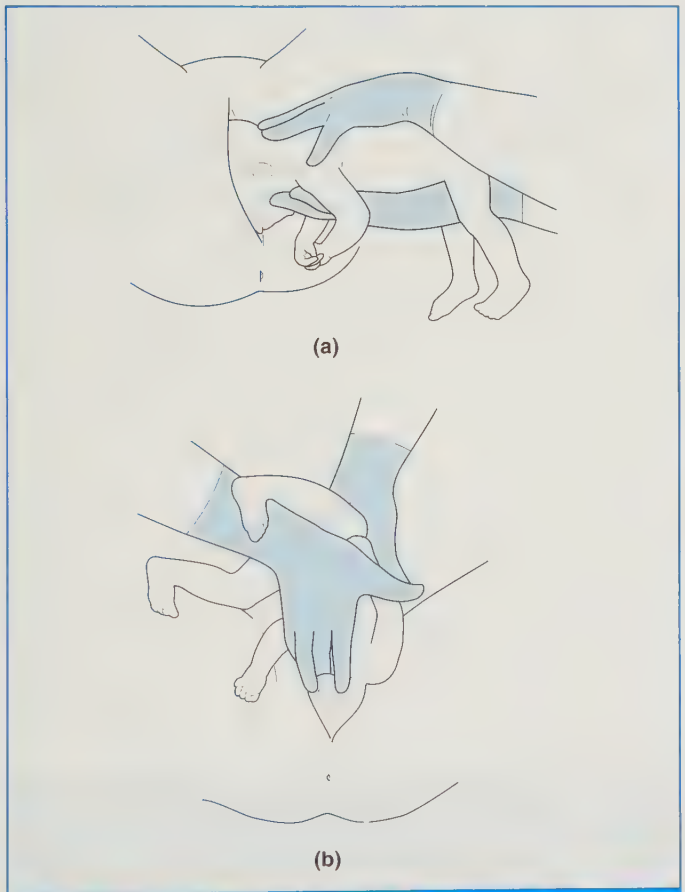

Figure 34.6 Mauriceau-Smellie Velt manoeuvre for delivering the after-coming head of breech presentation **(a)** The hands are in position before the body is lifted. **(b)** Extraction of the head

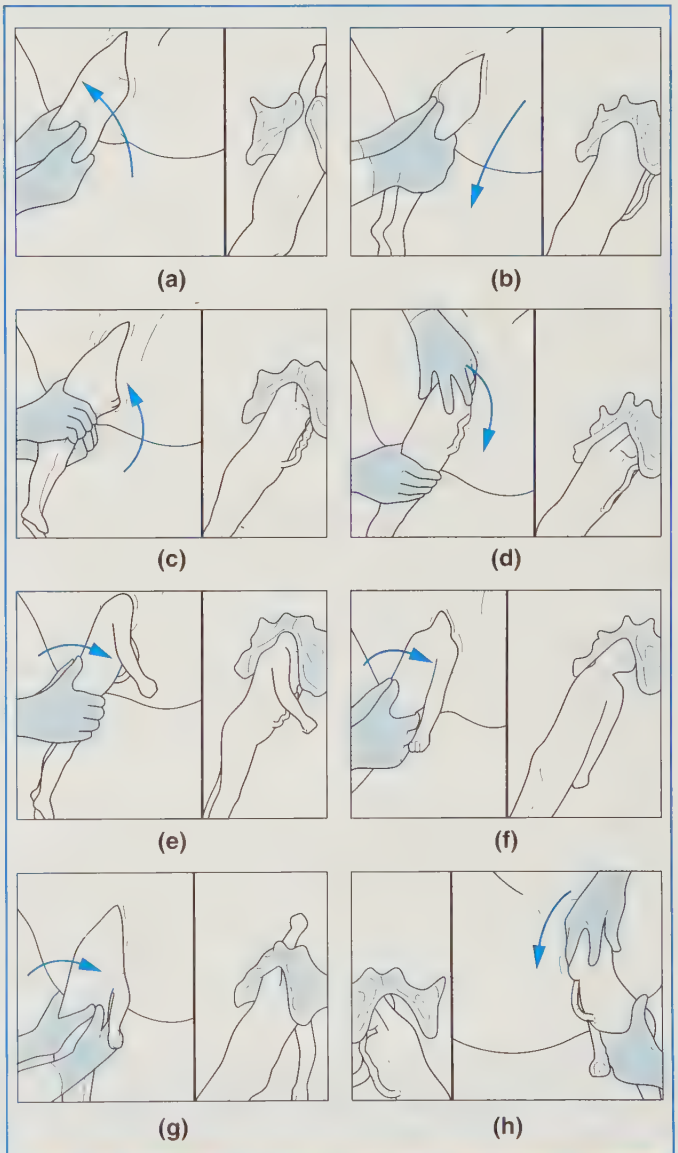

Figure 34.7 Lovset manoeuvre for delivery of extended arms (based on Fraser & Cooper 2003)

Zealand Guidelines Group 2004). Most versions are performed at about 37 weeks because at this stage most babies still in a breech position will not spontaneously revert to a cephalic presentation. In addition, if complications occur as a result of the ECV, the risk of preterm birth is eliminated.

Factors associated with a successful ECV

ECV is best carried out with the woman awake and facilities for emergency caesarean birth nearby. Lau and colleagues (1997) list nine factors that are good predictors of successful ECV:

- multiparity
- maternal weight
- placental site
- type of breech or presentation
- position of fetal spine
- adequate amniotic fluid volume
- engagement
- station of the breech at the pelvic brim
- estimated fetal weight.

Criteria for ECV

According to Hofmeyr and Kulier (2000), before an ECV is attempted, the following criteria should be met:

- The fetus must be a singleton.
- The breech must not be engaged.
- There must be adequate amniotic liquor.
- A reactive non-stress test (NST) should be obtained prior to the procedure.
- The fetus must be 36–37 weeks or more gestation.

Other authors such as Edelestone (2000) make the following recommendations:

- The woman should give informed consent for the procedure. She should be informed of the benefits and risks of ECV—failed version, reversion (2%), fetal stress related to cord entanglement or abruption, ruptured uterus and abruptio and unexplained fetal death. Benefits of a successful ECV (more than 50%) include decreased caesarean section rate. The woman and her support people also need information about alternatives to an ECV—postural exercises, moxibustion, visualisation.
- The ECV should only be performed in a maternity unit that can proceed to an immediate caesarean section.
- A real-time ultrasound should be performed prior to beginning the procedure to rule out placenta praevia and to confirm fetal presentation and position.
- A subcutaneous injection of a tocolytic drug such as terbutaline is administered to achieve uterine relaxation.

Contraindications for ECV

There are few absolute contraindications to ECV. These include any factors that may prevent successful vaginal birth, such as IUGR, multiple gestation, previous caesarean section, fetal or maternal compromise, placenta praevia and oligohydramnios and, of course, maternal refusal.

ECV procedure

The woman is admitted to a day-only unit or delivery suite in case an immediate caesarean section is necessary. Before the procedure begins, the obstetrician checks that the woman has given consent for the version and demonstrates that she understands the risks and benefits of the version and has all her questions answered. An ultrasound confirms that the baby is still in a breech position and that there is no evidence of congenital anomalies that preclude vaginal birth. An NST is performed for 20 minutes or until it is reactive. Maternal and fetal vital signs are recorded and documented. A tocolytic is sometimes administered according to the unit's protocols. The woman is placed in a supine position (with a wedge under her buttocks). Once she is relaxed, the obstetrician gently turns the baby by pushing the presenting part upwards, and the fetal head is pushed in the opposite direction towards the pelvis. This procedure should not be painful. After the version has been completed the CTG is reconnected and the FHR observed for signs of fetal compromise. If the woman is Rh-negative she will require one dose of immunoglobulin. Before she goes home, the woman should be asked to contact her lead

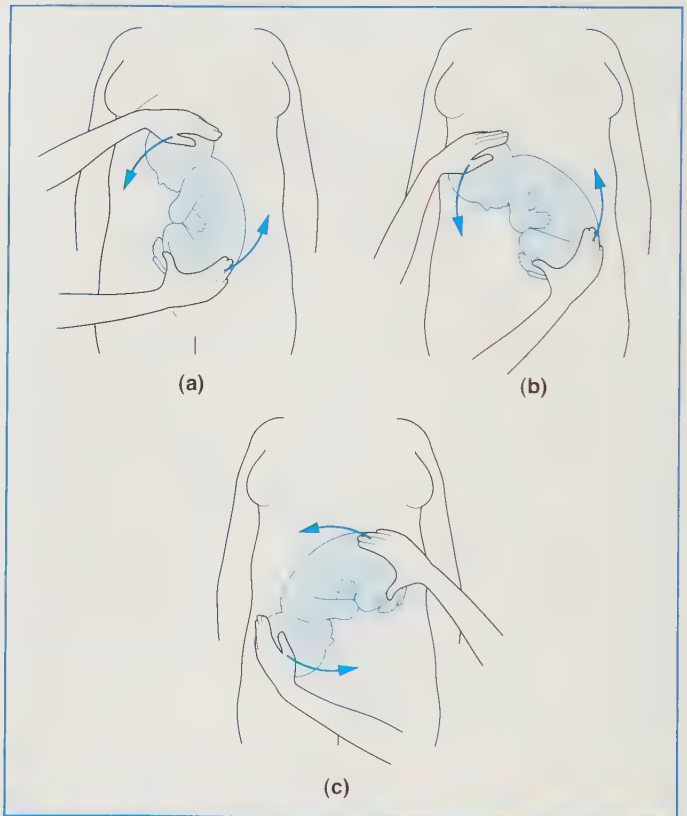

Figure 34.8 External cephalic version **(a)** The right hand lifts the breech out of the pelvis. The left hand makes the head follow the nose. Flexion of head and back is maintained throughout. **(b)** Flexion is continued. The left hand brings the head downwards. The right hand pushes the breech upwards. **(c)** Pressure is exerted on head and breech simultaneously until the head is lying at the pelvic brim (based on Fraser & Cooper 2003).

carer if there are signs of vaginal bleeding, if the membranes rupture, contractions begin or if she is worried about her own or the baby's wellbeing. Women are sometimes asked to complete a kick chart for 24 hours after the version. If the ECV is unsuccessful or if the fetus reverts to a breech, the version may be repeated in one week.

Alternative techniques to reduce the incidence of breech presentation

There is no evidence that postural management—'breech exercises'—are effective in converting a breech into a cephalic presentation (Hofmeyr & Kulier 2000). Similarly, although there is anecdotal evidence that moxibustion is effective in converting a breech into a cephalic presentation, there is as yet no firm evidence to support its use. On the other hand, there is no evidence that moxibustion is harmful. Moxibustion involves the application of a heated mixture made from the dried leaves of a herb, mugwort (*Artemis vulgaris*), directly to the designated meridian point (BL67), located beside the outer corner of the fifth toenail. Treatment may take from two to seven weeks. Alternatively, the heat from a burning moxa stick is used to warm acupuncture needles that have already been inserted in the appropriate meridian point. The heat and aroma of the mugwort is believed to stimulate the meridian point, so that energy moves through it, increasing fetal activity and encouraging the fetus to move to a cephalic presentation.

Shoulder presentation

This rare complication is associated with a transverse or oblique lie, where the long axis of the fetus lies transversely across the long axis of the mother's uterus (Fig 34.9). Causative factors include placenta praevia, fetal anomaly, lax multiparous uterus, polyhydramnios and uterine malformation. An abdominal palpation will reveal that the presenting part is the shoulder (in a compound presentation, the shoulder is presenting but a hand extends down into the vagina). The firm, ballottable fetal head is found near one iliac fossa and a softer mass on the other. It is important not to perform a vaginal examination until placenta previa has been excluded as the cause of the shoulder presentation. It is not possible to deliver a baby presenting by the shoulder vaginally and so the lead carer needs to inform the woman and her support persons of the diagnosis and, if necessary, arrange a referral for transfer to hospital for collaborative care.

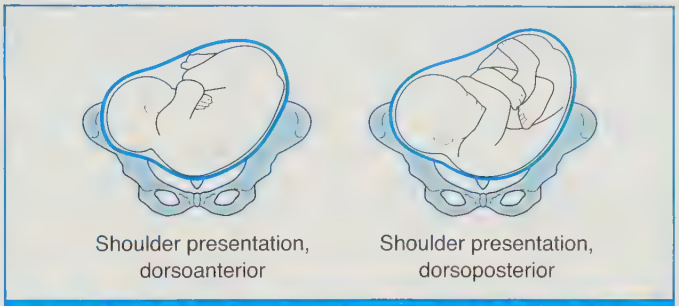

Figure 34.9 Shoulder presentation (based on Fraser & Cooper 2003)

An experienced obstetrician may choose to perform a cephalic version so that the fetal head lies over the pelvis, sometimes followed by an induction of labour with Syntocinon and an ARM. The fetal head is then pressed down into the pelvis as the liquor escapes. If the woman has commenced labour before the version can take place, an immediate emergency caesarean section is indicated.

Face and brow presentations

Face presentation

A face (mentum) presentation is also rare, occurring once in every 500 births (Parker & Napolitano 2005). The fetal head is in an attitude of extension rather than flexion; the denominator is the mentum (Fig 34.10). If the chin (mentum) is lying in the anterior quadrant of the pelvis (left mentoanterior (LMA) or right mentoanterior (RMA)), labour usually proceeds as with a normal vertex labour and vaginal birth is possible. This is because the widest diameter of the presenting part, the face, is similar (submental bregmatic, 9.5 cm) to the presenting diameter of an OA position (suboccipitobregmatic, 9.5 cm) and the neck easily glides around the symphysis pubis. A face presentation is rarely diagnosed before labour begins. Babies lying in a mentum posterior position, unless they rotate anteriorly, rarely achieve spontaneous vaginal birth because the chin wedges on the anterior surface of the sacrum. If the posterior position persists, an emergency caesarean section is necessary.

It is not possible to detect a face presentation by abdominal palpation but a vaginal examination will reveal the contours of the face, and often a mouth will suck incoming fingers. The midwife should be careful to lessen risks of facial and eye bruising during the examination and to take care that she excludes a breech presentation, because a soft breech and a face can often be confused.

Clinical point

On vaginal examination how would a midwife differentiate between a face and a frank breech presentation?

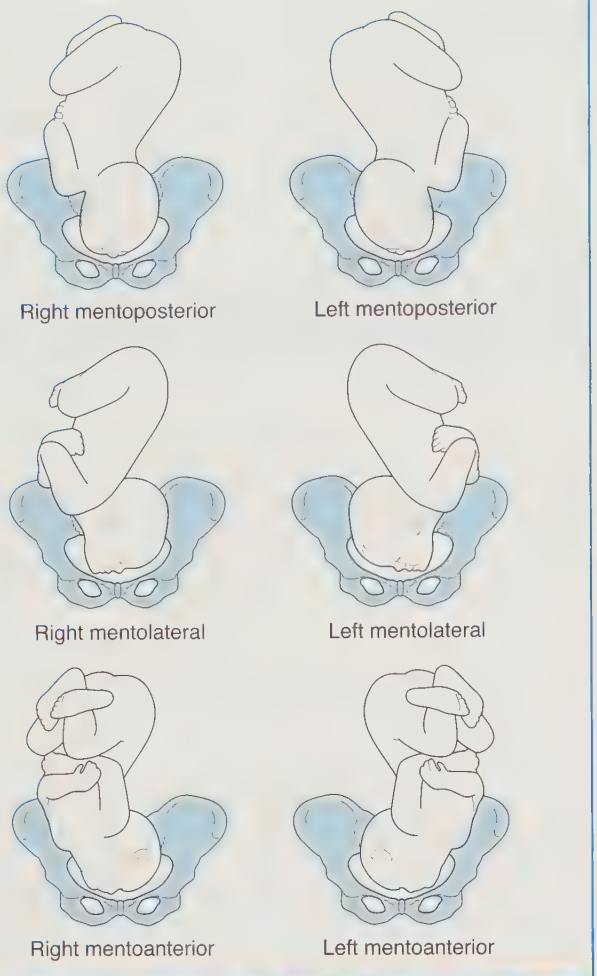

Figure 34.10 Face presentation (based on Fraser & Cooper 2003)

MIDWIFE'S STORY

I was supporting a woman in spontaneous labour with her third baby; labour was progressing well and abdominal palpation indicated a longitudinal lie and cephalic presentation. The baby's head was engaged and after the membranes ruptured physiologically and at the mother's request, I performed a vaginal examination to exclude a cord prolapse and to assess progress of labour. I had already examined her in early labour at home, again at her request, as she had been having the typical 'stop-start' labour with third babies so I knew it was a cephalic presentation. I had felt the bony head, and knew it was poorly applied to the 3 cm dilated cervix.

Now, five hours later and in hospital, the cervix was 8–9 cm dilated and I was very surprised to feel a nose and mouth. My first thought was, 'It's a breech', then, 'Don't be silly, it's a face'. I asked for midwife colleague support as I had not seen a face presentation birth before. Very shortly afterwards, the woman began to push strongly and the face birthed easily but she was very bruised as her 'lips came first'. The perineum was intact but the baby was quite small. We all reflected afterwards on how midwifery challenges us with variations of normal birth.

Understanding the 'mechanisms' of labour will help both midwife and mother deal with a face presentation.

The mechanism of labour for an RMA position is as follows:

- The lie is longitudinal.
- The attitude is one of extension of the head and back.
- The presentation is face.
- The position is right mentoanterior.
- The denominator is the mentum.

Descent occurs with increasing extension and the mentum becomes the leading part. Internal rotation of the head occurs as the chin meets the pelvic floor and rotates forward one-eighth of a circle, escaping under the symphysis pubis. Flexion occurs and the sinciput, vertex and occiput sweep the perineum and the head is born. Restitution takes place and the baby's chin faces the mother's right side. Internal rotation of the shoulders occurs as they enter the pelvis in the right oblique diameter; the anterior shoulder touches the pelvic floor and it too rotates forwards one-eighth of a circle along the left side of the pelvis. External rotation of the head takes place at the same time, with the chin rotating another one-eighth of a circle to the right. Lastly, the anterior shoulder escapes under the pelvic arch and the rest of the baby is born by lateral flexion.

Before birth, the parents need to be warned that their baby's head may remain in an extended position (head falls back) for a little while and that facial oedema and distortion of facial features, petechiae and ecchymoses will subside after 24 hours and completely disappear in a few days. If the mother consents, an injection of vitamin K for the baby is indicated.

Brow presentation

A brow presentation (Fig 34.11) occurs in only 1 in 1500 births (Parker & Napolitano 2005). The fetal head presents in a position midway between flexion and extension. The forehead (more precisely the glabella) is the presenting part. This means that the fetal head enters the pelvis with the widest diameter of the head (occipitomental, 13.5 cm) leading. Possible causative factors include multiparity, placenta praevia, uterine anomaly, hydramnios, prematurity, multiple births and macrosomia. It cannot reliably be detected before labour begins. Abdominal palpation may reveal a high fetal head that does not descend into the pelvis despite effective contractions and progressive dilatation of the cervix. Diagnosis is confirmed by vaginal examination; on vaginal examination, the midwife may detect the sagittal suture in a transverse or oblique position; the anterior fontanelle feels very large and orbital ridges are palpable. The mouth and chin are not palpable. These indicators are not easy to detect if a large caput succedaneum

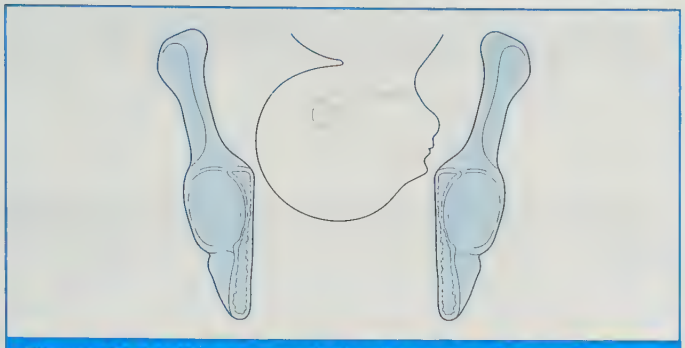

Figure 34.11 Brow presentation (based on Fraser & Cooper 2003)

has formed. There is no mechanism of labour for a brow presentation, unless the fetus is very small or it converts to a vertex or face presentation, and a caesarean section is often required.

BOX 34.3 Pelvic contracture

Clues to contracture of the maternal pelvis are:

- diagonal conjugate < 11.5 cm (contracture of inlet), outlet < 8 cm (contracture of the outlet)
- unengaged fetal head in early labour in primigravidas (consider contracture of inlet, malpresentation or malposition)
- hypotonic uterine contraction pattern (consider contracted pelvis)
- deflexion of fetal head (fetal head not flexed on fetal chest; may be associated with occipitoposterior)
- uncontrollable pushing prior to complete dilatation of cervix (may be associated with occipitoposterior)
- failure of fetal descent (consider contracture of the inlet, midpelvis or outlet)
- oedema of anterior portion (lip) of cervix (consider obstructed labour at the inlet).

(Source: Olds et al 2004)

Cephalo-pelvic disproportion

Cephalo-pelvic disproportion (CPD) is a disproportion between the size of the fetus and the size of the maternal pelvis—that is, the pelvis is not large enough to accommodate the passage of the fetus through the birth canal. CPD is usually relative because a pelvis that is adequate for a fetus weighing 2500 g may not be adequate for one weighing 3500 g. On the other hand, a healthy young woman in strong labour and effective contractions, who is not dehydrated and is coping well, may have a pelvis that accommodates a 4500 g fetus presenting as an LOA. In a second labour the same woman may be diagnosed with CPD because she has a malpresentation, an ineffective uterine action pattern, prolonged labour and is exhausted and disillusioned. This time her pelvis cannot accommodate a fetus weighing 3000 g. Therefore the adequacy of the pelvis must be re-evaluated with each pregnancy and birth.

In contrast, absolute CPD means that this fetus will never pass through the brim of the pelvis. In developed countries, it is most unusual to find a pelvis so severely contracted that labour is absolutely contraindicated. If this is the case, a caesarean section is the only option. Increasingly, midwives report that women tell them that they were told they needed an elective caesarean section because they had a 'big baby' and CPD. Clinical and ultrasound estimation of fetal size is often inaccurate, especially at the higher ranges of fetal weight. There is good evidence to suggest that estimation of fetal weight with ultrasound is no more accurate than estimations via abdominal palpation (American College of Obstetricians and Gynaecologists (ACOG) 2000a). Studies have shown that clinical estimation of fetal weight can be in error by a mean of 300 g (Zamorski & Biggs 2001). In most cases the only true test for relative CPD is labour—the so called 'trial of labour', a term that brings with it connotations of failure and inadequacy and should be avoided.

Care of the woman at risk of CPD

Absolute CPD in developed countries is rare and therefore all women should be encouraged to labour provided there are effective uterine contractions, the labour progresses, there is descent of the presenting part and progressive dilatation of the cervix, and both mother and baby are coping with the labour. If there are no signs of absolute CPD, but the uterine contractions are inefficient (fewer than three contractions in 10 minutes) augmentation with an ARM followed by an intravenous infusion of Syntocinon® may improve the effectiveness of the contractions and facilitate descent of the fetal head. Positioning (ambulation, standing, squatting) may help to maximise pelvic space and descent of the fetus through the pelvis. Avoiding the onset of exhaustion, judicious use of measures for pain relief, perhaps epidural analgesia, and prevention of dehydration and ketosis encourage effective uterine action. Careful assessment of the progress of labour, abdominal palpation to track descent of the presenting part (vaginal examination: presentation, position, attitude, dilatation, effacement, moulding and the presence of caput succedaneum), assessment of the contraction pattern and assessment of maternal and fetal wellbeing are essential components of midwifery support of the woman suspected of CPD. Ineffective contraction patterns, failure of the labour to progress, a poorly flexed head, oedematous cervix, increased fetal head moulding, asynclitism and slow or absent cervical dilatation are all signs that labour is obstructing and that an operative delivery is warranted unless it is managed appropriately.

According to Varney (2004), dysfunctional labour caused by CPD may result in the following tragedies:

- fetal damage (e.g. brain damage)

BOX 34.4 Cervical dilatation and CPD

Slow cervical dilatation may be an early warning of CPD in primigravidas, but may not be so in multiparas.

BOX 34.5 CPD or obstruction?

There is no sharp, easily discernable line between CPD and the onset of obstruction.

- fetal or neonatal death
- intrauterine infection
- uterine rupture
- maternal death.

The goal of all maternity care providers is birth to a healthy mother who is psychologically and emotionally ready to mother her well newborn infant, not a damaged baby and a severely traumatised mother. As Varney (2004) puts it: 'there are times when obstetric heroics with forceps or a vacuum extraction to satisfy the goal of a vaginal birth is not worth the price paid. Midwives should be just as well known for calling for a caesarean section when it is truly indicated as we are for promoting and facilitating vaginal birth'.

Obstructed labour

The term 'obstructed labour' indicates a failure of the labour to progress because of mechanical problems—there is a barrier to descent of the presenting part despite an effective contraction pattern. Most of the following causes of an obstructed labour are dealt with in earlier sections of this chapter. They are:

- deep transverse arrest
- cephalo-pelvic disproportion
- pelvic mass
- fetal abnormalities
- malpresentation.

Obstructed labour increases the risk of maternal and perinatal mortality and morbidity but is rare in developed nations, due to improved antenatal and labour support from qualified health professionals with access to well-equipped health services. In developed countries, more often than not an obstructed labour is the end result of a poorly managed labour, where clinicians have failed to detect absolute CPD or a malpresentation.

Clinical point

The midwife should be aware of the late signs that a labour is obstructing:

- no descent of the presenting part
- no further dilatation of the cervix, oedema of the cervix, poorly fitting presenting part
- severe moulding
- fetal compromise (caused by moulding, meconium-stained liquor, or offensive-smelling liquor)
- abnormal contraction pattern (weak, absent or hypertonic with very little resting phase). In primigravidas, uterine contractions will often cease, leading to 'secondary arrest'. In contrast, in multigravidas the uterine contractions try to overcome the obstruction and push the fetus through the pelvis. With each contraction, the myometrial fibres shorten (retraction) and the upper uterine segment becomes thicker and the lower segment progressively thinner. The junction between the two segments is known as a Bandl's pathological retraction ring (Fig 34.12). It is observed as a ridge of tissue lying obliquely across the abdomen and may be confused with a full bladder. General signs: maternal pyrexia, exhaustion, rapid pulse rate, anxiety.
- maternal abdominal tenderness over a Bandl's ring
- abdominal distension
- distended bladder, oliguria, bloodstained urine.

Uterine rupture after a previous caesarean section

Considerable attention has been given to assessing the risk of uterine rupture in subsequent pregnancies after a previous caesarean section. In 1916, Edward Craigin (1916) made his now famous statement: 'Once a caesarean always a caesarean', a dictum that still dominates obstetrics even though there is scant evidence to support it. His advice was probably influenced by the high rate of uterine rupture known to occur with the 'classic' or vertical uterine incision used at that time (Toppenberg & Block 2002). The introduction of a lower, non-contractile uterine segment caesarean section (LUSCS), improvements in maternity care and more reliable electronic fetal monitoring have made Craigin's dictum largely redundant.

Over the past 20 years in developed countries, the incidence of caesarean section has escalated from about 6% to 25% per year. Until recently, labour has been discouraged for women who have had a previous caesarean delivery (Guise et al 2004). There is still, however, a slightly increased risk of uterine rupture in subsequent births in a 'scarred uterus' irrespective of planned mode of delivery. Initial enthusiasm for VBAC (vaginal birth after caesarean section) has been tempered by reports of poor maternal and perinatal outcomes following attempts at a VBAC. Thus the proportion of women who attempt a VBAC after a prior caesarean delivery is again decreasing, largely because of alarm about issues of safety in general and uterine rupture in particular.

Clinical point

There are two types of uterine incisions for caesarean sections. A 'classical' or vertical incision involves the upper contractile uterine segment. The second type involves only the lower uterine segment. There may be a transverse (Pfannenstiel) or a vertical incision.

Why does a woman who needs an urgent caesarean section at 24 weeks gestation usually require a 'classical' (vertical) incision?

Landon and colleagues (2004) state that the absolute and relative risks associated with a trial of labour in women with a history of caesarean delivery, compared with elective repeated caesarean delivery without labour, are uncertain. The authors (Landon et al 2004) conducted a large, prospective four-year observational study of all women with a singleton pregnancy and a prior caesarean delivery at 19 teaching hospitals. Maternal and perinatal outcomes were compared between women who underwent a *trial of labour* (authors' emphasis) and women who had an elective repeated caesarean section prior to the onset of labour. The authors found that symptomatic uterine rupture occurred in 124 women who underwent a trial of labour (0.7%). Hypoxic–ischaemic encephalopathy occurred in none of the infants whose mothers underwent elective repeated caesarean delivery and in 12 infants born at term whose mothers underwent a trial of labour ($P < 0.001$). Of these 12, seven babies developed hypoxic–ischaemic encephalopathy after uterine rupture and there were two neonatal deaths. In addition, the rate of endometritis was somewhat higher in women undergoing a trial of labour than in women undergoing repeated elective caesarean delivery (2.9% vs 1.8%), as was the rate of blood transfusion (1.7% vs 1.0%). Neither the frequency of hysterectomy nor the rate of maternal death differed significantly between the groups (0.2% vs 0.3%, and 0.02% vs 0.04%, respectively). Given these results, the authors concluded that a trial of labour after prior caesarean delivery is associated with a greater perinatal risk than is elective repeated caesarean delivery without labour, although absolute risks were low.

In contrast, a systematic review of 568 articles concerned with the incidence and consequences of uterine rupture in women with previous caesarean section conducted by Guise et al (2004) concluded that although the literature on uterine rupture following an earlier caesarean section was imprecise and inconsistent, 7142 elective repeat caesarean section would need to be performed to prevent one rupture-related perinatal death, and 370 elective caesarean deliveries to prevent one symptomatic uterine rupture. In this review no maternal deaths were related to uterine rupture. In statistical terms, for women attempting a vaginal birth, the additional risk of perinatal death from rupture of a uterine scar was 1.4 per 10,000 births and the additional risk of hysterectomy following rupture was 3.4 per 10,000. The authors made the important point that most studies focus on the risk of uterine rupture in the VBAC group, assuming that a repeat caesarean section eliminates the risk of uterine rupture. However, elective caesarean section does not protect the woman from uterine rupture; the rates of asymptomatic uterine rupture do not differ significantly between VBAC and repeat caesarean section births.

Guise and colleagues (2004) comment that in two of the studies they reviewed, induction of labour with oxytocin was associated with a two- to four-fold increase of uterine rupture, although in the other reviewed studies the use of oxytocin or prostaglandins was not associated with a higher risk of uterine rupture. They make several other important points that women making choices about subsequent births after a caesarean section should reflect on. Indeed, all women considering an elective caesarean section should understand that any uterine scar increases the risk of uterine rupture irrespective of the mode of delivery; as many as a third of these ruptures will occur in pregnancy before labour begins (Toppenberg & Block 2002). However, a woman choosing VBAC faces an additional risk of uterine rupture of 0.27%. Thirdly, even if the rupture does occur, serious maternal and perinatal morbidity and mortality are rare. Therefore clinicians and women may wish to base their decisions on the likelihood of significant mortality or morbidity for the mother and baby rather than the uterine rupture itself (Guise et al 2004). Other causes of morbidity and mortality include risks from anaesthesia, inadvertent damage to the bladder and bowel, wound and uterine infection, haemorrhage, deep vein thrombosis and pulmonary oedema,

BOX 34.6 Uterine rupture

Conditions associated with uterine rupture:

- uterine scars
- prior caesarean section
- prior rupture
- trauma
- injury from instrumentation during an abortion
- significant myomectomy
- any cause of uterine perforation
- uterine anomalies (i.e. undeveloped uterine horn)
- prior invasive molar pregnancy
- history of placenta percreta or increta
- difficult forceps delivery
- malpresentation
- fetal anomaly
- obstructed labour
- induction of labour (suspected association)
- excessive uterine stimulation
- prostaglandins E_1 (misoprostol (Cytotec®))
- prostaglandins E_2 (dinaprostone (Cervidil®))
- oxytocin (pitocin), especially high infusion rates
- alkaloid/crack cocaine abuse.

(Source: Toppenberg & Block 2002)

as well as neonatal problems such as respiratory distress syndrome.

Detection and management

Timely detection and management are keys to the prevention and management of uterine rupture in labour.

In the past, clinicians were taught to look for classic signs of uterine rupture: the appearance of a Bandl's ring (an indication that the uterus may rupture at any time; Fig 34.12); sensation of sudden tearing uterine pain, abdominal or shoulder tip pain; cessation of uterine contractions, maternal shock, haemorrhage, andf regression of the fetus, signs of severe fetal compromise and fetal death (Toppenberg & Block 2002). It is now recognised that, apart from signs of fetal distress, these signs are unreliable and often absent, especially with the increased use of epidurals for VBAC births.

Because the presenting signs of uterine rupture are often non-specific (Toppenberg & Block 2002), management is often the same as for any other cause of severe fetal compromise. Delay in delivery may be catastrophic and both mother and baby may die. The woman is prepared for an immediate emergency caesarean section.

Before transport, resuscitation measures are put in place—adequate intravenous access, blood is taken for cross-match, and the emergency team (obstetricians, midwives, anaesthetist and paediatrician) is summoned.

In developed countries, maternal death is rare but the mother may die following a ruptured uterus from haemorrhage, infection and peritonitis. Perinatal outcomes depend on the speed with which the surgery can take place. The fetus may die from asphyxia, infection or irreversible brain damage. If they survive, most will require transfer to a neonatal nursery.

Neglected obstruction of labour and its aftermath

Many women, especially those living in developing countries, do not have access to health services that have the human and physical resources to perform an immediate caesarean section for an obstructed labour and impending uterine rupture. In Australia and New Zealand, clinicians do not see the effects of a neglected shoulder presentation, obstructed labour and uterine rupture, but these are common occurrences in many developing countries.

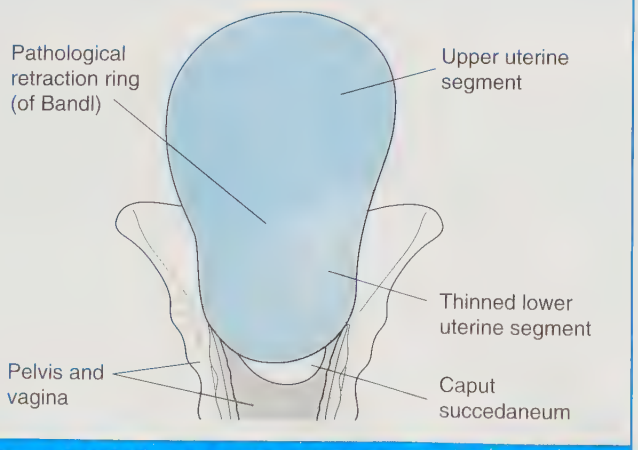

Figure 34.12 Bandl's pathological retraction ring (based on Oats & Abraham 2004)

Clinical point

Two types of uterine rupture may occur in a scarred uterus:

- *Catastrophic (symptomatic)*—the old scar separates along its length, the amniotic sac ruptures and the fetus is extruded into the abdominal cavity. There is significant bleeding and shock.
- *Asymptomatic*—more commonly, the scar dehisces part-way along its length, the amniotic membranes do not rupture, and so the fetus remains within the uterus. Bleeding and shock are minimal, and the fetus usually survives. This form of rupture may not be detected until subsequent births.

It is important to remember that rupture of a lower segment uterine scar, although a serious complication, is generally not catastrophic.

Clinical point

Prolonged late or variable fetal heart rate decelerations and bradycardia seen on an electronic fetal heart rate trace are the most common—and often the only—manifestation of uterine rupture (Toppenberg & Block 2002).

The prevalence of obstructed labour is more common in developing countries because of a lack of adequate health care services, poor nutrition and poverty (Konje & Ladipo 2000). In these countries, obstructed labour remains a frequent cause of maternal morbidity and death. If she survives, a primigravida may develop a vesico-vaginal fistula (between the bladder and vagina) or recto-vaginal fistula (between the rectum and vagina). In the famous fistula hospital in Ethiopia, 97% of vesico-vaginal fistulas occurred after obstructed labour; 65% of women were aged less than 25 years of age; and 63% were primigravida at the time of the labour (Kelly & Kwast 1993).

According to Konje and Ladipo (2000), prevention of this dreadful scourge can be achieved in the short term by identifying women at risk of obstructed labour and transferring them to centres with the resources to deal with obstruction of labour. In the long term, efforts need to centre on improving the health and nutrition of children and young women by detecting and treating diseases that lead to growth retardation. Early motherhood should be discouraged and strategies

to improve nutrition during infancy, childhood and early adulthood, and in pregnancy, put in place. Improving access to and promoting the use of reproductive and contraceptive services, including the prevention of HIV infections, will also help reduce the prevalence of this complication.

Induction of labour

Induction of labour is the artificial initiation of labour before its spontaneous onset, for the purpose of birthing the baby. The rate of induction varies between countries and between centres, and ranges from 10% to 30%. Enkin and colleagues (2000, p 375) make the point that 'the decision to bring pregnancy to an end before the spontaneous onset of labour is one of the most drastic ways of intervening in the natural history of pregnancy and childbirth'.

There are two forms of labour stimulation. The first, augmentation, has been discussed earlier in this chapter. It involves the stimulation of uterine contraction in a labour that has already begun. If the rhythms of labour are ineffective, contractions may be stimulated by augmenting labour with an ARM alone or in combination with an infusion of an oxytocic drug such as Syntocinon. It should only be used once non-invasive strategies, such as positioning and ambulation, emptying the bladder, relief of unbearable pain and anxiety (perhaps with hydrotherapy), and correcting dehydration and ketosis with fluid and nutrition, have been tried. In contrast, induction of labour refers to the artificial induction of labour with or without rupturing the amniotic sac before the spontaneous onset of labour for the purpose of accomplishing birth.

Clinical point

In an editorial in the *American Family Physician*, Elizabeth Baxley (2003) comments that induction of labour (social induction) is a common phenomenon in labour wards. Many women and their lead carers have valid reasons for wanting the 'labour to be brought on', including mutual convenience, logistic issues such as child care and transportation, and to ensure that a known and trusted caregiver will be present for the birth. As Baxley points out, since most induced births occur between the hours of 10.00 am and 8.00 pm, it is reasonable to presume that the obstetrician and staff will be alert and better able to respond to an emergency. However, she warns that elective induction is not without potential risks, including iatrogenic prematurity, uterine hyperstimulation, non-reassuring fetal heart rate tracing, and greater likelihood of operative delivery, shoulder dystocia and PPH. While these complications are rare in multiparous women, nulliparous women have significantly higher rates of caesarean delivery, instrumented delivery, epidural analgesia, and neonatal intensive care unit admission. Baxley concludes that because the risk of caesarean delivery with elective induction is potentially as high as 2.8 times that for spontaneous labour, it is difficult to advocate elective induction in a nulliparous woman.

Indications for induction

Induction of labour should only be performed if the health of both mother and baby would be compromised if pregnancy continues; that is, the benefits of imminent delivery outweigh the risks associated with the induction of labour. Table 34.1 summarises the indications for the induction of labour. Women are informed of the risks and benefits of an induction of labour as well as the difficulties associated with accurate determination of gestational age.

TABLE 34.1 Indications for induction of labour

Maternal	Fetal	Both
Prolonged pregnancy past 41 weeks	Severe congenital abnormalities	Placental abruption
Medical conditions, e.g. Type 1 diabetes, cardiac disease, reduced renal function, central nervous system disorders, pulmonary disease, antiphospholipid syndrome, chronic hypertension	Severe Rhesus isoimmunisation	Unstable lie
Prolonged and/or spontaneous rupture of membranes. Suspected or diagnosed chorioamnionitis	Fetal death	Complications of pregnancy, e.g. pre-eclampsia
Previous obstetric & reproductive history, e.g. previous stillborn baby, precipitate labour, cervical dystocia	Potential fetal compromise (significant growth restriction, oligohydramnios and placental insufficiency) Non-reassuring fetal surveillance	
Maternal request for social reasons, or logistic reasons		

Two indications for induction of labour have resulted in significant debate and controversy, and are discussed in more detail here.

Induction and post-date pregnancies

The most frequent indication for an induction of labour and the most difficult to assess is the so-called post-dates pregnancy. There is considerable confusion about the definitions of a term and a post-term pregnancy. Commonly accepted midwifery and obstetric language used to describe the indication for induction of labour from 37 completed weeks to 43 weeks gestation, include: 'term pregnancy', 'prolonged', 'post-mature', 'post-dates' and 'post-term', which many assume are synonymous albeit vague terms that differentiate between the 'normal' and 'abnormal' range of pregnancy. This terminology contributes to the confusion about options for optimum best care at this time.

Determining the woman's actual expected date of birth may not be easy. Records of the actual date of the first day of the last normal period, an appreciation of differing lengths of menstrual cycles and an accurate early scan dating may assist in this process. Two systematic reviews (Crowley 2003; Sanchez-Ramos et al 2003) report that routine ultrasonography in early pregnancy (even in 'low-risk' ones) reduced the number of women who needed their labours induced for apparent post-dates pregnancies. As the woman approaches 41 weeks of pregnancy, midwives need to have a conversation with her about the length of her pregnancy and the indications for induction of labour after 41 weeks. To aid informed choice and consent, full disclosure of potential risks associated with induction of labour needs to take place.

Despite evidence that actual benefits for the fetus from induction occur only after 41 completed weeks of pregnancy (Crowley 2003), inducing labour at term—38 weeks of gestation—is a commonly cited reason for inducing labour (Downe & McCourt 2004). A Cochrane Review by Crowley (2003) of 19 randomised controlled trials (RCTs) found that compared to a policy of expectant management, routine labour induction at 41 weeks gestation resulted in a decrease in perinatal deaths but similar caesarean section rates. Approximately 500 women needed to have their labours induced to prevent one perinatal death. Meconium-stained fluid was more common in the expectant management group, but rates of neonatal meconium aspiration syndrome and other similar morbidities were not significantly different between the two groups. In a more recent meta-analysis (Sanchez-Ramos et al 2003) of 16 RCTs comparing induction of labour at 41 weeks of pregnancy with a policy of expectant management, the women in the induction group were less likely to require a caesarean section. There was also a non-significant reduction in perinatal mortality in the induction group. The authors concluded that about 16,000 women would need to have their labours induced to detect a 50% reduction in perinatal mortality.

However, neither review (Crowley 2003; Sanchez-Ramos et al 2003) reported any adverse perinatal complications from labour induction of pregnancies greater than 40 weeks. Of significant interest for this chapter is that both reviews found that the results were consistent irrespective of the Bishop's score. An 'unfavourable' cervix at the time of the induction did not increase the number of caesarean sections or other adverse outcomes (Crowley 2003; Sanchez-Ramos et al 2003).

'Social' induction

Labour is sometimes induced for 'social' or 'geographic' reasons without a medical or obstetric indication. There have been no RCTs evaluating induction of labour for these reasons since 1983 (Crowley 2003). The induction of labour is not an isolated intervention. It frequently results in a cascade of interventions (see Box 34.7) that have the potential to negatively affect the childbirth process and its outcomes (Alexander et al 2000).

Contraindications for induction

All contraindications to spontaneous onset of labour and vaginal birth are also contraindications for the induction of labour. These include:

- maternal refusal
- any maternal or fetal condition that precludes vaginal birth
- malpresentation—transverse or oblique lie, compound or shoulder presentation
- previous major uterine surgery—'classical' caesarean section
- absolute cephalo-pelvic disproportion
- cord prolapse
- active genital herpes
- placenta previa
- invasive carcinoma of the cervix

BOX 34.7 Cascade of intervention

The cascade of intervention following induction of labour includes:

- intravenous lines
- enforced bed rest
- continuous electronic fetal heart rate monitoring
- amniotomy
- increased pain and discomfort
- epidural analgesia
- operative delivery
- prolonged hospital stay.

Clinical point

There is compelling evidence that elective induction of labour significantly increases the risk of caesarean section, especially for nulliparous women (ACOG 2000b).

- a severely compromised fetus.

Relative contraindications include:

- non-reassuring fetal heart rate trace
- breech presentation
- unknown fetal presentation
- multiple pregnancy
- polyhydramnios
- presenting part above the pelvic brim
- severe maternal hypertension
- maternal heart disease.

Risks of induction

Induction of labour is perceived by many midwives as the first step in an often irreversible cascade of interventions that ultimately culminates in an increased need for epidural analgesia, operative delivery and caesarean section, particularly among primigravid women. For example, in 2002 the New Zealand Maternal and Newborn Information System recorded a national induction rate of 19.7% (New Zealand Ministry of Health 2004) and a caesarean section rate of 22.7%. There were considerably more inductions for European women than for Maori, Pacific Island and Asian women. When induction of labour was combined with the use of epidural analgesia, only 44.4% had a normal vaginal birth and 31.2% required a caesarean section. However, for those women who did not require an epidural, the spontaneous birth rate increased to 77.6% and only 16.7% needed a caesarean section.

Prerequisites for induction

Induction of labour is associated with potential complications and so it should only be undertaken if there is a medical indication to do so and only after the woman has had the opportunity to make an informed decision about whether or not she wishes her labour to be induced and understands the risks and benefits of the procedure. The mother must be given full disclosure of the procedure, its risks and benefits, as well as information about the limitations of the birthing unit—for example, perhaps there is no 24-hour epidural service, or if she requires a caesarean section 'out of hours' she will have to be transferred to another hospital with these facilities. In addition, the following criteria should be met:

- There is documented evidence that the procedure has been discussed with the woman, that the risks and benefits of induction of her labour have been discussed and that she has given her consent for the procedure.
- There is a documented indication for the induction of labour as well as the presence of any contraindications.
- Parity is confirmed.
- The gestational age is confirmed.
- There is documented assessment of cervical favourability, fetal position and presentation and relationship of the fetal head to the pelvic brim.
- Membrane status has been assessed—intact or ruptured.
- The adequacy of the pelvis has been ascertained.
- The presence of uterine activity is known.
- The fetal heart rate has been recorded (NST).

Midwifery support prior to induction

Induction of labour may result in maternal feelings of loss of control, and loss of continuity of midwifery care if the maternity unit is some distance from the woman's place of residence, as well as other physical complications. Discussion about the indications for an induction of labour during pregnancy aids informed decision-making at a time when a woman who is already compromised in her ability to cope with the physical discomforts of late pregnancy is more vulnerable than usual to others' coercive decision-making.

The process of induction

There are various 'natural' methods for non-invasive induction of labour (Adair 2000; Kavanagh et al 2002; Kelly et al 2002; Smith & Crowther 2002). These include: cod liver oil; herbal remedies such as blue and black cohosh; acupuncture; nipple stimulation; sex (because semen has natural prostaglandins); and the use of raspberry leaf tea during the latter stages

MIDWIFE'S STORY

As a core midwife working in a tertiary maternity unit on the delivery suite, I was allocated a woman who was coming in from an outlying area at 0800 for an induction of labour. This was the first time I or the doctor on duty in the labour ward had met her. It was the woman's first baby and she was exactly 39 weeks gestation by sure dates. I welcomed her into the birthing room and completed her baseline observations, an abdominal palpation and assessment. Her uterine fundus was equal to dates; the baby was felt to be about 3500 g and on palpation I found a cephalic presentation with a right occipitolateral position, and a well-engaged flexed head deep in the pelvis. The baby's heart rate ranged from 120 to 140 bpm. Her baby had been moving well and there did not appear to be any medical indication for an induction of labour. I asked her what she understood was the reason for the induction and what she had been told about the procedure. She told me that her midwife, who was not in attendance due to distance, had made her a hospital appointment after seeing her at 40 weeks one week ago and she had been booked for induction today after seeing a doctor in another antenatal clinic three days before. She said that 'it was necessary to bring the labour on because she was overdue'. The woman gave no indication that she was aware she had alternative choices and options, or that she wanted to know about them. Nor did the woman seem to have much understanding about what was going to happen today or the risks and benefits of an induction of labour.

Reflection

Consider the above story and reflect on your responsibilities and subsequent actions, taking into consideration your philosophy of practice, research findings, hospital guidelines, Standards for Practice and Codes of Ethics. You might like to consider the ethical principle of 'best interests'.

of pregnancy. The risks and benefits of these methods are unknown because the quality of evidence is based on a long tradition of use and on anecdotal case reports rather than quality research. The only conclusion that can be drawn at this time is that the efficacy of all these interventions is still uncertain.

Both the New Zealand and Australian Colleges of Midwifery recommend that before using these therapies, the woman should seek advice from a registered therapist unless her midwife has undertaken a recognised education program that entitles her to use these treatments.

Bishop's score

Before induction takes place, assessment of the cervix to determine readiness for labour is essential, and is done using the Bishop's score (Bishop 1964). A Bishop's score (Table 34.2) is ascertained by assigning points to the parameters of cervical readiness (ripeness) for labour. The higher the Bishop's score, the greater the likelihood of a successful induction of labour. Although this is an attempt at objectivity, the care provider still makes a subjective assessment of the cervix. That is, she is still making a judgement that differs from that of another practitioner. Induction should not be attempted unless a mother has a favourable Bishop's score. If the cervix is unfavourable (Bishop's score is ≤ 6), cervical ripening prior to the induction with misoprostol (Cytotec®) or endogenous prostaglandin (PGE_2) to help ripen the cervix and improve the score is warranted, because if the cervix does not readily dilate then a long labour ending in a caesarean section with resulting potential complications is more likely (Enkin et al 2000). A score of eight or nine would indicate that the cervix was very ripe and induction has a high probability of success.

Pharmacological cervical ripening

Synthetic forms of prostaglandins—PGE_2 either as a gel or pessaries (dinaprostone: Prepidil®, Cervidil®, Prostin®)—are marketed for cervical ripening. Prostaglandins facilitate cervical ripening (softening and effacing the cervix) via a number of different mechanisms. The pre-labour production of PGE_2 by the amnion causes dissolution of the cervical collagen bundles and increases the activity of collagenase in the cervix, as well as the levels of elastin, glycosaminoglycan, dermatan sulphate and hyaluronic acid, thereby facilitating water absorption by the cervix, leading to a softer, more stretchable cervix. Relaxation of smooth muscle fibres facilitates cervical dilatation and may produce uterine contractions.

Types of PGE_2

Midwives should be aware of the clinical implications of each of the pharmacological agents used for cervical ripening. The types of exogenous PGE_2 are:

- intravaginal insert containing dinoprostone
- intracervical dinaprostone gels
- hospital compounded intravaginal gels.

A reactive NST should be obtained prior to the insertion of PGE_2 and the CTG trace is continued for at least half an hour after its insertion. Prostaglandins (PGE_2) as Prostin® comes as a 1 mg or 2 mg gel and is administered vaginally into the posterior fornix. The prescribed dose is determined by parity and the obstetrician's preferences, but the gel may be reapplied every 6–12 hours if necessary. The manufacturers recommend an initial dose of 1 mg followed by a second 1 mg or 2 mg dose six hours later if necessary, up to a maximum of three doses. The woman remains in a semi-recumbent position for several hours.

Cervidil® comes as a 10 mg controlled-release (over 10 hours) vaginal insert, which has a removable cord for easy removal if necessary. After administration, the woman must remain semi-recumbent for two hours before ambulating.

Misoprostol (Cytotec®) is a synthetic PGE_1 analogue. Although it has been suggested as a useful agent for pre-induction cervical ripening and labour induction, it has not been approved for use and should only be used in the context of clinical trials until it is approved by the appropriate authorities.

Complications

There have been no randomised trials evaluating the level or duration of fetal heart rate and uterine activity monitoring

TABLE 34.2 Bishop's score: pre-induction assessment of cervical ripening

	Score			
Examination findings	**0**	**1**	**2**	**3**
Dilatation (cm)	Closed	1–2	3–4	> 5
Effacement (%)	0-30	40–50	60–70	> 80
Station	3	2	1 or 0	+1, +2
Consistency	Firm	Medium	Soft	–
Position of cervix	Posterior	Midposition	Anterior	–

(Source: Bishop 1964)

post insertion of the gel. Uterine contractions usually start one hour after insertion and peak in the first four hours (Miller et al 1991). Uterine hyperstimulation with or without a non-reassuring fetal heart rate patterns occurs in a very small number of women. Other complications include gastrointestinal effects (nausea and diarrhoea), back pain, a warm feeling in the vagina and pyrexia. Treatment of uterine hyperstimulation includes: removing the gel, positioning the woman in the left lateral position and administering oxygen 6 L/min. A tocolytic drug such as a sub-cutaneous injection of 250 µg of terbutaline may be indicated.

Mechanical ways to ripen the cervix

Mechanical methods of cervical ripening share a similar mechanism of action: namely, local mechanical pressure stimulates the release of prostaglandins. They include Foley catheter (with or without extra-amniotic saline infusion), natural dilators (laminaria) and synthetic dilators. The risks associated with these methods include infection (endometritis and neonatal sepsis associated with natural osmotic dilators) (Kazzi et al 1982), antepartum bleeding and pre-labour membrane rupture.

Several RCTs have compared the use of a balloon device with administration of an extra-amniotic saline infusion, or prostaglandin E_2 (PGE_2). Results from these trials indicate that each of these methods is an effective means of cervical ripening with an unfavourable cervix and each has comparable caesarean-section delivery rates in women (Guinn et al 2000; Sherman et al 2001).

Membrane stripping/sweeping

This practice has long been advocated as a relatively non-invasive, albeit uncomfortable, means to induce labour. The amniotic fetal membrane is separated from the decidua of the lower uterine segment. It is believed that this process increases the release of $F_2\alpha$ prostaglandin production from the decidua and adjacent fetal membrane, thereby stimulating the onset of 'spontaneous' labour. According to the Cochrane Database (Boulvaine et al 2005), a review of 27 research trials demonstrates that this procedure does not appear to demonstrate clinically improved benefits when used to induce labour.

Induction of labour with oxytocin

Several options are available for labour induction. The ones considered here are amniotomy and oxytocin. Amniotomy is considered earlier in this chapter in the section on augmentation of labour. Intravenous oxytocin has been widely used to induce and augment labour for more than 50 years. Once the cervix is ripe, oxytocin is still the favoured pharmacological agent for inducing labour. Endogenous oxytocin, an octapeptide hormone, is secreted in the hypothalamus and transported to the posterior pituitary gland, where it is stored. It is chemically related to vasopressin (antidiuretic hormone, ADH). Its effects are enhanced by high levels of oestrogen—the highest levels occur just prior to term. Released in a pulsatile fashion, oxytocin stimulates both the frequency and strength of uterine contractions and has antidiuretic properties. Synthetic oxytocin—Syntocinon®—maintains these properties.

Low- and high-dose protocols for Syntocinon®

Oxytocin has been used for decades for induction of labour at term. It has a short biological half-life (10–12 minutes), making dosing easier than concomitant dosing with the PGE_2 dinaprostone (Cervidil®). Oxytocin has few adverse side-effects and therefore has been approved for use in the induction of labour at term. It should always be administered via an infusion pump and 'piggy-backed' to the main IV line and as close to the IV puncture site as possible.

There are a number of protocols for administering Syntocinon®. Studies indicate a wide range of effective dosages and change intervals, and no protocol has been shown to be clearly superior. The two commonly used protocols for dosage of oxytocin are the active or high-dose labour management protocol, and a low-dose one. There are variations between hospitals and so the ones provided here are examples of a 'typical protocol'.

The active management of labour (high-dose) protocol for Syntocinon® has been derived from the work of O'Driscoll and Meagher (1980). In rapid increments an oxytocin infusion is begun at 5–6 mU/min and increased by 5–6 mU/min to a maximum of 40 mU/min. A significant drawback to the protocol for active management of labour is the incidence of uterine hyperstimulation seen with rapid incremental dosing of oxytocin. Darwood (1995) noted that most women achieve adequate uterine activity with 12 mU/min of Syntocinon®.

The low-dose protocol for oxytocin was first advocated by Seitchik and Castillo (1982), who studied uterine hyperstimulation using both the active management of labour and low-dose oxytocin protocols. In a typical 'low-dose' approach, an infusion is prepared by placing 10 units of Syntocinon® in 1 L of an isotonic intravenous solution such as Hartmann's to achieve a concentration of 10 mU/mL. Because severe maternal hypotension or fetal compromise can occur with rapid bolus doses, the drug is 'piggy-backed' into the main IV line, and a controlled infusion pump *must* be used to determine its rate. The infusion is begun at 0.5–1 mU/min and increased every 30 to 60 minutes by 1 mU/min until adequate uterine contractions are established or until the infusion reaches 40 mU/min. The dose is always titrated according to the maternal–fetal response to the labour. The lowest dose possible to achieve adequate progress of labour is recommended. An effect is noted within three to five minutes, and a steady state is achieved within 15 to 30 minutes. Once the cervix is 6 cm dilated, often the oxytocin infusion can be reduced in similar decrements.

Contractions should not be closer than every two minutes. Low-dose protocol resulted in less uterine hyperstimulation and an overall decrease in induction to delivery time over a high-dose active labour management protocol. The disadvantage in the low-dose oxytocin protocol was the amount of time required to complete successful induction in nulliparous women with an 'unfavourable cervix'.

Complications

Oxytocin has a short half-life and is generally well tolerated by mother and baby, although induction of labour is never without some risk.

Hyperstimulation of the uterus, resulting in hypertonic uterine contractions, may occur (see Clinical point below). If this complication is not managed appropriately, the uterus may rupture. Because synthetic oxytocin is close to vasopressin in structure, it has an antidiuretic effect when given in high dosages (40 mU/min), and therefore water intoxication is a possibility in prolonged inductions—a strict input and output chart needs to be maintained.

When the uterine resting tone remains above 20 mmHg, uteroplacental insufficiency and fetal hypoxia can result. This complication underscores the importance of close FHR monitoring. There have as yet been no randomised trials of the level of fetal heart rate monitoring required for women whose labours are being induced. However, the need for close assessment of uterine activity and maternal and fetal wellbeing necessitates one-to-one midwifery care.

If fetal compromise is suspected, the oxytocin dosage can usually be lowered rather than stopped completely. This allows the fetus to recover without unnecessarily slowing the entire labour. Other steps include changing the mother's position, assessing maternal blood pressure, administering oxygen and increasing intravenous fluid administration. In emergency situations, the infusion is discontinued. A vaginal examination is performed to assess the progress of labour and rule out umbilical cord prolapse.

The intensity of uterine activity and the rapid and early onset of contractions, often from the start of labour, often means that the pain relief method of choice is frequently an epidural, and this too increases the likelihood of further interventions (Gilbert & Harmon 2003). An actively managed third stage of labour is recommended due to the increased risk of PPH.

Uterine hyperstimulation

Uterine hyperstimulation from the use of intravenous oxytocin or the administration of prostaglandins occurs in 1–5% of women (Kelly et al 2001). Other potential risks include an increased rate of operative delivery (Crowley 1995), caesarean birth (Seyb et al 1999), non-reassuring fetal heart rate patterns (Kelly et al 2001), uterine rupture (Flanelly et al 1993), delivery of preterm infant due to incorrect estimation of fetal maturity, and possible umbilical cord prolapse following an ARM when the fetal head is still above the pelvic brim.

Clinical point

Uterine hyperstimulation

Uterine hyperstimulation (five or more contractions in 10 minutes or lasting more than 90 seconds) results in decelerations in the fetal heart rate and/or other signs of fetal compromise.

If hyperstimulation occurs with signs of fetal compromise:

- Discontinue oxytocin infusion.
- Position the woman on her left side.
- Administer oxygen 10 L/min.
- Consider increasing infusion rate in the main line.
- Notify the lead carer.
- Prepare for possible caesarean section if the fetal heart rate does not return to normal.
- Consider tocolysis: IV nitroglycerine 50–200 mg, or 1–2 metered doses of a sub-lingual spray (400–800 mg); terbutaline 250 µg subcutaneously.
- If intrauterine resuscitation is successful, re-start oxytocin infusion at half the last dose.

Should hyperstimulation occur without fetal compromise, decrease infusion rate and reassess its effects on the uterine contraction pattern and the fetal heart rate. It may be possible to increase the infusion rate once the contraction pattern returns to its normal state.

Midwifery assessments for induction of labour

Before induction

Pre-induction assessments:

- Ensure that the woman has given informed consent for the labour to be induced.
- Identify indications for, contraindications to, or risk factors for the procedure.
- Determine lie, presentation of the fetus and the relationship of the fetal head to the pelvis.
- Ensure that the Bishop's score has been calculated.
- Assess amniotic membrane status.
- Obtain a baseline CTG if hospital policy requires this, and analyse it for non-reassuring features.
- Obtain baseline assessments of mother's blood pressure, pulse rate, temperature and respiratory rate.
- Assess for the onset of labour.

During induction

Midwives often question the feasibility of documenting maternal and fetal status every 15 minutes during an induction of the first stage of labour and every five minutes during the second stage. Automated devices are sometimes used to record the maternal blood pressure and pulse rate. The inaccuracies of these devices are well documented (Marx et al 1993). One study (Marx et al 1993) assessed the concordance of recording the blood pressure with an automated blood pressure device and those obtained with the auscultatory method. The authors concluded that in labouring women there is a discrepancy between systolic and diastolic pressures obtained by the auscultatory versus the oscillatory method of measurement, although mean pressures are not significantly different. They therefore recommended that during labour the diagnoses of hypertension and hypotension be based on the mean rather than the systolic or diastolic pressure.

Clinical point

Monitoring during induction of labour with oxytocin

- Administer the drug in the labour ward (or room) where the FHR and uterine activity can be monitored simultaneously.
- There is no clear evidence for continuous FHR monitoring, but because of the increased risks to mother and fetus, many units recommend continuous electronic FHR monitoring and evaluation every 15–30 minutes during the first stage of labour and every five minutes during the second stage.
- Before each increase in the rate of oxytocin infusion, assess FHR baseline, variability, presence of accelerations, periodic or non-periodic decelerations.
- Unless an intrauterine pressure transducer is in situ, the uterine contraction pattern should be manually palpated every 15–30 minutes.
- If intermittent auscultation is used, determine and record the FHR and palpate uterine contractions at least every 15 minutes during the first stage and at least every five minutes during the second stage.
- Maternal vital signs, response to contractions and urinary output are recorded either at each incremental dose of oxytocin or at least every four hours.
- Ascertain the mother's response to contractions.

Critical thinking exercise

You are a midwife in a busy maternity unit caring for Eunice (G3P2) during an induction of her labour. The induction began four hours ago. You examine Eunice and find that the fetal head is deeply engaged in the pelvis and ROA. The uterine contractions are occurring every three minutes; they are strong and last 70 seconds. The FHR shows average variability and there are no non-reassuring features, the fetal heart ranges from 130 bpm to 150 bpm. Eunice's cervix is 7 cm dilated and effaced and +1 below the ischial spines. The oxytocin infusion is now running at 6 mU/min (36 L/hr). Will you continue the same infusion rate? If yes, why and if no, why not?

Preterm labour

Preterm labour, or, as it is often referred to, premature labour (PTL), is defined as one that begins after 20 weeks but before 37 completed weeks of pregnancy (259 days). Most mortality and morbidity occurs in babies born before 34 weeks. Despite new diagnostic and therapeutic modalities, efforts to prevent the onset of PTL have largely been ineffective and it remains the leading cause of neonatal mortality and morbidity (Norwitz & Robinson 2001).

Epidemiology of preterm labour

Approximately 5–10% of all births are preterm. For example, the 2004 New Zealand Ministry of Health report of the Maternal and Newborn Information Services from 2002 showed a 7.4% rate of premature births, a slight increase from 7.2% in 1999 (NZMOH 2004). Preterm birth was the most common cause of death for babies in New Zealand in 2002. A similar pattern is apparent in other industrialised nations including Australia—the frequency has not decreased for more than 20 years; indeed, there is some evidence that it may be increasing (Challis 2001). The increased use of reproductive technologies and the escalating frequency of multiple births are the primary causes of this increase (Gilbert & Harmon 2003).

McNamara (2003, p 79) makes the important point that PTL is 'not a disease but an event, which may result from single or multiple, independent or interdependent pathways. Preterm labour is often the final step in a multifactorial process'. Although the actual cause of PTL is unknown, there are a number of identified risk factors and these can be divided into four main areas: reproductive history; biological/medical factors; current pregnancy; and socioeconomic, behavioural and stress-related factors. According to Haram et al (2003, p 690), the two strongest risk factors for idiopathic PTL are low socio-economic status and previous preterm birth. Approximately 85% of women with one previous preterm birth between 20 and 36 weeks of gestation will birth at term next time. After two preterm births, only 70% of women will deliver their next baby at term, although about 20% of preterm births are iatrogenic.

McNamara (2003, p 80) comments that the relationships between genetics, infection and preterm labour are continually under investigation because scientists believe that these may shed further light on the precise aetiology of preterm labour, either independently or in combination. In terms of other variables, such as socio-economic status, social behaviour and stress-related issues, research will need to re-examine whether these so-called 'social' issues are causal, or have confounding or modifying effects on other causal factors. These interrelationships seem to be the key to understanding the multiple interrelated aetiologies of preterm labour.

Prevention, identification and management

The identification of women at risk of PTL, and its prevention and management, have been widely studied and are important challenges in reducing the number of preterm births and improving outcomes for mothers and babies. Maternal health is not usually adversely influenced by preterm labour, although psychosocial morbidities are high and include increased levels of anxiety and the potential for feelings of failure unless there

BOX 34.8 Risk factors for premature delivery

Risk factors for premature delivery are:

- anaemia (haemoglobin <11 and S-ferritin 12–15 µg/L)
- abnormal uterine anatomy
- abruptio placentae
- cervix insufficiency
- drug use (heroin and cocaine)
- fetal anomalies
- iatrogenic
- infections (UTIs, infections caused by GBS, intrauterine infections, bacterial vaginosis)
- low maternal weight
- low social status
- multiple gestations
- placenta praevia
- polyhydramnios
- premature rupture of membranes
- previous preterm birth
- smoking
- stressful lifestyle
- young mother (< 15–19 years)
- domestic violence.

(Source: Haram et al 2003, p 689)

are medical and or obstetric indications such as pre-eclampsia or cardiac disease. The baby's ability to cope with extrauterine life depends greatly on the gestation at birth and significantly affects mortality and morbidity (Enkin et al 2000; Gilbert & Harmon 2003). Perinatal survival rates have improved substantially in recent years because of developments in neonatal technology, facilities and appropriately trained staff.

Assessing risk of PTL in pregnancy

Assessing a woman's risk of PTL and birth is part of the midwife's standard care in pregnancy. Beginning with an extensive booking history early in pregnancy, the midwife assesses for and documents risk factors for preterm labour and birth, making an appropriate early referral in consultation and with consent from the women to a specialist if necessary. Nevertheless, in 60% of cases PTL will occur in women with no risk factors. The midwife should inform the woman that if, at any time, signs of labour are apparent before 37 weeks she should contact the midwife immediately. This is of particular importance for women residing in rural areas with limited access to secondary or tertiary maternity and paediatric services, as TPL may mean a transfer of considerable distance to an appropriate facility.

Later, as her relationship with the woman grows, the midwife gathers information about the woman's past and present birthing, her physical and social histories including stressors (such as housing and food availability), social support, cultural safety, financial stressors, history of family violence, the presence of infections or the earlier diagnosis

Research

Effects of domestic violence on preterm birth and low birthweight (Neggers et al 2004)

Background: Domestic violence is increasingly recognised as a potentially modifiable risk factor for adverse pregnancy outcomes. This study evaluated the relationship between abuse during pregnancy or within the last year and low birthweight and preterm birth.

Methods: From 1997 to 2001, 3149 low-income, relatively low-risk pregnant women (82% African-American) participated in this prospective study. The Abuse Assessment Screen, which assesses emotional, physical or sexual abuse, injuries due to physical abuse and physical abuse in the index pregnancy, was completed by 3103 women.

Results: Of the women screened, 26.6% reported emotional abuse, 18.7% reported physical abuse in the past year and 10.3% women reported being beaten, bruised and threatened with a weapon or being permanently injured. Abuse during pregnancy was reported by 5.9% of the women. Low birthweight and preterm birth occurred in 10.9% and 10.2% of the pregnant women, respectively. Logistic regression analyses indicated that injury due to physical abuse within the past year was significantly associated with both low birthweight and preterm birth. The mean birthweight of infants born to women who were injured due to physical assault was significantly lower than the mean birthweight of infants of women who were not physically injured.

Clinical point

Many pregnant women experience symptoms that suggest preterm labour. These may include uterine contractions, changes in vaginal discharge, backaches, pelvic pressure, cramping and cervical dilatation. Not all symptomatic women will actually have a preterm birth.

of antiphospholipid syndrome, anticardiolipin antibodies and lupus anticoagulant antibodies as well as the presence of structural abnormalities.

Tests for preterm labour

No risk assessment tool has proved effective in lowering the incidence of PTL. The most common clinical tests used to determine the risk of PTL are transvaginal ultrasonography (TVS) to measure the length of the endocervix (the shorter the cervix the greater the risk of PTL and birth), and the cervicovaginal fibronectin (fFn) test. Among women with *symptoms* of PTL, cervicovaginal fibronectin appears to be the

Clinical point

Women are valuable resources in making diagnoses in relation to preterm labour but they must know what to expect. For example, some women can have 'spotting' in pregnancy and think this is not serious. Others may pass cramping or painful uterine contractions off as normal. Midwives need to help women acquire the knowledge they require in order to know when to contact their lead carer. All pregnant women should be able to recognise symptoms of preterm labour, which can be stimulated by:

- urinary tract infection
- diarrhoea
- dehydration
- laxatives.

most effective predictor of PTL (Haram et al 2003). In early pregnancy, fibronectin is normally found in cervicovaginal fluid but after 22 weeks it can no longer be found in normal vaginal secretions. It reappears two weeks before the onset of either preterm or term labour. Unfortunately, neither the fFn test nor TVS has proved its clinical usefulness as a *predictor* of PTL. Although there does not seem to be a role for either of these two procedures as routine screening tests for PTL, both have high negative predictive values and are useful in that they may help to prevent unnecessary intervention and family stress. A negative fFn means that there is a 95% probability that a woman will not begin labour for the next 7–10 days. This finding may provide the woman and her caregivers with the confidence to stay in her community and support for a decision not to commence immediate tocolytic therapy or administer corticosteroids to mature fetal lungs.

Signs of preterm labour

Accurate diagnosis of PTL is difficult. McNamara (2003, p 80) makes the point that 50% of women diagnosed with PTL do not go on to have a preterm birth. In the past this has been attributed to 'false' labour or an 'incorrect' diagnosis but this may not be the case. An alternative explanation is that 50% of PTLs do not result in preterm birth, which, as McNamara (2003) says, is a completely different issue.

Many of the early signs of PTL are common in normal pregnancy. They include:

- abdominal pain or increased painful or painless uterine contractions
- dull, low back pain
- painful menstrual-like cramps
- vaginal bleeding
- change in character of or increased vaginal discharge
- supra-pubic and pelvic pressure with a sensation of 'heaviness'
- urinary frequency
- diarrhoea.

Clinical point

Fetal fibronectin (fFn) is used to screen pregnant women who are within 26 weeks and 34 weeks of gestation and are having symptoms of premature labour. The test may be beneficial in predicting the risk of premature delivery.

The fetal fibronectin test should only be used on those who:

- have intact amniotic membranes
- have a cervix that has not dilated more than 3 cm
- do not have more than slight vaginal bleeding
- do not have cervical cerclage
- have not had sexual intercourse or a pelvic examination in the past 24 hours.

The fFn test is not recommended for screening asymptomatic women even if they are considered to be at high risk for premature labour and birth.

Collaborative support

When a woman who has not completed 37 weeks of pregnancy reports any of the above signs, she needs to be referred to a hospital-based specialist medical team who will decide whether she is in 'true' labour. The diagnosis of PTL is usually made in the presence of four uterine contractions in 20 minutes plus the presence of cervical changes—dilatation and effacement. A sterile speculum examination is performed to estimate cervical length and dilatation, look for signs of bleeding or amniotic liquor and obtain endocervical swabs for microbiological examination. If possible, digital vaginal examination is avoided. A CTG trace is useful to identify the presence of uterine contractions, and to assess fetal wellbeing. Fetal tachycardia and reduced baseline variability are often the first signs of maternal and fetal infection, such as chorioamnionitis. Nevertheless, interpretation of a CTG trace at early gestation is difficult. Diagnostic data that can be used to guide management decisions are:

- complete blood cell count with differential and platelet counts
- urinalysis for microscopy and sensitivity to rule out urinary tract infection
- cervical, high vaginal and ano-rectal swabs for bacterial vaginosis, gonorrheae, chlamydia and *Trichomonas vaginalis*, to rule out infection
- fetal surveillance studies to determine signs of fetal compromise
- ultrasonography to determine biometry, fetal size, presentation, amniotic fluid volume, fetal anomalies, placentography
- Doppler studies of the umbilical artery
- fibronectin evaluation
- transvaginal ultrasound to determine cervical length.

Ongoing care and support in preterm labour takes place in collaboration with midwifery, obstetric and paediatric secondary/tertiary services. Management depends on

gestation, the availability of neonatal intensive care unit (NICU), stage of labour, and evidence of complicating factors such as: cause of the preterm labour, viability of the fetus, presence of infection, state of the membranes, or maternal illness. Thus, if there is evidence of maternal or fetal infection, management centres on treating the infection and, if necessary, the administration of corticosteroids and tocolysis to inhibit labour so that the woman can be transferred to a Level III hospital with a NICU.

McNamara (2003, p 82) describes some of the critical issues concerned with PTL and maternal transport. She contends that the critical issue is the clarification of which team is 'sending' or 'receiving', and is responsible for the woman while she is in transit. McNamara (2003) makes the crucial point that the best location for a preterm birth is in a tertiary referral centre and the worst is in a transport vehicle en route to the hospital. The following factors influence decisions about when to transfer, how it will take place and where the woman will be transferred to:

- availability of NICU beds/neonatal care
- length of time before birth
- transfer time
- availability of space for the mother at a tertiary centre/perinatal care facility
- fetal weight
- gestational age
- availability of two qualified transporting staff—one for the mother and one for the baby—should complicated delivery take place en route
- cervical dilatation—reassess immediately prior to transport; if the cervix is > 6 cm dilated, transport is generally not advised (McNamara 2003, p 82).

Inhibition of preterm labour

In up to 50% of women, uterine contractions will stop spontaneously and the pregnancy will continue to term without any medical treatment. Clinicians need to discern those in whom drug therapy (tocolysis) is warranted and whether it is the drug of choice. Tocolytic therapy can successfully, albeit temporarily, inhibit labour. Its main function is to delay labour for 24–48 hours to enable the woman and her fetus to be transferred to a suitable facility and to allow maximal effect of corticosteroids used to induce pulmonary surfactant in the fetal lungs. Generally, if the pregnancy is between 24 and 34 weeks gestation, and the baby has an estimated weight of > 2500 g, it is not recommended that uterine action be suppressed with drug therapies. After 34 weeks it is reasonable to let labour continue.

A wide variety of drugs are used to inhibit uterine activity in TPL, and some have significant side-effects. These drugs should be used if the fetus is not viable, or if fetal wellbeing is in jeopardy, or if maternal health is severely compromised, such as with an abruption.

β-adrenergic receptor agents

The most common β-adrenergic receptor agents are ritodrine hydrochloride, salbutamol and terbutaline sulfate. These

Scenario

It is afternoon, you are recently qualified and the only midwife on duty in a rural health centre about 40 minutes from the nearest maternity unit. A woman arrives at the front door exhibiting signs of advanced labour. It is her third baby and she says she is 32 weeks pregnant. You take baseline observations, and assess the strength, length and regularity of her contractions, which appear to be two to three minutes apart, becoming expulsive and strong. Abdominal palpation reveals a breech presentation, deeply engaged, with a fetal heart rate of 140–160 bpm. There are no signs of bleeding and the membranes are intact.

You inform the woman and her support persons of your findings and what you plan to do, also taking into account her birth plan, which is rather sketchy at this stage. You resist the urge to panic, ask an enrolled nurse to quickly telephone the maternity unit and a medical practitioner for consultation. He suggests that you perform a vaginal examination to determine the degree of cervical dilatation and, depending on these findings, transfer the woman to the referral centre. The hospital contacts the referral team for you. Vaginal examination reveals that the woman's cervix is 8–9 cm dilated with a well-flexed breech presentation at the ischial spines. Shortly afterwards she begins to push, shouting loudly, 'I can't stop!' even though you advise her not to. Quickly you prepare for birth, heating the room and checking resuscitation equipment.

She stands up, the membranes rupture and the baby births, with you gently supporting the buttocks once they come out, to prevent sudden birth of the head and the added risk of a tentorial tear. The baby is born with Apgar scores of eight at one minute and nine at five minutes; the baby is carefully wrapped, and nestled close to mum's skin to keep warm. A physiological third stage occurs after five minutes, with minimal blood loss, then you carefully examine the baby, noting indicators for gestational age and signs of respiratory distress.

The paediatric retrieval team phones to tell you it is ten minutes away. Documentation is completed and you accompany the family to the hospital.

Reflection

On reflection, what would you have done differently? In this situation, what are your legal and professional responsibilities? Are there particular learning points for you in this story?

Clinical point

Tocolytics are only of value in about a quarter of preterm labours.

drugs are well known for their side-effects: tachycardia and pulmonary oedema, palpitations, headache, skin flushing, hyperkalaemia, hypotension, rarely right-sided heart failure, hyperglycaemia, fetal tachycardia, hypoglycaemia and hyperinsulinism.

Calcium channel blockers

Calcium channel blockers prevent the entry of calcium through cell membranes, which inhibits contractions of the smooth muscle of the uterus. Nifedipine (Adalat®) in slow release is an effective oral tocolytic agent and increasingly popular tocolytic. Side-effects are less distressing than those occurring with the β-adrenergic receptor agents. Maternal tachycardia, headache and dizziness are the most common. One regimen involves an initial dose of 10 mg sublingually every 20 minutes for three doses and then 10–30 mg every six hours orally.

Magnesium sulfate

Magnesium sulfate ($MgSO_4$) acts as a uterine muscle relaxant, by substituting for calcium. It is as effective as the β-adrenergic receptor agents but without many of their distressing side-effects and is the first line of choice in the United States. A loading dose of 4–6 g is given intravenously, followed by a maintenance dose of 2–6 g/hr until uterine contractions cease or signs of toxicity appear. Signs of toxicity include respiratory depression, absence of deep tendon reflexes, severe hypotension and eventually respiratory and cardiac arrest. $MgSO_4$ crosses the placenta, leading to reduced baseline variability and making interpretation of a CTG difficult.

Oxytocin antagonists

Atosiban (Tractocile®) has recently been developed to avoid the side-effects of some of the other tocolytic drugs but it is more expensive than the β-adrenergic receptor agents. It acts as an oxytocin antagonist. Its clinical efficacy is yet to be determined. A typical regimen is: IV bolus 6.75 mg then 300 μg/min IV for three hours, followed by 100 μg/min IV for up to 18–48 hours. Side-effects are nausea and vomiting, headache, chest pain and dysgeusia.

Antimicrobial therapy

The relationship between infection (chorioamnionitis, bacterial vaginosis, Group B streptococcal infections as well as urinary tract infection) and PTL is well documented. Consequently the use of therapeutic and prophylactic broad-spectrum antibiotics has become popular in some centres. Randomised studies and two meta-analyses have demonstrated that in the presence of ruptured membranes, especially in mothers who have Group B streptococcal infections, antibiotic therapy prolongs pregnancy and reduces the incidence of chorioamnionitis, and postpartum and neonatal sepsis. In a review of the literature, Kenyon et al (2004) concluded that the administration of antibiotics after pre-labour rupture of the membranes (PROM) is associated with a delay in delivery and a reduction in maternal and neonatal morbidity. The findings are not so clear in the presence of intact membranes (King & Flenady 2002). A review by King and Flenady for the Cochrane Database (2002) failed to demonstrate a clear overall benefit from prophylactic antibiotic treatment for preterm labour

Research activity

Coping with the stress of premature labour (Lowenkron 1999)

Preterm birth, the leading cause of perinatal morbidity and mortality in the United States, affects between 8% and 12% of all live births. Approximately 80% of preterm births are preceded by preterm labour. Significant progress has been made in the physical treatment of preterm labour; however, the psychological cost to women being treated needs further study. This study assessed the stress experienced by women treated at home for premature labour and to examine methods they used to cope. The theoretical framework was provided by Lazarus's model of Stress, Coping, and Emotion. A total of 50 women participated. Twenty responded to a questionnaire that included the Perceived Stress Scale (PSS) and the Ways of Coping Questionnaire only, 10 were interviewed only, and 20 completed the questionnaire and the interview.

Results: The women reported experiencing a moderate amount of stress. Their mean stress score was 26.75, just below the mean for the instrument (M = 28) and slightly less than the stress score of 27.52 reported by women experiencing a 'normal' pregnancy. Appraisal was assessed by analysing the data from the interviews. The women appraised their situation as both threatening and challenging. They described their emotional response most frequently as frustration because of fear concerning the pregnancy outcome, loss of control over their life, and inability to perform their usual roles of mother, wife and worker. The women reported on the Ways of Coping Questionnaire that they used strategies from three subscales to cope with the premature labour. Those subscales were Seeking Social Support, Planful Problem-Solving, and Positive Reappraisal.

Questions

After reading the abstract above, respond to the questions below as if you were explaining the study's findings to women attending childbirth parenting classes.

1 What is this study about?
2 How was the study done?
3 What were the results of the study?
4 What are its strengths and weaknesses?

When you have done that, ask yourself the next two questions:

5 What additional information do I need?
6 How can I use this study in my work?

with intact membranes on neonatal outcomes, and raised concerns about increased neonatal mortality in those infants who received antibiotics.

Midwifery support

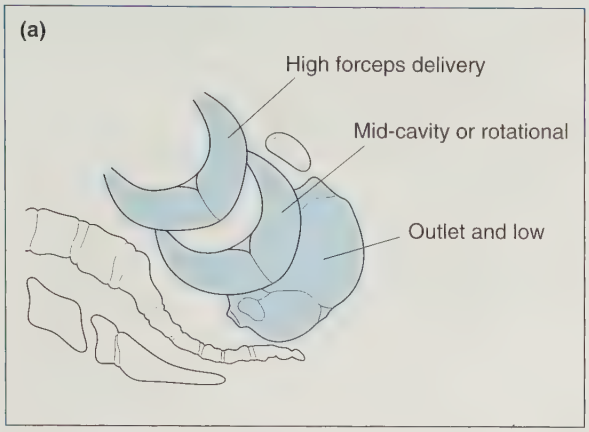
The midwife's role in supporting women at risk of or in PTL is to administer the prescribed treatments according to local protocols, make ongoing regular assessments of maternal and fetal wellbeing, provide psychological and emotional support, and take appropriate action if labour continues, ensuring that the documentation is up to date. If labour does proceed, tocolysis will be discontinued and the labouring woman will be offered labour support, and pain relief if required, although narcotic drugs are not recommended because of the respiratory suppressant effect upon the preterm baby. Midwives need to take the time to provide psychological as well as physical support and education on the processes of labour, especially if, as is often the case, no childbirth preparation sessions have been accessed.

Continuous CTG is usually recommended to monitor fetal wellbeing during labour to detect fetal compromise, as the premature baby has less tolerance to stress and has an increased risk of hypoxia at birth. The midwife should carefully observe and assess the woman in PTL as the progress of labour may vary from that expected of a term baby, and specialist help including a paediatrician should be present at the birth. Timely preparations for receiving and transfer to the newborn unit after immediate resuscitation is required. Preterm contractions are not as easily palpated as those at term and the CTG monitor will not accurately indicate the strength of contractions, which depend upon maternal position. There is no evidence to support IV hydration unless the woman is already dehydrated. Nor is there any evidence to support bed rest either in hospital or at home if labour 'stops'.

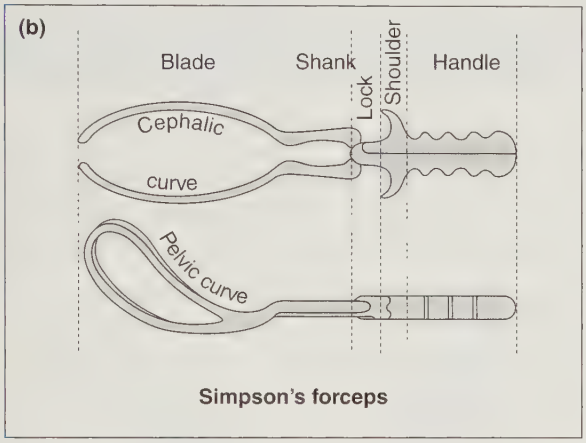
There is still controversy over the type of birth recommended for preterm babies. Caesarean section is often advocated, to decrease fetal trauma associated with vaginal birth, but these assumptions have never been substantiated (Atalla et al 2000). Moreover, an elective caesarean does not reduce fetal mortality or morbidity if the presentation is cephalic and the delivery may lead to additional complications. Labour debriefing is advised following preterm birth for mother and family/whanau to reduce the likelihood of post-traumatic stress disorder and other potential postnatal psychological complications.

Operative birth

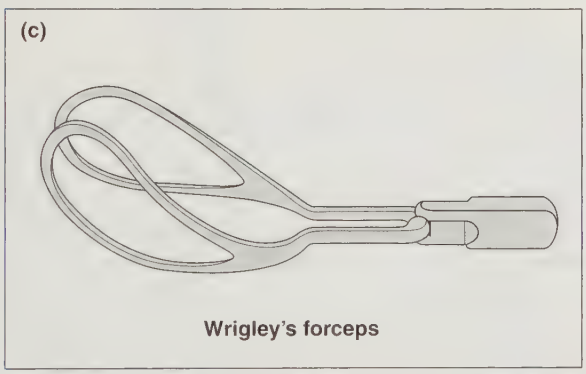
An operative or instrumental delivery is performed if it is necessary to expedite the birth of the baby. Chamberlain and Steer (1999) subdivide operative deliveries into abdominal methods (caesarean section) and vaginal assisted births (forceps deliveries and vacuum extractions). This section focuses on vaginal assisted deliveries. At present, both forceps and the vacuum extractor are in widespread use, although there is some evidence that, as the rate of caesarean section continues to rise, the incidence of forceps deliveries declines (Patel & Murphy 2004). Controversy continues concerning whether and when to conduct operative vaginal deliveries and which instruments are best. Currently as many as 25% of women in industrialised countries have a vaginal assisted birth. Both forceps and vacuum extractors (Ventouse) are acceptable and safe instruments for operative vaginal delivery. While the procedures fall outside the scope of midwifery practice, it is important that all clinicians understand the indications for an assisted vaginal delivery, the risks and benefits associated with both, and the principles of management.



Forceps



The history of obstetric forceps is long and colourful. Sanskrit writings from approximately 1500 BC contain evidence of single and paired instruments. These were designed to deliver the baby only after it had died. The credit for the invention of the precursor of the modern forceps used on live infants goes to Peter Chamberlen (1575–1628), an English man-midwife. The family kept his invention a secret for more than 100 years and only his sons were privy to their design and use. Even when the design became public knowledge, their use was restricted to man-midwives (the forerunner of today's obstetrician) and were used primarily as a measure to save the life of the mother once the fetus was dead. In 1845, Sir James Simpson developed a forceps that was designed to appropriately fit both cephalic and pelvic curves. According to Patel and Murphy (2004, p 1302), there are more than 700 types of obstetric forceps. Three of the most common are Wrigley's, Simpson's and Kielland's, used for rotational deliveries (Fig 34.13 (b) to (d)). Each of the three main types (outlet, mid-cavity or rotational) is designed for specific clinical situations and requires different levels of expertise (Fig 34.13 (a)). The criteria for an outlet forceps delivery are that the vertex (the bony skull) is visible at the introitus and the sagittal suture is in the anteroposterior position of the pelvis. For a low (outlet) forceps application, the vertex must be at station +2 or more below the ischial spines but on the pelvic floor. The fetus must be lying in an occipitoanterior position. In a mid-cavity delivery, which often requires rotation of the fetal head, the head must be engaged in the pelvis and the vertex positioned at station +1 or +2. There is no place for a 'high forceps'—the biparietal diameter of the fetal head is above the pelvic inlet—in modern obstetrics.



Structure of forceps

Forceps have four major components (Fig 34.13 (b)):

- *blades*—this is the portion of the instrument that fits around the fetal head (each blade is curved so that it fits around the head)
- *shanks*—these connect the blades to the handles and are either parallel or crossing
- *lock*—this is the articulation between the shanks
- *handles*—these are for the accoucheur to hold when applying traction to the fetal head.

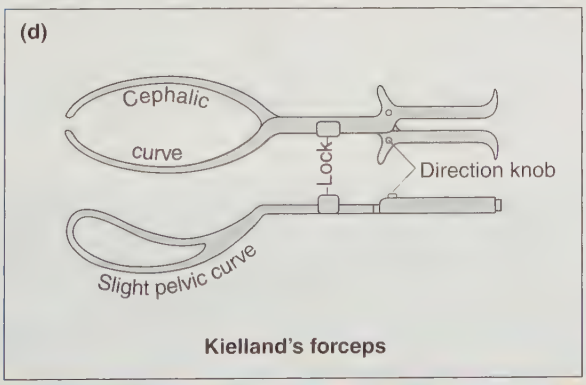


Figure 34.13 Obstetric forceps. Top panel shows the station of the head when the forceps is applied (based on Oats & Abraham 2004)

Indications for forceps delivery

Indications for the use of forceps include the presence of any condition that threatens the wellbeing of the mother or fetus if she proceeds to a spontaneous vaginal birth. Absolute and relative conditions that put the woman at risk include:

- maternal:
  - need for prophylactic shortening of the second stage of labour (cardiovascular disease and hypertension, including severe pre-eclampsia)
  - pulmonary oedema
  - infection
  - neurological disease (spinal cord injury, myasthenia gravis)
- obstetric:
  - maternal distress and exhaustion
  - malposition of the fetus
  - forceps to the after-coming head in a breech birth
  - controlled delivery of the head in a caesarean section
  - cord prolapse in the second stage of labour
  - lack of advance of the fetal head in the second stage of labour
  - dense epidural block (ineffective pushing efforts in second stage)
- fetal:
  - signs of fetal compromise (non-reassuring fetal heart rate)
  - placental abruption in the second stage.

Contraindications

Contraindications for forceps delivery include:

- incompletely dilated cervix
- unknown fetal position
- station higher than +1 or > 1/5 palpable abdominally
- inexperienced accoucheur
- evidence of absolute CPD.

Prerequisites

Prerequisites for forceps delivery include the following:

- As with any invasive procedure, the woman must consent to the procedure.
- Adequate anaesthesia must be administered.
- The head must be engaged in the pelvis.
- The station, presentation and position of the head must be known.
- The cervix must be fully dilated.
- The amniotic membranes must be ruptured.
- The bladder should be empty.
- There should be no evidence of absolute CPD.
- Episiotomy may be performed.
- Adequate facilities and supportive elements should be available.
- The accoucheur should be competent in the use of the instruments and the recognition and management of potential complications.
- The accoucheur should be prepared to stop (i.e. to not 'force the issue').

Critical thinking exercise

How will you respond to a woman who asks the folllowing questions?

- Why are forceps deliveries and vacuum extractions necessary?
- What can I do to avoid them?
- If I do need one, which is safer and less traumatic?
- If both are available to me, should I be the one to choose?

Research

Women's views on the impact of operative delivery in the second stage of labour: qualitative interview study (Murphy et al 2003)

This qualitative study aimed to obtain the views of British women on the impact of operative delivery in the second stage of labour. Results showed that the women felt unprepared for operative delivery and thought that their birth plan or antenatal classes had not catered adequately for this event. They emphasised the importance of maintaining an open mind about the management of labour. They had difficulty understanding the need for operative delivery despite a review by medical and midwifery staff before discharge. Operative delivery had a noticeable impact on women's views about future pregnancy and delivery. The authors concluded that women consider postnatal debriefing and medical review important deficiencies in current care. Those who experienced operative delivery in the second stage of labour would welcome the opportunity to have a later review of their intrapartum care, physical recovery, and management of future pregnancies.

Reflection

After reading the abstract above, reflect on how the authors' findings will lead you to make changes in your practice.

Complications

The medical literature contains considerable information about the risks and complications of forceps delivery. Reports of maternal and fetal complications vary depending on the skill and judgement of the accoucheur. The most common are associated with increased perineal and vaginal trauma (Patel & Murphy 2004). Other maternal complications associated with forceps-assisted vaginal deliveries are:

- postpartum haemorrhage (third stage should be actively managed)
- intrapartum rupture of the unscarred uterus
- late complications, which are mainly related to injury to the pelvic support tissues and organs, often leading to faecal and urinary incontinence.

Evidence evaluating neonatal morbidity is inconsistent (Patel & Murphy 2004). Neonatal complications include:

- transient facial forceps marks, bruising, lacerations and cephalohaematoma
- facial nerve palsy (cranial nerve VII)
- skull fractures, intracranial haemorrhage with falx, or tentorial lacerations
- an increased incidence of shoulder dystocia.

Vacuum extraction (Ventouse)

A vacuum extraction is an obstetric procedure used to facilitate the birth of the fetus by applying suction to the fetal head (Fig 34.14). The indications for its use are mostly the same as for a forceps delivery. However, it is contraindicated in preterm births and malpresentations including a face presentation. Cups are available in various sizes. Some (Bird) are metal and the newer ones consist of a plastic or silastic cup connected to silastic tubing, which in turn is attached to a hand- or foot-controlled pump or wall-connected device that produces the negative pressure necessary to create a vacuum (approximately 60–80 kPa or 600–800 cmH_2O). The suction creates an artificial caput or 'chignon' as the scalp is pulled into the cup (Fig 34.15). It is important that the accoucheur ensures that no

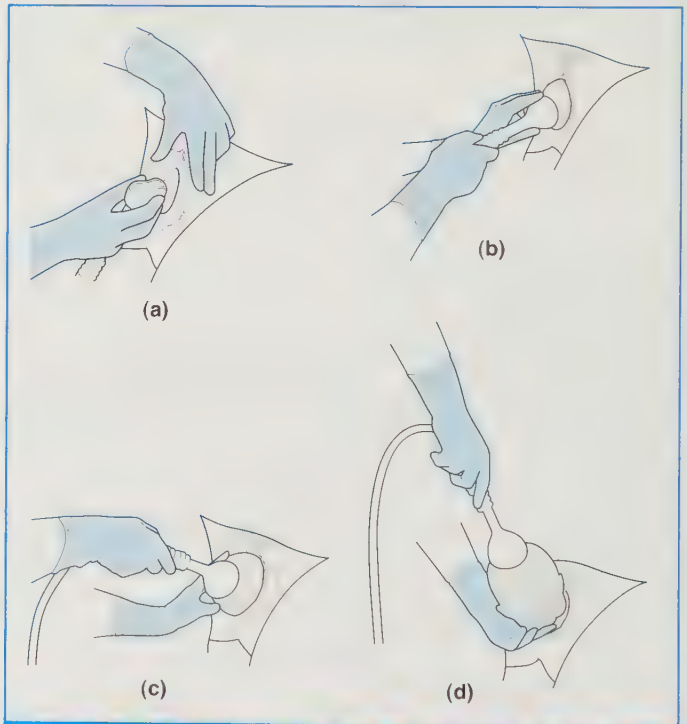

Figure 34.14 Ventouse extraction. **(a)** Application of the vacuum cup so that the centre of the cup is placed over the flexion point of the fetal skull (1 cm anterior to the posterior fontanelle). **(b)** to **(d)** With each contraction, traction is applied in a line perpendicular to the plane of the cup's ring. The fetal head is slowly lifted out of the vagina. Only two or three pulls should be required for the fetal head to birth. (based on Henderson & Macdonald 2004)

Figure 34.15 Baby with chignon (Henderson & Macdonald 2004)

vaginal tissue (if the cervix is not completely dilated) is caught by the cup. With maternal expulsive aid during contraction, the accoucheur applies traction to the fetal head. If there is no evidence of bony descent after three pulls, or if the baby is not born after 20 minutes, the procedure is stopped. Compared with forceps delivery, the vacuum extractor is associated with an increased incidence of neonatal cephalohaematoma, retinal haemorrhages and jaundice. Midwives should always remember that when the natural process and movements of birthing are disrupted, as with an instrumental delivery, there is always a higher risk of shoulder dystocia.

Mothers' perspectives on operative delivery

Most women anticipate a spontaneous vaginal birth in a joyous atmosphere, and so unexpected outcomes can often lead to disappointment and regret. Women's experience of birth determines their attitudes and feelings towards subsequent ones, and affects what they tell their daughters, friends and relatives. Murphy and colleagues (2003) (see Research box earlier) explored women's experiences of operative delivery in the second stage of labour. They explored how prepared the women felt for operative delivery, the perceived usefulness of their birth plan, their understanding of why operative delivery was needed, their views on debriefing after delivery, and their preferences for future pregnancy and delivery. Of significant interest to midwives is that while the vast majority had a good knowledge of the apparatus used for assisted birth, in more than 50% of cases this information was gathered from non-professional sources, such as magazines, books, friends, family and television. Most study participants made birth plans but these were poorly predictive of obstetric outcomes and, importantly, maternal satisfaction with their birth. The challenge is for midwives to ensure that in pregnancy, women are empowered to make informed choices about their care and that they have an opportunity to create realistic birth plans. Moreover, all women should be given the chance to discuss the events leading up to, during and after the birth. As one of the women in Murphy et al's (2003) study said, 'I'd like to have sat down and talked it through, but yes there are things that are left unanswered'(p 1134). Another said, 'The consultants came round but they never actually came and seen me' (Murphy et al 2003, p 1134).

Web activities

1. Use a search engine such as Google, PubMed or Ovid to research a specific complication discussed in this chapter.
2. Use the information you gain from these sites to help you create teaching–learning activities for the women you work in partnership with during pregnancy and birthing.

Review questions

1. How is the diagnosis of preterm labour made?
2. Discuss the advantages and disadvantages of forceps deliveries and vacuum extraction, including indications, procedures, complications and related midwifery support.
3. Discuss the advantages and disadvantages of amniotomy during a 'normal' labour.
4. How might midwives help women view external cephalic version positively?
5. Describe the impact of selected interventions in labour on the childbearing woman and her support team.
6. How might a midwife support a woman dealing with a slower than expected labour?
7. Should women be offered fluids during labour? Provide arguments for and against. If a woman asks your advice on this issue, what will you tell her?
8. What are the risks and benefits of vaginal birth following caesarean section (VBAC)? What information will you provide to a woman and her partner when asked about this procedure?
9. How do you describe the progress of labour? As an exercise, ask 10 of your colleagues how they recognise progress during labour.

Review questions—cont'd

10 You are asked to give a talk to a group of pregnant women about what to expect in terms of the progress or natural rhythm of labour. Outline the main points you would cover and provide references to back up the points you make.

CHAPTER 35

Interventions in pregnancy, labour and birth

Sally K Tracy

Key terms

dural tap, post dural puncture headache, acupuncture, admission trace, antenatal fetal surveillance, biophysical profile, birth asphyxia, blood patch, caesarean section (C section), cascade of intervention, caulophylum, combined spinal and epidural block, electronic fetal monitoring, epidural analgesia and anaesthesia, fetal blood sampling, induction of labour, intermittent auscultation, intrathecal injection, intravascular injection, antenatal cardiotocograph, non-stress tests, non-reassuring trace, opioids, patient-controlled epidural analgesia, post-neonatal cerebral palsy, spinal block, subdural injection, umbilical artery Doppler velocimetry, unfavourable cervix, vaginal birth after caesarean section

Chapter overview

In both New Zealand and Australia, only about two-thirds of all childbearing women have spontaneous vaginal births. Even though we live in an age of evidence-informed practice, offering women many interventions for which the evidence is either nonexistent or very weak has become almost routine. The difficulty for student midwives is in separating practices based on sound evidence from those driven by opinion, authority, dogma, market or business principles, or other needs. This chapter will discuss common interventions in pregnancy, labour and birth in the light of findings from recently published research.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe interventions in birth in relation to the normal physiology of birth
2. To explore the cascade of intervention in pregnancy, labour and birth, including the known benefits and harms of each intervention
3. To outline the aetiology of cerebral palsy
4. To explore how various interventions contribute to antenatal surveillance in pregnancy
5. To explore the use of electronic fetal monitoring and the cardiotocograph in labour, including indications and contraindications in relation to current evidence and best practice
6. To discuss the reasons for induction of labour in relation to the current evidence and best practice models, and to identify the outcomes associated with induction of labour
7. To outline the use of augmentation of labour
8. To describe the implications of epidurals and combined spinal epidurals for labour and birth
9. To explore indications and outcomes of caesarean section deliveries.

Introduction

Routine use of interventions during pregnancy, labour and childbirth is common in both Australia and New Zealand. These interventions include electronic fetal monitoring, epidurals, oxytocin, episiotomies, instrumental birth with either forceps or vacuum, and caesarean section.

Evidence is available to guide practice on a number of interventions during pregnancy, labour and childbirth, such as: restricting the use of episiotomy; promotion or discontinuation of active management of the third stage of labour; routine use of 10 units of oxytocin; routine amniotomy; continuous electronic fetal heart rate (FHR) monitoring; epidural analgesia; and use of oxytocin–ergometrine to prevent postpartum haemorrhage. However, there is no evidence for the routine use of many interventions and technologies such as electronic fetal monitoring, epidurals, oxytocin or episiotomies in women who have normal, uncomplicated pregnancies. Evidence does exist for alternatives such as intermittent auscultation of the fetal heart, non-pharmacological measures for pain relief, low-technology strategies such as walking and baths for comfort and stimulation in labour. Further evidence is required on how women cope emotionally with the consequences of labour interventions.

As confusing as this may seem, there are several other factors worth considering. Physiologists claim that a woman should not be removed from her safe environment for labour because this will invariably result in inhibition of uterine contractions. We are advised that the safest way to help labouring women is to 'respect nature and not to interfere with spontaneous events unless there is clear evidence that to do so would be beneficial' (Naaktgeboren 1989). However, there is an opposing view that labour might be best avoided altogether and women delivered routinely by abdominal operation (Hannah 2004).

Avoiding unnecessary intervention

There are two golden rules for midwives faced with the plethora of routine interventions found in most hospitals in New Zealand and Australia today:

- There must be a good reason for intervening in a woman's labour. This means that you must be able to describe and support with good evidence the 'clinical indications' that require you to do anything that would interfere with the normal physiological process of labour and birth. Then you must weigh up the evidence to show that the intervention you are about to undertake will not cause more harm than good.
- By supporting a woman fully with appropriate and adequate information, you will find that many unnecessary interventions can be avoided.

Much of the intervention that is routinely used in hospitals today evolved from the use of technology to 'save' mothers or babies when they were in distress during birth. 'Distress' itself is a subjective term and now there are parameters—or measurements—that enable us to see whether or not a woman may need medical intervention. Figure 35.1 shows an 'intervention clock', which was presented in the journal *Birth* in 1991. Even though it is over 20 years old, it still resonates for many of us. Twenty years ago, Iain Chalmers described the need to intervene in pregnancy and childbirth in terms of a 'decision to intervene' clock: 'As you go around the clock ... from unambiguous 'need' at 1 o'clock to 'commercial interests' at 11 o'clock, the factors that influence the decision to intervene become less and less defensible' (Chalmers 1991, p 137). Several published studies demonstrate that there is still a need to question the effect of non-clinical factors on the rates of operative intervention during childbirth (Carey 1990; Roberts et al 2000; Shorten and Shorten 1999).

There are two other influences that must be considered when addressing the rates and role of intervention in childbirth: the 'seductive' nature of technology, and the belief that all forms of intervention will avert or prevent an adverse outcome such as brain damage or cerebral palsy. Our technocratic society places great value on intervention and the use of machines and monitors, and as a result, midwives and obstetricians are confronted with an ever-expanding array of technologies, both reproductive and information-based, that have a significant impact on the level and nature of care provided.

Cerebral palsy

A major influence on the use of intervention was the belief until very recently that intervention in birth would be effective in preventing cerebral palsy (Blair & Stanley 1997). In some cases this may be so, but the birth prevalence of cerebral palsy

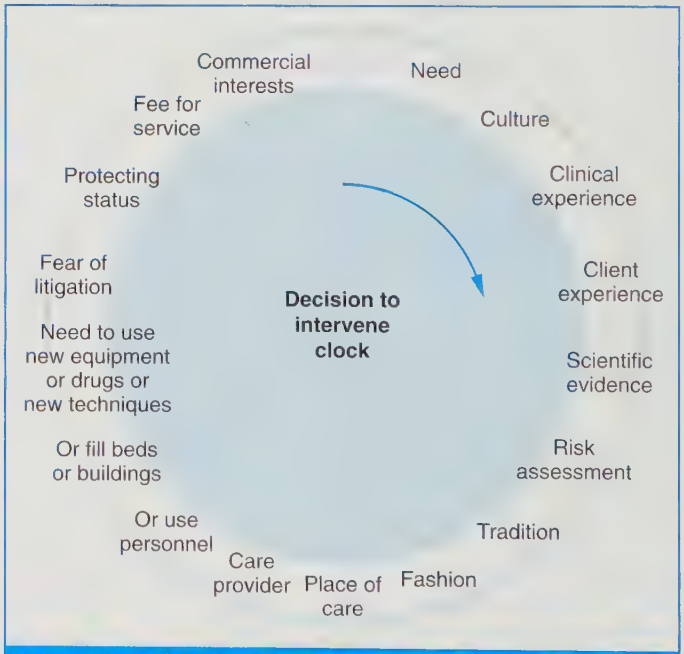

Figure 35.1 The 'decision to intervene' clock (based on Chalmers 1991)

in the developed world has not declined since the mid-1950s, in contrast to perinatal mortality. In developed countries, the majority of aetiological paths are likely to commence before labour and birth. Approximately 10% of cases are believed to now be causally associated with adverse intrapartum events. This is less than the proportion traditionally assumed to be due to intrapartum damage, and less than the proportion caused post-neonatally (after the baby is born) (Blair & Stanley 1997).

Cerebral palsy (CP) is a term of convenience applied to a group of motor disorders or motor impairment, stemming from a malfunction of the brain (rather than spinal cord or muscles). CP refers to brain malfunction that is non-progressive and manifests early in life. It is not a diagnosis, because it infers nothing about pathology, aetiology or prognosis. It is an umbrella term covering a wide range of cerebral disorders that result in childhood motor impairment (Badawi et al 1998).

In a study that reviewed data from the Western Australian Cerebral Palsy Register, three major areas were examined, to see:

- if the prevalence of cerebral palsy has fallen with increasing use of obstetric and neonatal interventions aimed at reducing birth asphyxia
- if there is any evidence that cerebral palsy is caused by birth asphyxia
- if there is any evidence that intrapartum fetal monitoring or caesarean section reduces the prevalence of cerebral palsy.

The study found that that:

- cerebral palsy proportions are not falling in spite of significant increases in obstetric and neonatal interventions aimed at reducing asphyxia
- cerebral palsy proportions in low birthweight infants are rising in most developed countries, coincident with increases in the neonatal survival of low birthweight babies
- few cases of cerebral palsy seem to be caused by birth asphyxia, and those that are may not have been preventable by obstetric care.

The study concluded that parents will continue to sue if obstetricians keep promising perfection from obstetric care in the face of 2.0–2.5 cases of cerebral palsy per 1000 children born (Stanley & Blair 1991).

In pregnancy, the risk of cerebral palsy is inversely associated with birthweight ratio (Blair & Stanley 1997; Palmer et al 1995). Researchers agree, however, that it is not low birthweight alone that increases the risk of cerebral palsy, but rather, birthweight in association with intrauterine growth restriction (Blair & Stanley 1997).

Primary antenatal causes of cerebral palsy are thought to be:

- intrauterine viral infections (Stanley et al 1986)
- iodine deficiency (Pharoah et al 1971)
- exposure to methyl mercury during pregnancy (Amin-Zaki et al 1979; Murakami 1972).
- maternal thyroid abnormalities (Blair & Stanley 1993).

More recent suggestions support a causal role for chorioamnionitis (Leviton 1993).

Some causes of poor growth may interfere with brain development, or it may be that a previously brain-damaged fetus moves and grows less well (Blair & Stanley 1997). Multiple birth is also strongly associated with cerebral palsy, and the risk increases with the number of fetuses. The rate of cerebral palsy in twins of > 2500 g birthweight is about four times that of singletons of > 2500 g birthweight, suggesting aetiological factors specific to multiple gestation (Blair & Stanley 1997).

Intrapartum factors

Intrapartum factors producing hypoxia and/or trauma have traditionally been assumed to be the principal cause of cerebral palsy. This has, no doubt, contributed to the increasing use of obstetric intervention and is responsible for malpractice suits being brought against perinatal caregivers (Tito 1995).

Birth asphyxia is a poorly defined term relating to an exposure–response–outcome sequence initiated by hypoxia (Blair & Stanley 1993). Hypoxia is normal during vaginal delivery. For hypoxia to constitute asphyxia, it must have pathological effects. There is no definitive test for asphyxia (Blair & Stanley 1997). Recent studies suggest that:

- birth asphyxia may not be as important a cause of cerebral palsy as previously assumed; it may sometimes constitute one step of a multifactorial cause
- neonatal signs associated with birth asphyxia may be early manifestations of cerebral palsy from a variety of causes, of which birth asphyxia is only one
- most pathways to cerebral palsy commence before birth
- infants with evidence of damaging birth asphyxia may not have fared better with alternative obstetric care (Blair & Stanley 1997; Stanley & Blair 1991).

The risk of developing cerebral palsy appears to be elevated in infants:

- with Apgar scores 0–3 at 5 min
- with pH in the umbilical artery < 7.00
- with a base deficit in the umbilical artery < –16
- who develop hypoxic ischaemic encephalopathy (HIE) in the immediate neonatal period (MacLennan 1999; van Geijn 2005).

BOX 35.1 Birth asphyxia

Birth asphyxia is evident in a newborn baby who has had significant reduction in oxygenation or perfusion in utero and prior to birth. The clinical features are described in the clinical syndrome of hypoxic ischaemic encephalopathy (HIE). The measurement of hypoxic stress at birth includes:

- an umbilical blood gas of pH < 7.0 or a base excess of ≥ 12 mmol/L
- an umbilical arterial lactate of > 6 mmol/L
- a five-minute Apgar score of < 7.

The baby may have seizures or be in a coma together with multi-system organ failure (e.g. cardiovascular, renal, haematological, pulmonary).

Clinical point

Risk factors
Risk factors cannot be assumed to be causes, even when they do have a causal potential. Risk factors are markers that we interpret as needing further intervention or assistance.

BOX 35.2 Anti-D and cerebral palsy

A success story in the prevention of cerebral palsy
Anti-D immunoglobulin is now administered to Rh-negative women at risk of an Rh-positive feto-maternal haemorrhage. This prevents the possibility of maternal Rh isoimmunisation producing maternal Rh antibodies, which can cause kernicterus and choreoathetosis with deafness in a subsequent Rh-positive fetus. This anti-D injection has almost eliminated choreoathetosis with deafness in developed countries.
(Source: Blair & Stanley 1993)

Post-neonatal cerebral palsy

After birth, the causes of cerebral palsy (CP) are known to be infective, anoxic or traumatic, with septicaemia and meningitis accounting for the majority, particularly in developing countries. In developed countries, there is a greater variety of post-neonatal aetiology, with trauma accounting for up to 24% (including motor vehicle accidents and non-accidental injury), and cerebrovascular accident and postoperative causes accounting for up to another 25%. Because these are the most aetiologically obvious, they may also be the most preventable (Blair & Stanley 1997).

Interventions in pregnancy

Assessing the wellbeing of the fetus

Interventions to assess the wellbeing of the baby while it is in utero are intended to provide obstetricians and mothers with the best information about the optimum time for birth. Intrauterine growth restriction (IUGR) affects approximately 10% of pregnancies and is associated with significant adverse perinatal outcomes. Severe IUGR results from multiple causes, such as genetic syndromes, aneuploidy or congenital infections, and is thought to be the result of a 'compromised' placenta. When a placenta is not functioning optimally, there is a risk that the fetus will suffer from a lack of oxygen (known as 'placental respiratory failure' or 'fetal hypoxemia'). Obstetricians believe that the inherent risks of delaying delivery of the severely growth-restricted fetus include those of worsening hypoxia, long-term neurodevelopmental complications and even perinatal death. Antenatal tests of fetal wellbeing are performed with the intention of identifying severely growth-restricted fetuses with early signs of compensatory failure and fetuses who are most at risk for adverse outcomes. However, the optimal antenatal test to guide obstetricians about the timing of delivery for the preterm fetus with severe IUGR remains uncertain.

Fetal movements

Fetal movements (FM) are one of the first signs of fetal life and are an indirect measure of central nervous system integrity and function. Because of this, FM are regarded as an expression of fetal wellbeing (Olesen & Svare 2004). Pregnant women usually sense FM from 18 to 20 weeks of gestation in a first pregnancy, and at about 16 weeks of gestation in the second or subsequent pregnancy. As pregnancy proceeds, the weekly number of FM increases, peaking between 29 and 38 weeks of gestation (Olesen & Svare 2004). The movements are related to neuromuscular development and a normal metabolic state of the central nervous system of the fetus (Olesen & Svare 2004). A gradual decline in the total number of FM during the last trimester is suggested to be due to improved coordination and reduced amniotic fluid volume coupled with the increased fetal size (Rayburn 1990). On average, the fetus is active between 9% and 18% of the time in late pregnancy (Olesen & Svare 2004), or has movements of about 4 to 100 an hour (Mangesi & Hofmeyr 2004).

On ultrasound it can be observed that babies display chest wall movements that appear to be 'breathing' movements. During the last couple of months in a normal pregnancy, these 'breathing' movements may become irregular and have a frequency between 10 and 200 breaths/min (Adelson et al 1999). The complete absence of breathing is observed in some normal fetuses for up to 122 min (fetal apnoea), which indicates that monitoring of respiratory movements may require long observation time (Adelson et al 1999, Rayburn 1990). Women often report fetal hiccup movements that can be very intense, but there is no known pathology associated with this.

During the past decades, new methods for fetal assessment in various clinical settings have been introduced. Antenatal

BOX 35.3 Count to 10 method

Fetal movements in a day
In the 'count to 10' method of counting fetal movements, the woman is asked to count 10 movements from a specific time each day. She is advised to report whether the fetus takes longer than usual to achieve the 10 movements, or whether there are fewer than 10 movements in 12 hours. This is taken as a warning sign that the fetus may be becoming compromised.

When counting fetal movements at rest, a woman may be asked to empty her bladder, lie on her side, relax, put her hand on her abdomen and count the fetal movements over the period specified for the method used. Fetal movements may also be counted during normal activity.
(Sources: Bennet & Brown 1999; Mangesi & Hofmeyr 2004)

tests currently used to evaluate fetal wellbeing include the non-stress test (NST) or antenatal cardiotocogram (CTG), Doppler velocimetry (DV) and fetal biophysical profile (BPP). Earlier methods of detecting fetal wellbeing depended largely on the mother recognising fetal movements.

Methods of antenatal fetal surveillance

For each admission to hospital for birth in Australia, there are about 15–20 antenatal admissions (Adelson et al 1999). During these admissions, women very often undergo one or other of the following tests to ascertain fetal wellbeing.

Non-stress test (antenatal cardiotocography)

In the 1960s and 1970s, before the introduction of antenatal CTG, biochemical tests of placental or feto-placental function were widely used in high-risk pregnancies to try to predict, and thus avoid, adverse fetal outcome. Because the placenta provides nourishment for the baby in the uterus during pregnancy, it had been thought that testing women's hormone levels during pregnancy might show how well the placenta was functioning and whether the baby was growing as would be expected. A review of trials in the Cochrane Database found evidence that measuring oestriol levels in high-risk pregnancies did not affect the outcome of the pregnancy (Neilson 2003). Trials of antenatal CTG or non-stress tests were conducted in the early 1980s when the antenatal CTG was being introduced and at a time when biochemical tests were the benchmark of fetal monitoring.

The Cochrane Reviewers stated that:

> It is not possible to judge whether the CTGs would have been interpreted and acted upon as they would today. There have been no trials in recent years despite the CTG being used extensively in modern practice ... For high risk patients: A considerably larger study would be necessary to address the question of the effect of the antenatal CTG on perinatal mortality. Such a study is unlikely in the current environment, where the CTG has become an integral part of modern antenatal care (Pattison & McCowan 2003).

Antenatal CTG (or non-stress test, NST) has become widely accepted as the primary method of antenatal fetal monitoring in conjunction with ultrasound imaging and Doppler measurements. It has been used routinely to monitor post-term pregnancies, reduced FM, hypertensive disease, growth restriction and bleeding in pregnancy since its introduction in the 1980s. There is no doubt that clinicians and women are reassured by the findings of antenatal CTGs. They are able to record movements that the mother may not have felt. However, like many other interventions in pregnancy and labour, there is no definitive evidence for their efficacy. The Cochrane reviewers conclude that:

> on the basis of the information presented in this review the antenatal CTG has no significant effect on perinatal outcome or interventions such as early elective delivery. The suggested effect on reduced antenatal intervention is the main reason for the widespread current use of the CTG. The content of this review neither adds to nor detracts from current practice where the CTG is used extensively to monitor the high risk pregnancy (Pattison & McCowan 2003, p 3).

Fetal biophysical profile

Although there have been no trials of antenatal fetal surveillance, and antenatal fetal surveillance has not definitively demonstrated improved perinatal outcome, the indications for antenatal testing should be considered somewhat relative. Conditions in which testing is usually advised include the following:

- maternal conditions:
  - antiphospholipid syndrome
  - poorly controlled hyperthyroidism
  - haemoglobinopathies such as thalassemia
  - cyanotic heart disease
  - systemic lupus erythematosus
  - chronic renal disease
  - Type 1 diabetes mellitus
  - hypertensive disorders.
- pregnancy-related conditions:
  - pregnancy-induced hypertension
  - decreased fetal movement
  - oligohydramnios
  - polyhydramnios
  - intrauterine growth restriction
  - post-term pregnancy
  - moderate to severe isoimmunisation
  - previous fetal demise (unexplained or recurrent risk)

BOX 35.4 The antenatal CTG

The antenatal CTG or NST is a continuous record of the FHR obtained via an ultrasound transducer placed on the maternal abdomen. The FHR, including variability, accelerations and decelerations, if any occur, is recorded electronically on a paper trace. Interpretation of the FHR pattern can be difficult.

A reactive (normal) CTG is deemed by two accelerations exceeding 15 bpm, sustained for at least 15 seconds in a 20-minute period (Pattison et al 2005).

Or

The NST is considered reactive, or normal, if there are two or more FHR accelerations within a 20-minute period, with or without FM discernible by the woman (ACOG 2000).

Reduced variability and the presence of decelerations are abnormal.

Various scoring systems have been devised to classify the CTG. Initial observational studies have showed a strong correlation between the abnormal CTG and poor fetal outcome (Freeman 1982; Phelan 1981).

Introduction of this test followed rapidly without supportive evidence of benefit from randomised trials.

(Sources: ACOG 2000; Freeman et al 1982; Pattison & McCowan 2003; Phelan 1981)

- multiple gestation with significant growth discrepancy.

The biophysical profile (BPP) usually includes ultrasound monitoring of fetal movements, fetal tone and fetal breathing, ultrasound assessment of amniotic fluid volume and assessment of FHR by electronic monitoring.

The BPP method of fetal assessment was derived, as a concept, from the Apgar score, which is used to assess the condition of a baby at birth. The method was introduced in the 1980s, again without substantial evidence from randomised controlled trials. However, substantial and extensive observational literature over the years suggests a link between low biophysical scores and poor pregnancy outcome. This has resulted in wide clinical use of BPP in the United States, Canada, Australia and New Zealand.

Preboth (2000) explains the BPP as follows:

> The biophysical profile consists of a non-stress test plus four observations made by real-time ultrasonography. The five components of the biophysical profile are as follows:
> 1 non-stress test
> 2 fetal breathing movements (one or more episodes of rhythmic fetal breathing movements of 30 seconds or more within 30 minutes);
> 3 fetal movement (three or more discrete body or limb movements within 30 minutes);
> 4 fetal tone (one or more episodes of extension of a fetal extremity with return to flexion, or opening or closing of a hand); and
> 5 determination of the amniotic fluid volume (a single vertical pocket of amniotic fluid exceeding 2 cm is considered evidence of adequate amniotic fluid).
>
> Each of the components is given a score of 2 (normal or present as defined previously) or 0 (abnormal, absent or insufficient). A composite score of 8 or 10 is normal, a score of 6 is equivocal and a score of 4 or less is abnormal. In the presence of oligohydramnios, further evaluation is warranted regardless of the composite score.
>
> During the late second or third trimester, the amniotic fluid reflects fetal urine production. Placental dysfunction may cause diminished fetal renal perfusion, which can lead to oligohydramnios. Therefore, assessment of amniotic fluid volume can be used to evaluate long-term uteroplacental function. The modified biophysical profile combines the nonstress test with the amniotic fluid index, which is the sum of measurements of the deepest cord-free amniotic fluid pocket in each of the abdominal quadrants, as an indicator of long-term function of the placenta. An amniotic fluid index of more than 5 cm is thought to be an adequate volume of amniotic fluid. The modified biophysical profile is considered normal if the non-stress test is reactive and the amniotic fluid index is greater than 5 cm and abnormal if the non-stress test is non-reactive or the amniotic fluid index is 5 cm or less (Preboth 2000, p 2).

Umbilical artery Doppler velocimetry

Doppler ultrasonography is used to assess the flow velocity waveforms in the fetal umbilical artery. Some clinicians also observe the maternal vessels supplying the placental intervillous space and (especially since the development of colour-flow imaging) other fetal vessels, including aorta and cerebral arteries (Alfirevic et al 1995). The study of the

TABLE 35.1 Components of the biophysical profile

Biophysical variable*	Normal score (score = 2)	Abnormal score (score = 0)
Fetal breathing movements	At least one episode of fetal breathing of ≥ 30 s duration	Absent fetal breathing, or no episode of ≥ 30 s duration
Gross fetal body movement	At least one episode of active extension with return to flexion of fetal limbs or trunk. Includes opening or closing of the hand.	Slow extension with return to partial flexion or limb movement without flexion or absent fetal movement
Fetal heart rate		
< 26 weeks	At least two episodes of ≥ 10 beat accelerations of ≥ 10 s duration	Fewer than two episodes of accelerations and durations as specified
26–36 weeks	At least two episodes of ≥ 10 beat accelerations of ≥ 15 s duration	
> 36 weeks	At least two accelerations of ≥ 20 beat accelerations of ≥ 20 s duration	
Amniotic fluid volume	At least one amniotic fluid pocket of 2 × 2 cm in perpendicular plane	No amniotic fluid pocket of 2 × 2 cm in perpendicular plane

*All parameters are examined in a 30-minute monitoring interval.
(Sources: Manning 1999; Preboth 2000)

umbilical artery has remained the most widely used approach, however, because less experienced operators can achieve highly reproducible results with simple, inexpensive continuous-wave equipment. Umbilical artery Doppler flow velocimetry has been adapted as a fetal surveillance technique because it is believed that flow velocity waveforms in the umbilical artery of fetuses with normal growth differ from those of fetuses with growth restriction. The umbilical flow velocity waveform of a normally growing fetus has high-velocity diastolic flow, while in cases of intrauterine growth restriction (IUGR), the umbilical artery diastolic flow is diminished. With extreme IUGR, the flow may be absent or even reversed. There is a high perinatal mortality rate among such pregnancies. It became clear from observational data that many of the fetuses with extremely abnormal waveforms had a poor outcome (Bricker & Neilson 2000). A meta-analysis published in 1995 (Alfirevic et al 1995) shows that assessment of umbilical artery waveforms by Doppler ultrasonography in high-risk pregnancies reduces the odds of perinatal death by 38% (CI 15–55%) (Alfirevic et al 1995).

A Cochrane Review of routine Doppler in pregnancy concluded that 'Abnormal waveforms from Doppler ultrasound may indicate poor fetal prognosis. The use of Doppler ultrasound in high-risk pregnancies appears to improve a number of obstetric care outcomes and appears promising in helping to reducing perinatal deaths' (Bricker & Neilson 2000). The review concludes, however, that although the study of umbilical artery waveforms helps identify the compromised fetus in 'high-risk' pregnancies, based on existing evidence, routine Doppler ultrasound in low-risk or unselected populations does not confer benefit on mother or baby. Future research should be powerful enough to address small changes in perinatal outcome, and should include evaluation of maternal psychological effects, long-term outcomes such as neurodevelopment, and issues of safety. Doppler ultrasound uses sound waves to detect the movement of blood. It is used in pregnancy to study blood circulation in the baby, uterus and placenta. Using it in high-risk pregnancies where there is concern about the baby's condition reduces the risk of the baby dying and the need for interventions around birth, such as caesarean section. However, its value as a screening tool in all pregnancies is limited by the rarity of complications, and the greater possibility of unnecessary intervention and adverse effects. A review of trials of routine Doppler ultrasound in pregnancy found that it does not improve the health of either the woman or the baby, and may do some harm (Bricker & Neilson 2000).

The techniques discussed here are the most commonly used interventions to monitor and study the growth and development of the fetus while is it is still in utero. Women whose babies appear to be at risk are often advised to have their labour induced in order to give birth to their babies early. Depending on how preterm or how growth restricted these infants are, they may stay for days or weeks in the neonatal intensive care unit (NICU) until they are strong enough to go home.

Interventions in labour

Electronic fetal monitoring

Electronic fetal monitoring (EFM) is defined as 'the use of electronic fetal heart-rate monitoring for the evaluation of fetal wellbeing in labour' (NICE 2003).

EFM was introduced with the aim of reducing perinatal mortality and cerebral palsy; however, systematic reviews of randomised controlled trials (RCTs) have not demonstrated their effectiveness to date (NICE 2003), and an increase in maternal intervention rates has been shown (NICE 2003).

Both the admission CTG and continuous EFM are the subject of widespread concern in midwifery. The student must discern, in collaboration with the woman she is caring for, what to do in practice.

This section will address the specific objective of reducing inappropriate or inadequate intrapartum fetal surveillance and reducing adverse perinatal outcomes, with special reference to:

- decisions relating to the use of admission CTG
- decisions relating to the use of EFM (both continuous and intermittent) or intermittent auscultation.

Admission CTG

The following statement is reprinted from the Royal Australian and New Zealand College of Obstetricians and Gynaecologists recommendations for the admission CTG (RANZCOG 2004).

> The admission cardiotocogram is a short, usually 20 minute, recording of the fetal heart rate immediately after admission to the labour ward. The most commonly heard rationale or routine justification for the admission cardiotocography is that the uterine contractions of labour put stress on the placental circulation and therefore an abnormal tracing might indicate a deficiency and hence identify potential fetal compromise at an early enough stage to allow intervention. Furthermore, a normal admission cardiotocogram offers reassurance. However, the incidence of intrapartum fetal compromise is low in pregnancies that have been uncomplicated before the onset of labour. Thus, labour admission cardiotocography may represent unnecessary intervention. In such low risk cases, confirmation of a normal fetal heart rate by Doppler auscultation should be sufficient (RANZCOG 2004).

The most important finding from a recent RCT of admission CTG by Mires et al (2001) is the increased rate of operative delivery in women who had admission CTG. Among women who were low-risk at admission, there was an absolute increase of 5.5% in operative delivery and 1.5% increase in caesarean sections. The increased use of continuous monitoring of FHR in labour in women who had admission CTG in this study is likely to be a contributing factor. This study has confirmed that among women with low-risk features at the onset of labour, the admission CTG is no better than Doppler auscultation of the fetal heart in identifying a potentially compromised fetus. Admission CTG was associated with increased obstetric intervention, including higher rates of operative delivery.

Although caution is needed in generalising conclusions to the whole population, the results point to potential problems with admission CTG. These problems are likely to persist while difficulties remain in interpreting CTGs.

The student is advised to watch very carefully for evidence to support the use of the routine admission trace for women with no other risk markers. There appears to be no substantial evidence for its use.

Continuous EFM

> The assessment of fetal wellbeing is only one component of intrapartum care. It is an important area where due consideration must be given to maternal preference and priorities in the light of potential risk factors to both mother and baby, i.e. one that strikes the right balance between the objective of maximising the detection of potentially compromised babies and the objective of minimising the number of unnecessary maternal interventions. The provision of accurate information in these circumstances is essential to allow each woman to make the right decision for her (NICE 2001, p 35) .
>
> In the last century some asphyxiated babies were noted to have abnormally fast—or slow—heart rates, and auscultation evolved as a component of intrapartum care. The human ear is insensitive to subtle changes in rate, so electronic methods of recording were developed. These generate paper traces that show features not obvious on auscultation, including the degree of variation of the heart rate and the shape of accelerations and decelerations in rate. But more information is not necessarily more instructive, or we should judge textbooks simply by their size (Neilson 1993, p 347).

The use of continuous EFM for intrapartum fetal surveillance has now become entrenched in obstetric practice without robust RCT evidence to support it. The RCTs that have been undertaken confirm that the use of continuous EFM significantly increases the rate of operative delivery. To a certain extent, this can be minimised with the concomitant use of fetal blood sampling. No statistically significant improvements in long-term neonatal outcomes such as cerebral palsy have been demonstrated in these RCTs. Not surprisingly, concerns about maternal hazards and small or absent perinatal benefit have led some authorities to advise against the routine use of continuous EFM for low-risk labours (RANZCOG 2004, p 10). The NICE guidelines from the United Kingdom recommend that continuous EFM be offered and recommended for high-risk pregnancies where there is an increased risk of perinatal death, cerebral palsy or neonatal encephalopathy. They also recommend that continuous EFM be used where oxytocin is being used for induction or augmentation of labour.

Fetal heat rate monitoring is a highly complex task, often undertaken in a stressful working environment. It requires:

- a sound understanding of fetal physiological responses to hypoxia
- good pattern-recognition skills
- the ability to integrate this knowledge with each clinical situation.

In a review assessing the efficacy and safety of EFM, Thacker et al (2003) included nine trials of 18,561 pregnant women and their 18,695 infants in both high- and low-risk pregnancies from seven clinical centres in the United States, Europe and Australia. Overall, a statistically significant decrease was associated with routine EFM for neonatal seizures (relative risk (RR) 0.51, 95% CI 0.32–0.82). The protective effect for neonatal seizures was only evident in studies with high-quality scores. No significant differences were observed in one-minute Apgar scores below four or seven, rate of admissions to NICUs, perinatal deaths or cerebral palsy. An increase associated with the use of EFM was observed in the rate of caesarean delivery (RR 1.41, 95% CI 1.23–1.61) and operative vaginal delivery (RR 1.20, 95% CI 1.11–1.30). The authors concluded that the only clinically significant benefit from the use of routine continuous EFM was in the reduction of neonatal seizures. In view of the increase in caesarean and operative vaginal deliveries, the long-term benefit of this reduction must be evaluated in the decision reached jointly by the pregnant woman and her clinician to use continuous EFM or intermittent auscultation during labour (Thacker et al 2003). In the rare instances in which long-term outcomes of childbirth are measured, the findings are sometimes unexpected. Continuous electronic FHR monitoring in labour was associated with reduced neonatal convulsions, yet long-term follow-up in two studies showed a trend to increased cerebral palsy compared with the intermittent auscultation group (RR 1.66, 95% CI 0.92–3.0) (Hofmeyr 2004; Thacker et al 2004).

Following this review, Banta and Thacker (2002) concluded that:

> Our findings of insufficient evidence of efficacy and concerns about safety have been confirmed by subsequent research. Still, despite findings and recommendations of prominent professional and governmental bodies, EFM continues in widespread use in the United States and Europe and is spreading into developing countries around the world. Aggressive attacks on our assessment as well as our skills and integrity have been mirrored in recent years by criticism of other researchers in health technology assessment. The case of EFM points to the limitations of assessment without other actions to assure the implementation of results. Health technologies that are accepted by the majority of clinicians in a particular field may require extraordinary efforts to assure appropriate use of technology assessments (Banta & Thacker 2002, p 762).

EFM is a complex technology applied to monitor the fetus during labour and delivery. Introduced in the 1960s as an alternative to the traditional auscultation by stethoscope or fetoscope, it involves monitoring the FHR by either internal or external methods. The external method uses Doppler ultrasound. The internal method uses electrocardiographic leads attached directly to the fetus after rupture of the amniotic sac. Sampling of the fetal scalp blood during labour and delivery and testing it for pH (a measure of acid–base balance) complements the external and internal methods. EFM diffused rapidly into practice in the 1970s; it was used in the majority of deliveries in the United States by 1975. By 1976, when assessment of EFM began, it was already becoming controversial, but no systematic assessment had been carried out.

Reflective exercise

You are encouraged to read an account of the attempts to assess the technology, and reactions to the assessment, as well as some factors that might have prevented the assessment from influencing practice substantially, recounted in a paper by Banta and Thacker (2002), entitled 'Electronic fetal monitoring: lessons from a formative case of health technology assessment'.

BOX 35.5 Monitoring a 'normal' pregnancy

Appropriate monitoring in an uncomplicated 'normal' pregnancy

Intermittent auscultation

For a woman who is healthy and has had an otherwise uncomplicated pregnancy, intermitten auscultation should be offered and recommended in labour to monitor fetal wellbeing.

In the active stages of labour, intermittent auscultation should occur after a contraction, for a minimum of 60 seconds, and at least:

- every 15 mins in the first stage
- every 5 mins in the second stage.

Continuous EFM

Continuous EFM should be offered and recommended in pregnancies previously monitored with intermittent auscultation:

- if there is evidence on auscultation of a baseline less than 110 or greater than 160 bpm
- if there is evidence on auscultation of any decelerations
- if any intrapartum risk factors develop.

Admission CTG

Current evidence does not support the use of the admission CTG in low-risk pregnancy and it is therefore not recommended.

(Source: NICE 2003)

BOX 35.6 EFM policy

Before any form of fetal monitoring is undertaken, it is always wise to palpate the maternal pulse simultaneously with FHR auscultation in order to differentiate between maternal and fetal heart rates.

- The date and time clocks on the EFM machine should be correctly set.
- Traces should be labelled with the mother's name, date and hospital ID number.
- Any intrapartum events that may affect the FHR should be noted when they happen on the EFM trace, signed and the date and time noted (e.g. vaginal examination, fetal blood sample, insertion of an epidural).
- Any member of staff who is asked to provide an opinion on a trace should note their findings on both the trace and the maternal case notes, along with date, time and signature.
- Following the birth, it is good policy for the midwife to sign and note the date, time and mode of birth on the EFM trace.
- The EFM trace should be stored securely with the maternal notes at the end of the monitoring prcess.

(Source: NICE 2003)

BOX 35.7 CTG settings

It is recommended that settings on cardiotocographs in institutions in Australia and New Zealand show:

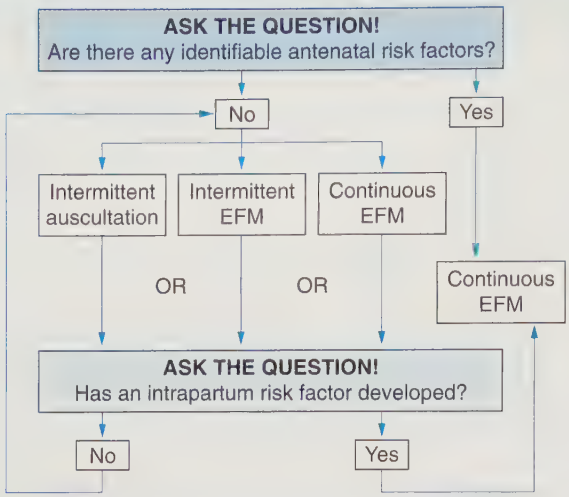
- paper speed of 1 cm/min
- sensitivity displays of 20 bpm/cm
- FHR range displays of 50–210 bpm.

(Source: RANZCOG 2004)

TABLE 35.2 Categorisation of fetal heart traces

Category	Definition
Normal	A CTG where all four features fall into the reassuring category (see Table 35.3).
Suspicious	A CTG where features fall into one of the non-reassuring categories and the remainder of the features are reassuring (see Table 35.3).
Pathological	A CTG whose features fall into two or more non-reassuring categories or one or more abnormal categories (see Table 35.3).

(Source: NICE 2001)



Intermittent auscultation

In a pregnancy where there are no identified risk markers, the preferred method for assessing the wellbeing of babies is intermittent auscultation. This should be carried out in the following way:

- The FHR should be auscultated at specified intervals (usually every 15 minutes in the first stage and every five minutes in the second stage. This of course depends on whether the woman is comfortable with this arrangement.).
- Any intrapartum events that may affect the FHR should be noted, at the time that they happen, in the mother's notes and signed, and the time noted as usual.

Measuring lactate through fetal blood sample

The pH analysis is the standard technique of determining metabolic acidosis in the fetus during labour. However, it may be time consuming and there are difficulties in getting adequate samples, as a minimum of 35–50 mL is needed for most machines for automated analysis. Fetal blood analysis using lactate levels is comparable to pH in fetal scalp blood in predicting fetal compromise. The procedure for measuring

ANTENATAL RISK FACTORS

Evidence of fetal compromise, including:

- Abnormal Doppler artery velocimetry
- Abnormal antenatal CTG
- Suspected intrauterine growth restriction
- Oligohydramnios
- Prolonged pregnancy > 42°
- Multiple pregnancy
- Breech presentation
- Antepartum haemorrhage (significant)
- Prolonged rupture of membranes (> 24 hours)
- Known fetal abnormality which requires monitoring
- Prior uterine scar/caesarean section
- Pre-eclampsia (current pregnancy)
- Diabetes on insulin or poorly controlled
- Other medical conditions which constitute a significant risk of fetal compromise

INTRAPARTUM RISK FACTORS

- Induction of labour with prostaglandin/syntocinon
- Abnormal admission CTG (if performed)
- Oxytocin augmentation
- Epidural analgesia
- Excessive vaginal bleeding in labour
- Maternal pyrexia > 38°C
- Meconium or blood-stained liquor
- Oligohydramnios at amniotomy
- Active first stage labour > 12 hours (ie regular uterine activity, cervix > / = 4cm dilated)
- Active second stage (ie pushing) > 1 hour
- Abnormal auscultation

DISCLAIMER: *This algorithm is for general guidance only and is subject to a clinician's expert judgement. The algorithm should not be relied upon as a substitute for clinical advice.*

Figure 35.2 The Australian and New Zealand College of Obstetricians and Gynaecologists algorithm for fetal surveillance in labour (based on RANZCOG 2002)

lactate has been shown to be more successful than that for pH because the sample volume needed for this bedside analysis is 5 mL. Lactate analysis as an alternative for detecting acidosis is preferred in some centres because less blood is required and can usually be obtained with a single scalp incision and sampling attempt (Okosun & Arulkumaran 2005; Pennell & Tracy 1999).

Induction of labour

Induction of labour is one of the fastest-growing obstetric interventions in modern maternity care. In New Zealand in 2002, the rate of induction was 19.7% of all births recorded by the Ministry of Health (MOHNZ 2002). In the United States, the rate of labour induction has increased from 9.0% to 20.6%, for all births between 1989 and 2002 (a 129% increase since 1989). Australia has higher rates of induction than New Zealand and the United States (Martin et al 2002). In Australia in 2002, labour was induced in 26.6% of women and augmented in 19.2% of all births (Laws & Sullivan 2004). There is evidence that induction of labour may be efficacious where a pregnancy is well overdue and the woman is feeling anxious about being post term, or where the mother or infant is sufficiently ill to make continuation of the pregnancy hazardous. However, the recent rapid increase in induction, and particularly the doubling of the induction rate for preterm pregnancies in the United States (from 6.7% in 1989 to 13.4% in 1998), is cause for concern (MacDorman et al 2002).

In the Netherlands, the labour induction rates remained fairly constant at about 15% between 1993 and 2002, although large differences have been demonstrated in the frequencies of labour induction rates in Dutch hospitals even after adjustment for population differences (Elferink-Stinkens et al 1996; Rayburn & Zhang 2002).

Reasons for these differences relate to the widespread availability of cervical ripening agents, pressure from patients, convenience for physicians, logistic factors, psychosocial reasons and litigious constraint (Rayburn & Zhang 2002).

Indications for induction of labour are not absolute. Examples of maternal or fetal conditions that may be indications include:

- placental abruption, where the mother and baby are in danger if the pregnancy continues
- premature rupture of membranes, where the baby or mother are in danger of complications due to infection
- post-term pregnancy, when the mother or baby appear to be at risk
- medical conditions that are threatening the health of the mother or baby
- fetal compromise
- pre-eclampsia/eclampsia.

Better detection has identified pregnancies at risk. For example, borderline hypertensive disorders or an abnormally low volume of amniotic fluid are common indications for induced labour (Zhang et al 2002). It is difficult to precisely measure the effect of induction of labour in terms of cost, psychological effects and intrapartum procedures such as epidural analgesia, instrumental delivery or caesarean delivery. Research undertaken in New South Wales demonstrated the effect of a cascade of intervention associated with the

TABLE 35.3 Categorisation of fetal heart rate features

Feature	Baseline (bpm)	Variability (bpm)	Decelerations	Accelerations
Reassuring	110–160	≥ 5	None	Present
Non-reassuring	100–109 161–180	< 5 for more than 40 and less than 90 minutes	Early deceleration Variable deceleration Single prolonged deceleration up to 3 mins	The absence of accelerations with an otherwise normal CTG is of uncertain significance
Abnormal	< 100 > 180 Sinusoidal pattern ≥ 10 mins	< 5 for greater than or equal to 90 mins	Atypical variable decelerations Late decelerations Single prolonged Single prolonged deceleration > 3 mins	The absence of accelerations with an otherwise normal CTG is of uncertain significance

(Source: NICE 2001)

BOX 35.8 FBS guidelines

Classification of fetal blood sample (FBS) results

- pH > 7.25 FBS should be repeated if the FHR abnormality persists.
- ph 7.21–7.24 Repeat FBS within 30 minutes or consider operative delivery if rapid fall since last sample
- pH < 7.20 Operative delivery is indicated.

Note: All scalp pH estimations should be interpreted taking into account the previous pH measurement, the rate of progress in labour and the clinical fetaures of the mother and baby.

Contraindications to FBS

Contraindications include:

- maternal infection (e.g. HIV, hepatitis viruses and HSV virus)
- fetal bleeding disorders (e.g. haemophilia)
- prematurity (< 34 weeks).

Prolonged use of maternal facial oxygen therapy may be harmful to the fetus and should be avoided. There is no research evidence evaluating the benefits or risks associated with the short-term use of maternal facial oxygen theapy in cases of suspected fetal compromise.

During episodes of abnormal FHR patterns when the mother is lying supine, the mother should adopt the left-lateral position.

In cases of uterine hypercontractility in association with oxytocin infusion and with a suspicious or pathological CTG, the oxytocin infusion should be decreased or discontinued.

(Source: NICE 2001)

introduction of induction or augmentation (Roberts et al 2000) and further research demonstrated the incremental cost as interventions are introduced (Tracy & Tracy 2003).

Much emphasis has been placed on looking at clinical outcomes and the cost of different methods of induction. Very little is known about how women view the experience of being induced (Grant 2001). Responses to labour induction have varied from dissatisfaction with the entire birthing experience (Bramadat 1994) and mainly negative views (Out et al 1985; Salmon & Drew 1992; Salmon et al 1990) to a response where 80% of women reported that they would accept induction in any subsequent pregnancy (Nautila 1999).

What the Cochrane says

A Cochrane Systematic Review assessing the effects of interventions aimed at either reducing the incidence or improving the outcome of post-term pregnancy (pregnancies of more than 42 weeks that were otherwise 'low risk') (Crowley 1997) concluded that:

> In health systems in which reliable early pregnancy ultrasound is available at an acceptable cost, it should be performed routinely and the expected date of delivery should be revised, to avoid unnecessary induction of labour for a mistaken diagnosis of post term pregnancy.
>
> In health systems in which induction of labour is a safe and acceptable option, the question of induction of labour should be discussed with women after 41 weeks' gestation. They should be informed that about 500 inductions of labour may be necessary to prevent one perinatal death, and that there is no evidence that induction either increases or reduces the likelihood of delivery by caesarean section.
>
> If the woman opts for induction of labour, the choice of method of induction should be based on evidence from randomized trials comparing the available methods.
>
> Women or obstetricians who opt for conservative management should be aware of the lack of evidence to support the effectiveness of any particular method of antenatal fetal surveillance.
>
> The implications for practice in developing countries are likely to be different. Access to early pregnancy ultrasound is unlikely, the cost of induction of labour with vaginal prostaglandins is likely to be unacceptable and any reduction in perinatal mortality must be viewed in the context of overall perinatal and maternal risks locally (Crowley 1997, p 2).

Outcomes vary for women when they undergo 'cervical ripening' with pharmacological agents. Vahratian and colleagues (2005) found that women who had an elective induction with cervical ripening, indicating an unfavourable cervix, had a significantly longer latent and early active phase and a two- to three-fold increased risk of caesarean delivery compared with those with a spontaneous onset of labour. After controlling for potential confounders, women who had an elective induction with cervical ripening had 3.5 times the risk of caesarean delivery during the first stage of labour (95% CI 2.7–4.5), compared with those admitted in spontaneous labour. Elective induction without cervical ripening, on the other hand, was associated with a faster labour progression from 4 cm to 10 cm (266 mins compared with 358 mins, $P < 0.01$) and did not increase the risk of caesarean delivery, compared with those in spontaneous labour (Vahratian et al 2005).

The Cochrane Library also records the effectiveness (according to RCT evidence) of complementary therapies. In a review of acupuncture for induction of labour, the authors report:

> Acupuncture involves the insertion of very fine needles into specific points of the body. The limited observational studies to date suggest acupuncture for induction of labour appears safe, has no known teratogenic effects, and may be effective. The evidence regarding the clinical effectiveness of this technique is limited (Smith & Crowther 2004).

The effectiveness (measured by RCTs) of homeopathic methods is also reported in the following way:

> There is insufficient evidence to recommend the use of homoeopathy as a method of induction. It is likely that the demand for complementary medicine will continue and women will continue to consult a homoeopath during their pregnancy. Although caulophyllum is a commonly used homoeopathic therapy to induce labour, the treatment strategy used in the one trial in which it was evaluated may not reflect routine homoeopathy practice. Rigorous evaluations of individualised homeopathic therapies for induction of labour are needed (Smith 2003).

Epidural analgesia and anaesthesia

The popularity of epidural anaesthesia for childbirth is a relatively recent phenomenon. It blocks pain without rendering the mother unconscious. No other current drug or technique has that degree of selectivity. Epidural anaesthesia is also adaptable to the wide variety of pain patterns encountered during the course of a normal labour (Caton 2002). The character and neurological basis of childbirth pain change during the course of labour. During the first stage, the primary nerves mediating pain are small fibres of the sympathetic division of the autonomic nervous system. This pain is also known as visceral pain, mediated by the nerve fibres from T10 to L1 of the spine (Eltzschig et al 2003). Women typically perceive this pain as diffuse abdominal cramps, in phase with each uterine contraction. In contrast, pain of the second stage of labour is more continuous than rhythmic, sharper in character, and sensed in the perineum rather than in the abdomen or back. It is mediated by larger, somatic sensory fibres from sacral portions of the spinal cord (Caton 2002) mediated by fibres from S1 to S4 of the spinal cord (Eltzschig et al 2003).

Other types of pain may superimpose on the basic patterns described above. For example, when the head of the fetus is pushed hard against a large nerve against the posterior wall of the pelvis, the woman may experience intense pain in the lower back or in a discrete area of a hip or leg. If this pressure is prolonged or severe, it may result in temporary or even permanent nerve damage. A full, distended bladder may cause continuous suprapubic pain that may be confused with the pain of labour. Other patterns of pain may be caused by placental abruption or a ruptured uterus. An experienced midwife may easily evaluate the distribution and character of labour pain, but judging its severity may be far more difficult. Individuals respond to pain differently according to personal, familial and cultural factors (Caton 2002).

In Australia each year, about 125,000 women—51% of all women who give birth—experience either an epidural or a spinal block during labour (Tracy et al 2006). In the United States approximately 60% of women, or 2.4 million each year, choose epidural or combined spinal–epidural analgesia for pain relief during labour (Eltzschig et al 2003). In New Zealand each year, approximately 13,500 women, nearly 25% of all women giving birth, have an epidural (MOHNZ 2004)

Current popularity of epidurals

A study of women's attitudes to analgesia in labour between 1995 and 2001 found that the preference for epidural analgesia rose from 57% in 1995 to 66.5% in 2001, and the preference for opioids decreased from 31.5% in 1995 to 18.5% in 2001 ($P < 0.001$). The rate of epidural use in a previous birth rose accordingly, from 26% to 63%. The rates of satisfaction with the method used in previous births were similar in 1995 and 2001—about 30% not satisfied, 50% satisfied, and 20% very satisfied. The study found that in 1995, none of the women questioned opted for avoiding all kinds of analgesia, whereas in 2001, 8% did so. The research showed that women's attitudes to analgesia during labour changed during the six years of the study. Epidural block has become very popular, while

BOX 35.9 150 years on

One and a half centuries since Scottish obstetrician James Simpson expressed concern about the possible adverse effects of anaesthesia in 1847, saying, 'It will be necessary to ascertain anaesthesia's precise effect, both upon the action of the uterus and on the assistant abdominal muscles; its influence, if any, upon the child; whether it has a tendency to haemorrhage or other complications', it has become increasingly clear that potentially unwanted effects of analgesia for women in labour and their children cannot be determined easily.

(Source: Eltzschig et al 2003)

opioids lost popularity, and the number of women who prefer to avoid all analgesia during labour has increased (Horowitz et al 2004).

Mechanism of epidural and spinal anaesthesia

Labour pain is transmitted through lower thoracic, lumbar and sacral nerve roots, which are amenable to epidural blockade (Eltzschig et al 2003). Epidural analgesia is achieved by placement of a catheter into the lumbar epidural space or the space between the dura mater and the ligamentum flavum at spinal cord levels C7 to C10. The space is filled with loose adipose tissue lymphatics and blood vessels, and the solution tends to remain localised at the level where injected. The solution does not contact the spinal cord or the cerebrospinal fluid, so there is less risk of central nervous dystem infection than with a spinal injection. Postoperative urinary retention is common, as parasympathetic nerves are blocked (Bryant et al 2003, p 229). Solutions of a local anaesthetic, opioid or both can then be administered as intermittent rapid doses or as a continuous infusion. In the alternative technique of combined spinal–epidural analgesia, a single bolus of an opioid, sometimes in combination with local anaesthetic, is injected into the subarachnoid space, in addition to the placement of an epidural catheter (Eltzschig et al 2003, p 319).

In spinal anaesthesia, the local anaesthetic is injected into the cerebrospinal fluid in the subarachnoid space below the level of termination of the spinal cord—at about the level of L3–4 or L4–5. The needle and solution come into contact with the cerebrospinal fluid, necessitating strict aseptic techniques in order to prevent infections such as meningitis occurring (Bryant et al 2003, p 229).

The use of a subarachnoid bolus of opioids results in the rapid onset of regional anaesthesia with virtually no motor blockade. In contrast to epidural local anaesthetics, spinal opioids do not cause impairment of balance, giving the labouring woman the option to continue moving around (Eltzschig et al 2003). Some studies have suggested that there may be an increase in the frequency of non-reassuring patterns in the FHR, particularly bradycardia, with combined spinal–epidural analgesia, and such patterns may necessitate emergency caesarean delivery (Clark et al 1994; Eltzschig et al 2003; Gambling et al 1998). Other studies have demonstrated that regional analgesia during labour, compared with other methods of pharmacological pain relief, does not necessarily increase the risk of caesarean delivery (Sharma et al 2004; Segal et al 2000). Although there are insufficient data to establish whether there is a causal association, there are no studies that suggest that combined spinal–epidural analgesia is associated with an increase in adverse outcomes for the fetus (Eltzschig et al 2003, p 321).

For many years there has been debate about the efficacy of an epidural offered early in labour. There is a widely held opinion that having an epidural early in labour—before about 4–5 cm dilatation—increases the risk of operative intervention. However, in the United States, a recent large RCT of 750 women at term having their first baby who had a cervical dilatation of less than 4.0 cm were randomly assigned to receive epidural or systemic opioids at the first request for analgesia. The researchers showed that women who were assigned to 'early' regional analgesia had the combined spinal–epidural analgesia administered truly early in labour, in most cases at or near a cervical dilatation of 2.0 cm, whereas most of the women assigned to receive regional analgesia after a delay had a cervical dilatation at or near 5.0 cm when it was initiated. The primary outcome was caesarean section and the results show no significant difference between the two groups in the rates of caesarean delivery and instrumental vaginal delivery (Wong et al 2005). One of the alarming things revealed by the study is the rate of infusion of oxytocin. More than 90% of women in both arms of the study experienced augmentation or induction of labour (Wong et al 2005). The results of a French study undertaken at this time demonstrate that the placement of epidural analgesia when cephalic presentation is still 'high' is associated with a higher percentage of occiput posterior and transverse positions during labour, independently of other risk factors studied (Le Ray et al 2005). Lieberman and colleagues (2005), in studying the position changes of the fetus during labour, concluded that the consistently higher rate of instrumental vaginal delivery associated with epidural analgesia in randomised trials (Lieberman et al 2002) could result from an increase in abnormal fetal position complicating delivery. Use of epidural analgesia for pain relief has been consistently associated with a lower rate of spontaneous vaginal delivery (Howell et al 2001; Lieberman et al 2002; Roberts et al 2000, 2002). Almost all randomised studies have reported an increased rate of instrumental vaginal delivery, and a meta-analysis of randomised trials has estimated a two-fold increase (Leighton & Halpern 2002). The association of epidural analgesia with caesarean section is less clear and may vary across providers and institutions (Lieberman et al 2002; Roberts et al 2000, 2002). The reason for the lower rate of spontaneous vaginal delivery is not clear. It has been hypothesised that women who receive epidural analgesia are unable to push as effectively during the second stage of labour (Lieberman et al 2005). A large prospective cohort study undertaken by Lieberman et al (2005) found that epidural analgesia may contribute to an increase in the occurrence of occiput posterior position, representing a mechanism by which epidural analgesia may decrease spontaneous vaginal deliveries (Lieberman et al 2005).

Managing an epidural

Midwives will be guided in their management of the epidural by the policies and procedures of each institution. There are no hard and fast rules about epidurals—it is another area of practice that has evolved through expert opinion and received wisdom. As far as research-based evidence goes, there is very little to guide midwives in the best way to look after a woman who has requested an epidural.

This section outlines for the student some of the most commonly observed side-effects and the most commonly used techniques for managing epidurals. Figures 35.3 and 35.4 show the mechanism and the pathways affected by the epidural and spinal anaesthesia.

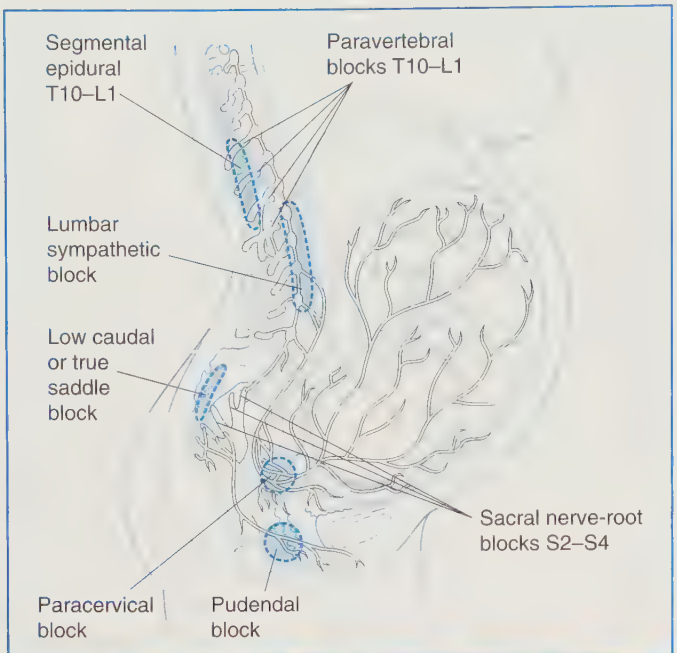


Figure 35.3 Pathways of analgesics and anaesthetics used in labour (based on Eltzschig et al 2003)

Eltzschig et al (2003) describe the pathways of labour pain and its blockage as follows:

> Labour pain has a visceral component and a somatic component. Uterine contractions may result in myometrial ischemia, causing the release of potassium, bradykinin, histamine, and serotonin. In addition, stretching and distension of the lower segments of the uterus and the cervix stimulate mechanoreceptors. These painful impulses follow sensory-nerve fibres that accompany sympathetic nerve endings, travelling through the paracervical region and the pelvic and hypogastric plexus to enter the lumbar sympathetic chain. Through the white rami communicants of the T10, T11, T12, and L1 spinal nerves, they enter the dorsal horn of the spinal cord. These pathways could be mapped successfully by a demonstration that blockade at different levels along this path (sacral nerve-root blocks S2 through S4, pudendal block, paracervical block, low caudal or true saddle block, lumbar sympathetic block, segmental epidural blocks T10 through L1, and paravertebral blocks T10 through L1) can alleviate the visceral component of labour pain (Eltzschig et al 2003, p 320).

Epidural analgesia [Fig 35.4 (a)] is achieved by placement of a catheter into the lumbar epidural space (1). After the desired intervertebral space (e.g., between L3 and L4) has been identified and infiltrated with local anaesthetic, a hollow epidural needle is placed in the intervertebral ligaments. These ligaments are characterized by a high degree of resistance to penetration. A syringe connected to the epidural needle allows the anaesthetist to confirm the resistance of these ligaments. In contrast, the epidural space has a low degree of resistance. When the anaesthetist slowly advances the needle while feeling for resistance, he or she recognizes the epidural space by a sudden loss of resistance as the epidural needle enters the epidural space (2). Next, an epidural catheter is advanced into the space. Solutions of a local anaesthetic, opioids, or a combination of the two can now be administered through the catheter. For combined spinal–epidural analgesia

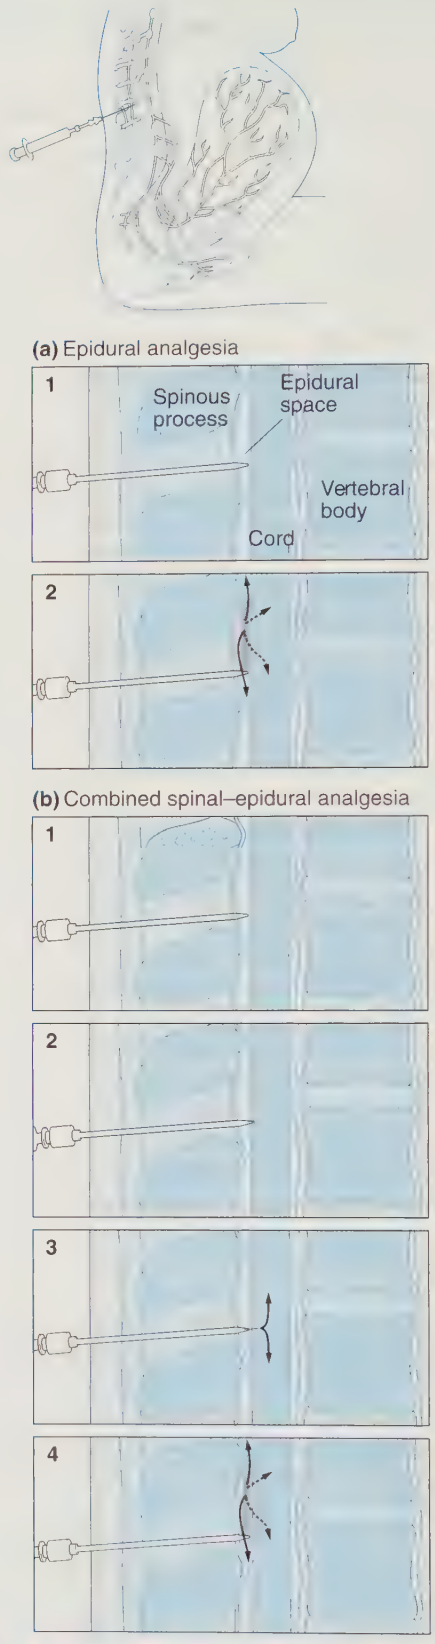

Figure 35.4 Epidural and combined spinal–epidural anaesthesia (based on Eltzschig et al 2003)

[Fig 35.4 (b)], the lumbar epidural space is also identified with an epidural needle (1). Next, a very thin spinal needle is introduced through the epidural needle into the subarachnoid space (2). Correct placement can be confirmed by free flow of cerebrospinal fluid. A single bolus of local anaesthetic, opioid, or a combination of the two is injected through this needle into the subarachnoid space (3). Subsequently, the needle is removed, and a catheter is advanced into the epidural space through the epidural needle (4). When the single-shot spinal analgesic wears off, the epidural catheter can be used for the continuation of pain relief (Eltzschig et al 2003, p 322).

Siting an epidural or a spinal block

The method for siting an epidural or spinal block differs according to the practice of each anaesthetist. Women will be given instructions by the anaesthetist and the midwife is primarily called on to help position and attend to the comfort of the woman as she tries to position herself as directed by the anaesthetist. Depending on the stage of labour and the level of distress the woman is feeling, this could be a gruelling procedure for all concerned.

Additional interventions before placement of the epidural catheter

- Intravenous fluids are commenced prior to the introduction of spinal or epidural anaesthetics. This is to prevent the onset and effects of maternal hypotension. The most commonly used solutions include warmed (37.8°C) Ringer lactate solution IV before the induction of anaesthesia. The Cochrane recommendation for IV fluids (pre-load) is that 500–1000 mL of a non-glucose balanced sodium chloride solution may be administered 15 to 30 minutes before the procedure, to minimise the effect of hypotension. Glucose solutions are contraindicated because of the risk of fetal hyperglycaemia and rebound hypoglycaemia in the infant. A Cochrane Review of studies designed to assess the effect of prophylactic IV fluid preloading before epidural analgesia concluded that there may be beneficial fetal and maternal effects of this approach to minimising maternal hypotension (Hofmeyr 2000).
- If the woman is having an elective caesarean section, she may be prescribed an antibiotic prophylactic—this is not routine, although most hospitals have local policy and guidelines for these matters. The antibiotic most commonly prescribed is metoclopramide 10 mg and 10 mL/kg in the IV fluid. (Cochrane Reviews advise that the reduction of endometritis by two-thirds to three-quarters and a decrease in wound infections justifies a policy of recommending prophylactic antibiotics to women undergoing elective or non-elective caesarean section (Smaill & Hofmeyr 2002).)
- A urinary catheter is inserted. Before initiating an epidural, women should be encouraged to void because the sensation of a full bladder will not be felt after the introduction of intrathecal anaesthetic. Catheterisation ensures an empty bladder, preventing concerns about a full bladder impeding uterine contractility and the risk of bladder trauma during surgery. There may be a lack of postpartum bladder tone, and therefore it is most important to keep an eye on this following birth or post caesarean section where a woman has had an epidural or combined epidural/spinal block. Urinary catheterisation poses an additional risk for the development of subsequent postpartum infection (Mayberry & Clemmens 2002).
- Some hospitals routinely offer oxygen, 6 L/min, administered through a transparent face mask.
- An electrocardiogram is attached to monitor the FHR continuously.
- A blood pressure cuff is placed (in a permanent position) so that the maternal blood pressure can be measured at two-minute intervals (using an automatic cycling device, if the hospital has one) and following insertion of the block; the maternal blood pressure is measured every five minutes.
- An oxygen saturation monitor may be attached to the woman (if the hospital has one) to measure the heart rate and peripheral oxygen saturation continuously.

Combined spinal and epidural block

The anaesthetist will perform a lumbar puncture at the L2–3 or L3–4 interspace with the woman in a sitting position. The dural puncture is usually made with a 27 G (may use a 29 G) pencil-point needle after the introduction of a Tuohy needle and identification of the epidural space. Once correct placement of the spinal needle has been confirmed by the aspiration of cerebrospinal fluid, 1.5–1.8 mL of 0.5% hyperbaric bupivacaine is given (varying with each woman's height: 1.5 mL for women under 1.65 m tall; 1.8 mL for those 1.65 m tall or taller and over 30 s). A 20 G epidural catheter is inserted 3–4 cm into the epidural space and secured in place with adhesive tape after withdrawal of the spinal needle, and the woman is positioned supine with a 15 degree left lateral tilt achieved by placing a wedge under her right hip. Uterine displacement by either lateral tilt positioning or wedging the right hip minimises the maternal–fetal effects of compression of the aorta or inferior vena cava. (Compression of the aorta or inferior vena cava decreases the blood return to the right side of the heart, which in turn contributes to maternal hypotension, which in turn contributes to a decrease in uteroplacental perfusion (Conklin & Backus 1999; Poole 2003).) If the block does not reach the T4 level after about 10 minutes, 10 mL of 0.25% plain bupivacaine plus 50 mg fentanyl (top-up) may be given epidurally in addition. The aim of this technique is to raise the level of spinal block to T8–9 by using low doses of local anaesthetic and to cause it to reach the T4 level by means of a low epidural top-up dose given in the next 10 minutes. There is not as yet any consensus about the nature of the mechanism by which the epidural top-up dose works (Karaman et al 2005).

It takes about 10 minutes to achieve a block using the combined method. If the woman is having an elective caesarean section, it may be about 15 minutes before surgery begins.

This description is one way of inserting a spinal epidural block. There are many variations—different anaesthetists will use different-sized needles and catheters, and different cocktails of anaesthetic.

Epidural block

The woman is placed in the sitting position and a lumbar puncture is made with an 18 G Tuohy needle at the L2–3 or L3–4 interspace. An epidural catheter is introduced, and 3 mL 2% lignocaine may be injected as a test dose. The epidural solution may consist of 16 mL 0.5% bupivacaine mixed with 100 mg Fentanyl. After an initial dose, an additional 2 mL 0.5% bupivacaine per unblocked segment may be given until a sensory block extending to the T4 level is achieved. It takes about 20 minutes to achieve a good block using the epidural (without added spinal) method, and for women having a caesarean section it may be about 25 minutes before surgery begins.

Once again, this is a description of one way of inserting an epidural block. Different anaesthetists and different hospitals will have different policies and protocols for anaesthetics and procedures. The midwifery student will always be instructed on what to do in assisting in this procedure. *Always* ask if you are in any doubt about any part of these procedures. Anaesthetics is a very complicated and potentially life-threatening business, and midwives are not permitted or expected to make any *autonomous* decisions concerning the insertion or safe maintenance of an anaesthetic. The midwife will always follow an anaesthetic policy or guideline on these matters. The midwife is always expected to safely monitor, report and document anything that she feels calls for consultation and advice.

Advantages of combined spinal and epidural blocks

Combined spinal and epidural blocks have become popular because they combine the rapid onset and intensity of a subarachnoid block with the facility of having an epidural catheter in place for follow-up intraoperative extension of anaesthesia, if necessary, and post-caesarean epidural analgesia. A spinal lumbar block requires a smaller amount of local anaesthetic to produce an effective block with complete muscle relaxation (Karaman et al 2005). The use of combined spinal–epidural analgesia (which involves the injection of minimal doses of medications directly into the spinal, rather than the epidural, space) has facilitated profound analgesia without concomitant motor block; moreover, the ability of women to ambulate while receiving this method of pain relief has added even greater flexibility to analgesic options (Camann 2005). The disadvantages of spinal lumbar anaesthesia, such as the risk of an extensive block, the fixed duration of anaesthesia, hypotension, and the risk of post-dural puncture headache (PDPH), have given rise to the use of epidural anaesthesia as an alternative method (Thoren et al 1994). In placing an epidural, the anaesthetist is able to target the exact level the block will extend to and maintain the block with supplementary doses. The catheter can remain in place for surgical anaesthesia and subsequently for postoperative pain relief. However, epidural anaesthesia is more time consuming and involves a higher incidence of insufficient or superficial block, especially of the motor roots, despite the use of larger doses of local anaesthetic agent (Karaman et al 2005). The use of epidural anaesthesia for caesarean sections has been criticised because of the 25–38% rate of ineffective anaesthesia. It is difficult to obtain complete anaesthesia during this operation in pregnant women, because of the anatomical changes in the epidural space (Choi et al 2000). This is why fentanyl, epinephrine and $NaHCO_3$, with proven effects of potentiating the effects of local anaesthetics, are used to increase the efficacy of epidural analgesia (Choi et al 2000; Davies et al 1997; Karaman et al 2005).

Patient-controlled epidural analgesia

Patient-controlled epidural analgesia (PCEA) is becoming a more popular method for the administration of epidural anaesthetic because it allows the woman to control the rate of anaesthetic drug according to her needs rather than having to call someone to 'top up' the epidural. It differs from continuous epidural infusions in reducing the dose of local anaesthetic used. PCEA provides equivalent analgesia with lower anaesthetic usage, lower rates of supplementation, and higher patient satisfaction. Currently, there is no consensus on the most appropriate PCEA solutions, basal infusion rates, lockout intervals and demand dosing (Poole 2003). Threats to maternal safety, including hypotension, catheter misplacement, high blocks and respiratory depression, appear to be lessened with PCEA. Hypotension is more common following the initial placement of the epidural with the initial sympathetic blockade. PCEA maintains a more stable maternal haemodynamic status, and hypotension is rare, even after self-administered boluses (Paech 2000; Poole 2003).

Positions during labour with an epidural

After the insertion of an epidural, depending on the type, some women may be advised to move cautiously during labour (walking epidural). Other women may find the trailing leads of IV fluids, catheter bags and CTG leads too cumbersome to contemplate moving from a stationary position for the duration of the labour. A controversial area of management of epidurals in labour has to do with how long a woman remains in 'second stage' without pushing the baby out. Soo Downe and colleagues (2003) used an RCT to study the different positions women might best use for the second stage of labour with an epidural. Women are normally encouraged to sit up, to maximise the use of gravity in encouraging descent of the fetus (Downe et al 2003). However, the women randomised to the lateral position had a greater chance of a spontaneous birth, and of avoiding an episiotomy, than those randomised to the sitting position. The number-needed-to-treat calculation indicates that, for every five women using the lateral position (as opposed to the sitting position), one more experienced a normal birth, and one less an episiotomy. However, the 95% upper limit of 1.01 for the relative risk ratio implies that, for the population as a whole, there may be no advantage in the use of the lateral position in the context of epidural analgesia in labour (Downe et al 2003).

BOX 35.10 Common terms

Commonly used terms in analgesia/anaesthesia:

- *analgesia*—the use of medication to decrease or alter the normal sensation of pain
- *anaesthesia*—the use of medication to provide partial or complete loss of sensation with or without the loss of consciousness
- *combined spinal/epidural*—the simultaneous combination of both spinal and epidural anaesthesia
- *local anaesthetic agent*—a pharmacological agent capable of producing a loss of sensation in an area of the body
- *epidural (lumbar or peridural) block*—injection of an anaesthetic again with or without added opioid and/or epinephrine into the epidural space (lumbar spinous interspace between L4 and L5) as intermittent boluses or a continuous infusion
- *neuraxial analgesia*—administration of analgesic agents (local anaesthetic or opioids) either continuously or intermittently into the epidural or intrathecal space to relieve visceral pain
- *patient-controlled epidural*—a technique that allows the woman to self-administer a dose of epidural medication
- *regional (as opposed to general) anaesthetic*—the use of local anaesthetic agents to induce anaesthesia through the effect onto the spinal cord and nerve roots. Techniques include epidural, spinal, combined epidural and spinal. Obstetric regional generally refers to a partial or complete loss of sensation below the T8 to T10 level.
- *spinal anaesthesia (saddle block)*—an injection of an anaesthetic agent with or without added opioid and/or adrenaline into the subarachnoid space (lumbar spinous interspace between L4 and L5) as single-dose intermittent boluses or as a continuous infusion.

(Sources: Poole 2003a,b)

BOX 35.11 Commonly used drugs

Opioids

- *morphine*—crosses placenta rapidly; fetal effects dose and GA dependent; decreased FHR variability; maternal and neonatal CNS depression; inhibits oxytocin release and decreases uterine contractions
- *fentanyl*—potent respiratory depressant; cumulative effect with large dose over time; crosses placenta rapidly; excreted in breast milk

Analgesia/anaesthesia

- *provocaine/novocaine*—slow onset with short duration; one of the first ester local anaesthetics; poor spreading and penetrating properties; has been used for spinals but because of short duration is generally combined with another agent for labour
- *lignocaine/xylocaine*—relatively fast onset with intermediate duration; produces profound motor blockade; generally used for surgical block; 5% hyperbaric lignocaine may produce transient neurological symptoms involving lower back and extremities when used for spinal injections; crosses placenta rapidly; fetus and newborn can metabolise; elimination half-life in newborns is approx. 3 hrs; may produce CNS depression in newborn; small amounts excreted into breast milk but considered compatible with breastfeeding
- *ropivacaine*—moderate onset with long duration; less potent than bupivacaine; similar blocking properties to bupivacaine; intensity and duration of motor blockade shorter than that of bupivacaine when used for caesarean.
- *bupivacaine/marcaine or sensorcaine*—moderate onset and long duration; used for subarachnoid blockade for caesarean birth; duration and extent of blockade is dose-related; approx. four times as potent as lignocaine; duration is enhanced if adrenaline is added; accidental IV administration can cause acute cardiovascular collapse.

(Sources: Poole 2003a,b)

Side-effects of epidural and spinal anaesthesia

Side-effects of epidural and spinal anaesthetic in childbirth range from moderately mild to catastrophic. Lumbar epidural block provides safe obstetric analgesia and anaesthesia, but inadvertent intravascular, intrathecal or subdural injection are potentially life-threatening. There were four maternal deaths due to high spinal block reported in the Confidential Enquiries into Maternal Deaths in the United Kingdom, between 1982 and 1999 (Jenkins 2004).

The signs of catastrophic side-effects are described by Jenkins et al (2004) as follows:

- *Intravascular injection* is diagnosed when the woman complains of perioral paraesthesia, visual disturbance or tinnitus, usually following the test dose or an incremental dose of low concentration local anaesthetic. Intravascular injection of local anaesthetic may lead to convulsions, loss of consciousness and cardiac arrest. However, these symptoms are frequently preceded by premonitory signs, such as minor auditory or visual symptoms and complaints of a metallic taste. Incidence 1 in 5000 epidurals.
- *Intrathecal injection* is diagnosed when injection of local anaesthetic, usually the test dose or an incremental dose of low concentration local anaesthetic, leads to a rapid onset of dense sensory and motor block with sacral involvement. Incidence 1 in 2900 epidurals.
- *Subdural injection* is diagnosed when injection of local anaesthetic leads to an unexpectedly high block, often asymmetric and involving the arms and face nerve roots. Subdural block is slower in onset than subarachnoid block, taking 15 to 30 minutes, and motor block and hypotension may be minimal or absent. However, it can also lead to life-threatening collapse with hypotension and apnoea. Incidence 1 in 4200 epidurals.

- *High or total spinal block* due to subarachnoid or subdural injection of local anaesthetic is diagnosed in the presence of a rapidly progressing motor and sensory block followed by respiratory paralysis requiring intubation, hypotension and loss of consciousness occurring within seconds to 20 minutes. High spinal block may occur after an apparently normal test dose. Incidence 1 in 16,200 epidurals.

Headache caused by 'dural tap'

A common and very unpleasant side-effect of an epidural is known as a 'dural tap'. Insertion of an epidural needle for obstetric epidural analgesia or anaesthesia is complicated by accidental dural puncture in 1 in 50–250 cases (Paech et al 2001), or a 1.5% risk of accidental dural puncture, with the rate among maternity units in the United Kingdom ranging from 0.19% to 3.6% (Baraz & Collis 2005). Accidental dural puncture is the most common major complication of epidural pain relief, and the headache following this complication can be very distressing and extremely disabling to the mother who is trying to nurse her newborn in the postnatal period. Following a dural tap, postdural puncture headache (PDPH) develops in at least 80% of women. Although serious, morbidity is rare, severe and prolonged headache is common, and the health care costs are enormous. According to Paech et al (2001), the Australian Patient Safety Foundation calculated that, based on an estimated 180,000 deliveries with a 33% epidural rate, a 1% incidence of dural puncture, inpatient costs of A$500 per day and an additional hospital stay of three days, the penalty imposed on the national health budget exceeds A$1 million per year.

As the use of epidurals is burgeoning, and the incidence of dural tap has not improved much, this poses a real cost to women and the health system. PDPH has implications for the mental and physical health of the mother. It often lasts several days, prolongs hospitalisation, and may be associated with auditory and visual disturbances, nausea and vomiting, and cranial nerve palsy.

The early or immediate headache that follows puncture with an epidural needle is attributed to the effects of rapid caesarean section and accidental subarachnoid injection of air (Paech et al 2001). PDPH usually presents within 24 hours. Despite a variety of definitions, most women report that PDPH after accidental dural puncture is severe. Many symptomatic therapies have been tried during expectant management, including systemic opioids, NSAIDs and cerebral vasoconstrictors such as caffeine. Epidural or systemic morphine appears to relieve established PDPH. Caffeine has been advocated, but has a weak and transient effect, is occasionally associated with postpartum seizures and is not widely used. Untreated PDPH after dural puncture is said to last six to eight days, but many patients remain symptomatic for weeks if untreated (Paech et al 2001). After several days of persistent PDPH, closure of the dural hole by a blood patch is advisable, to avoid not only chronic headache but also serious complications such as subdural haematoma or durocutaneous fistula (Paech et al 2001).

Inserting a blood patch

Contraindications to blood patch are fever and risk of bleeding.

The woman is usually placed in the left lateral position and the procedure carried out under strict aseptic conditions, including skin preparation and the wearing of mask, gloves and gown when identifying the epidural space, and mask and gloves when performing venipuncture.

Autologous blood is collected by the second anaesthetist and handed to the first, who injects slowly into the epidural space until 15–20 mL is delivered or a feeling of intense pressure or pain is reported by the woman. Women are advised to remain recumbent for two hours (Banks et al 2001). All patients are reviewed after the blood patch and discharged within a few hours. Patients are routinely informed that they should report back to the hospital if they have any concerns following discharge (Banks 2001).

Serious complications associated with epidural blood patch include lumbovertebral syndrome, arachnoiditis (thought to be due to injection of blood into the subarachnoid space via an intrathecally placed catheter), acute meningeal irritation, deterioration of mental status and seizures, subdural haematoma, acute exacerbation of PDPH and transient bradycardia (Banks et al 2001). The incidence of these events is unknown, but case reports are sporadic and infrequent. Nevertheless, because they may have serious consequences for the patient, such complications should be discussed when obtaining informed consent for a blood patch (Banks et al 2001).

Hypotension associated with epidural or spinal blocks

The incidence of hypotension among women having an epidural is between 0% and 50%, and hypotension is described as a maternal systolic arterial blood pressure either below 90–100 mmHg or a 20–30% decrease below baseline (Mayberry & Clemmens 2002). Blood pressure is carefully monitored in all patients receiving epidurals regardless of the technique or drug combination/dosage regimen. Maternal blood pressure should be assessed frequently (as often as every five minutes during the first 30 minutes and every 15 minutes thereafter with stabilisation, and then continued frequently throughout the remainder of labour). Each hospital will have a local policy for the management of fluids for women having epidurals. It is important for the student to be aware of local guidelines and standard procedures. A drop in blood pressure usually happens soon after the introduction of an epidural, but it is wise to continue monitoring during labour. The development of orthostatic hypotension when women move to an upright position or get out of the labour bed is also a potential risk for women receiving epidurals. Appropriate positioning to relieve potential aortal and inferior vena caval compression is necessary to minimise the risk of hypotension and the reduction of blood return to the heart, lowering of cardiac output and reduction of placental perfusion associated with recumbent positions in labour (Mayberry & Clemmens 2002). The lateral position is preferable to a supine position if

BOX 35.12 Epidural management

Standard management procedure for a first-time mother (primipara) who has an epidural in labour

Before progressing to an epidural, the woman may be offered either a non-pharmacological option, or an opioid (pethidine) or nitrous oxide.

When an epidural is decided upon, the following interventions are undertaken:

- An IV line is inserted to administer IV fluids.
- A urinary catheter is inserted.
- A continuous CTG monitor is applied.
- The woman is confined to bed.
- Regular blood pressue (BP) recordings are made (to watch for low BP).
- Most women are augmented with Syntocinon in the drip (62% of primiparous women).
- The delay before 'pushing' in second stage varies from three hours to no time limit (depending on hospital policy).
- The duration of second stage varies from 1.5–4 hours to no time limit (depending on hospital policy).

Based on a study of the 'standard' primiparous woman having an epidural in New South Wales, in 2000.

(Source: Roberts et al 2003)

there are problems with hypotension. If the hypotension persists and is not alleviated with positional changes after administration of an epidural, sometimes vasopressors may be required.

Overuse of electronic FHR monitoring has been an issue in obstetric care for at least the past five years, but the increased epidural rate is likely to be a primary reason for its continued use. Standard hospital protocols require that women be monitored using electronic FHR monitors throughout the duration of labour. One reason is that potential FHR changes in response to a decrease in uterine blood flow is a risk associated with maternal hypotension (Mayberry & Clemmens 2002).

Standard management of epidurals requires the woman to have IV fluid administration and regular monitoring. Blood pressure changes occurring with an epidural are associated with the blocked sympathetic outflow resulting in vascular vasodilatation.

Shivering

Shivering occurs in at least 20% of women during labour without neuraxial analgesia, and about 35% with epidural analgesia. Shivering can be distressing for women and can interfere with monitoring. Its impact can be minimised by warming IV fluids; and administering epidural fentanyl can reduce its incidence and severity (Karaman et al 2005).

It is curious that shivering is observed so often, because increased energy expenditure during labour presumably requires heat dissipation rather than heat production. Physiologists believe that the shivering in labour is largely nonthermoregulatory, and the causes of these responses remain unknown (Panzer et al 1999).

Pruritus associated with epidural and spinal blocks

Epidural morphine is used widely for pain relief because it has a prolonged analgesic effect but it produces many side-effects such as pruritus, nausea, vomiting, respiratory depression and difficulty in micturition. Epidural morphine produces better analgesia than IV morphine, but more severe pruritus. The exact mechanism of pruritus is not clear; medullary dorsal horn activation may be related (Jeon et al 2004). The treatment of opioid-induced side-effects remains a challenge. From a systematic review of the side-effects of epidurals, Mayberry et al (2002) found that the incidence of pruritus among women who were given drug combinations containing one or the other opioids (with or without anaesthetics) ranged between 8% and 100%, with an average of 62%. The highest incidences were noted in study groups in which the highest doses of narcotics were administered. The incidence of pruritus within studies in which women were not given a drug combination including either fentanyl or sufentanil was 0% to 4%. The average length of discomfort was not specified in the studies, but most investigators reported symptoms of pruritus that were not considered severe enough to require treatment. Women who have 'fentanyl-only' epidurals experienced more widespread body distribution of pruritus than the other groups, in which only facial symptoms predominated.

Treatments for pruritus may consist of IV administered opioid antagonist or diphenhydramine. Effectiveness in terms of the extent of relief (i.e. complete or not) and how long the medications took to work are not known.

Nausea and vomiting

The risk of nausea and vomiting in caesarean sections performed under local anaesthesia depends on the technique used, the severity of hypotension, surgical stimulus, the woman's position, and any medications given. The incidence varies from about 30% to 35% of women who have an epidural (Davies et al 1997; Karaman et al 2005) and between 20% and 25% of women who have a combined spinal and epidural block (Davies et al 1997; Karaman et al 2005). The occurrence of this side-effect is lower when women have a block not followed by caesarean section. The average incidence of nausea alone is about 7.3% (Mayberry & Clemmens 2002) and the average incidence of nausea accompanied by vomiting is about 5%, with a range of 0% to 13% (Mayberry & Clemmens 2002). Severe nausea accompanied by vomiting may be an added risk for hypoglycaemia associated with prolonged fasting, particularly for women who have spent a lengthy period in the labour and delivery ward without food (Mayberry & Clemmens 2002).

Maternal and neonatal outcomes

Randomised studies show that compared with other forms of analgesia, epidurals are associated with increased length

TABLE 35.4 Explaining epidural anaesthetic risks to women

		Epidural complication
1 in 1	Something happens every time	
1 in 10	Something happening to one person in a family	Progress to instrumental birth
		Difficulty moving legs
		Itching
		Difficulty passing urine
1 in 100	Something happening to someone in your street	Headache
		'Failure' of epidural
1 in 1000	Death from smoking > 10 a day	Severe fall in blood pressure
	Death in car accident in your lifetime	Neurological injury from spinal
		Neurological injury from epidural
1 in 5000		Intrathecal injection
		Intravescular injection of local anaesthetic
1 in 10,000		Total spinal block
		Meningitis
		Nerve damage
1 in 15,000		
1 in 100,000	Being murdered	Spinal haematoma after spinal
		Spinal haematoma afer epidural
		Paralysis
1 in 1,000,000	Death due to the Pill	
1 in 10,000,000	Struck by lightning	Maternal death from anaesthesia
1 in 100,000,000	Something happening to someone in Europe	
1 in 1,000,000,000	Something happening to one person in the world	

(Source: adapted from Adams & Smith 2001 and Bethune et al 2004)

of labour, oxytocin augmentation, instrumental deliveries, perineal trauma and maternal fever/neonatal sepsis evaluation (Leighton & Halpern 2002). There is little evidence from randomised trials specifically about labour management among women with epidurals (Lieberman & O'Donoghue 2002). In 2005 research was undertaken in Australia to determine the association between epidurals and other interventions in labour and birth (Tracy et al 2006). The cascade of interventions that follows the introduction of an epidural indicates that interventions such as epidurals during labour and birth should have been evaluated more thoroughly before their 'wholesale' introduction into maternity practices. Women are very often given no indication of the rate of risk associated with having an epidural for pain relief in labour. Figures 35.5 and 35.6 illustrate the association between interventions such as oxytocic induction of labour with or without an epidural for labour, and the resulting use of forceps or vacuum instrumental birth or caesarean section. The data were derived from a population of women who had no risk markers for obstetric complications such as gestational hypertension or gestational diabetes, or pre-medical problems such as hypertension or diabetes noted during pregnancy. They represent the average healthy woman in Australia or New Zealand who is about to give birth, or has given birth in the past five years. The graphs show that when an epidural is used during labour, the rate of spontaneous vaginal birth falls, for first-time mothers and for mothers having a subsequent baby.

Side-effects for the baby

A recent meta-analysis (Reynolds & Seed 2005) showed that spinal anaesthesia for caesarean section is associated with a greater degree of fetal metabolic acidosis than is either general or epidural anaesthesia. The study concluded that although the limited evidence from randomised studies is a reason for caution, it is entirely consistent with that from non-randomised studies.

Many factors may influence neonatal acid–base balance at caesarean section, such as a direct effect resulting from placental drug transfer, or an indirect effect resulting from maternal physiological or biochemical changes. There are numerous aspects of management that may affect the baby indirectly, including IV fluid loading, the use of vasopressors, maternal position or uterine displacement, the presence and extent of sympathetic blockade, inspired oxygen concentration, skin incision and uterine incision, delivery intervals and previous use of sedative drugs (Reynolds & Seed 2005). The normal umbilical artery pH has been taken as ≥ 7.2 and the base excess as -10 to 0 mEq/L (Reynolds & Seed 2005); consequently, fetal acidosis is defined as umbilical arterial blood pH < 7.20 (Kansal et al 2005). Metabolic acidosis is a marker of anaerobic metabolism and hypoxia, but it does not identify, by itself,

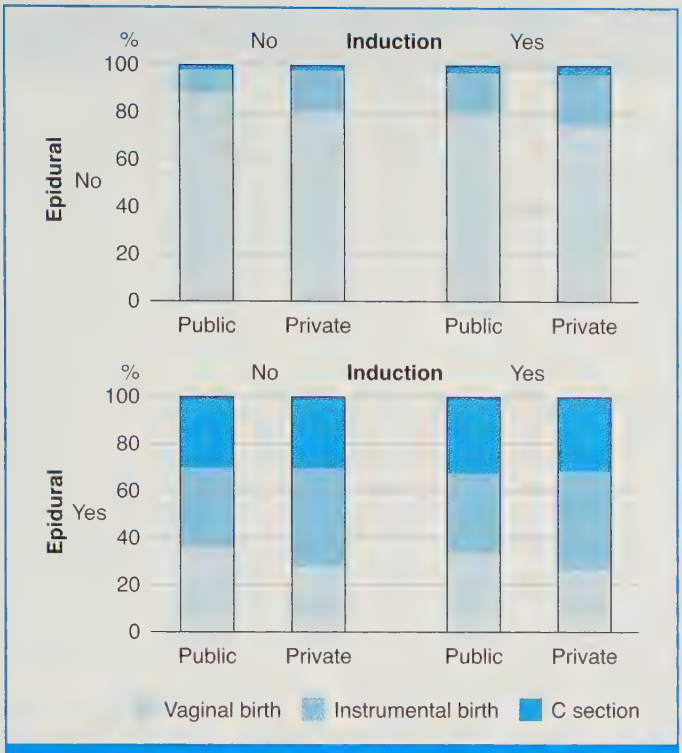

Figure 35.5 The cascade of labour interventions followed by birth interventions for primiparous women with medically uncomplicated pregnancies in Australia, 1999–2002, showing rates for women in public hospitals and women who had private health insurance. Interventions in labour are strongly associated with a falling rate of spontaneous vaginal birth and a rising rate of instrumental birth and caesarean birth (based on Tracy et al 2006)

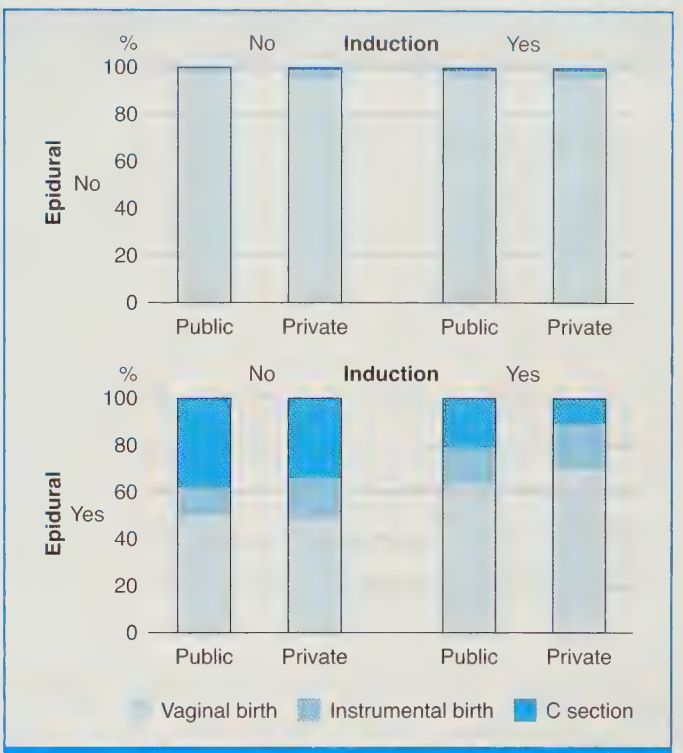

Figure 35.6 The cascade of labour and birth interventions for multiparous women with medically uncomplicated pregnancies in Australia, 1999–2002, showing rates for women in public hospitals and women who had private health insurance. As more interventions were introduced in labour, the rate of spontaneous vaginal birth fell and the rate of instrumental birth and caesarean birth rose (based on Tracy et al 2006)

newborn infants with a risk of long-term sequelae. Base excess measures or quantifies metabolic (non-respiratory) acid–base status (Reynolds & Seed 2005).

It is remarkable that spinal anaesthesia can induce a significant increase in fetal metabolic acidosis over the normally short time interval between administration of anaesthesia and delivery of the baby by caesarean section. Maternal blood pressure cannot be used as a surrogate for fetal outcome, as the changes may be too short-lived. Moreover, placental intervillous blood flow is dependent not solely on maternal blood pressure but also on maternal cardiac output and its distribution. It has been shown that spinal but not epidural anaesthesia is associated with a reduction in cardiac output even in the presence of a normal blood pressure (Reynolds & Seed 2005).

Breastfeeding

A dose–response relationship between fentanyl and artificial feeding was recently reported. When well-established determinants of infant feeding are accounted for, intrapartum fentanyl may impede establishment of breastfeeding, particularly at higher doses (Jordan et al 2005)

General anaesthesia

General anaesthesia is most likely to be used for a caesarean birth when there are no obstetric anaesthetists available to administer a spinal or epidural anaesthetic, or during an emergency, or if the woman has a contraindication to the use of regional anaesthesia. Pregnant women respond differently than non-pregnant women to the pharmacological agents used for general anaesthesia. Cricoid pressure may be called for to reduce the risk of aspiration of gastric contents. To reduce gastric acidity, an H_2-receptor antagonist, proton pump inhibitor, and/or metoclopramide and/or a clear antacid administered orally may be given (Poole 2003). Although maternal mortality from anaesthesia-related causes has declined since the mid-1980s (Poole 2003), anaesthetic-related deaths in Australia are still more likely to be related to general anaesthetic than to epidural or spinal anaesthetic (see Table 35.5).

Caesarean birth

There is a possible physiological explanation for the fact that epidural analgesia increases the likelihood of caesarean

TABLE 35.5 Leading principal causes of direct maternal deaths, Australia, 1973–1996

	1973–1984		1985–1996		1973–1996

section. Lower-body muscle weakness resulting from epidural analgesia may inhibit normal fetal rotation and descent and maternal expulsive efforts, particularly when the epidural agent is administered in early labour (Camann 2005). Some retrospective observational studies have shown a higher incidence of fetal malpresentations among women who received an epidural analgesic during labour; particularly early labour (Eltzschig et al 2003). However, Wong et al (2005) report the results of an RCT of 750 primiparous women who had a spontaneous onset of labour and were offered opioids by a combined spinal–epidural 'early' in labour (at about 2.0 cm) compared with a control group who were administered analgesia at cervical dilatation of about 5.0 cm. The results showed that there were no significant differences observed between the two groups in the rates of caesarean delivery and instrumental vaginal delivery (Wong et al 2005). Even so, the caesarean rate was 17.8% (65/366) in the intervention group and 20.7% (75/362) in the control group. In addition, the instrumental rate was 19.6% and 16% respectively, with over 90% of all women in the trial being augmented with an oxytocin infusion (Wong et al 2005).

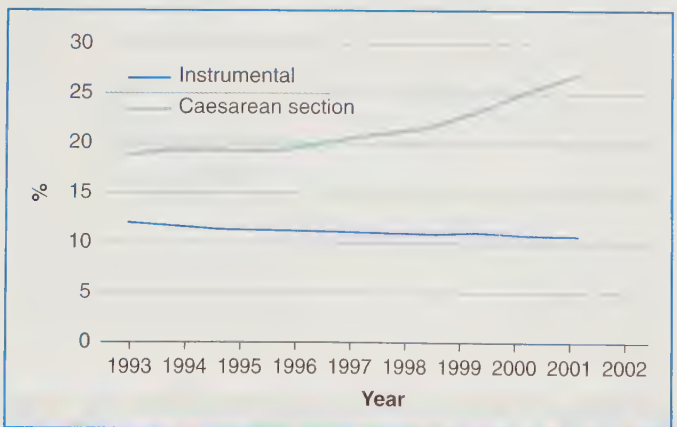

Figure 35.7 Rates of caesarean and instrumental births for women in Australia, 1993–2002 (based on Laws & Sullivan 2004)

Why caesarean delivery?

The rates of caesarean delivery continue to rise in Australia, New Zealand and the rest of the industrialised world. There is evidence that elective caesarean delivery is increasingly chosen by healthcare professionals and women. The rise in proportion of deliveries by caesarean does not seem to be explained by a change or increase in obstetric complications (Bell et al 2001). It is therefore of public health importance that the short- and long-term consequences of caesarean delivery are well understood and available to inform choice (Black et al 2005). There were 67,806 caesarean sections performed in Australia in 2002 (Laws & Sullivan 2004), representing 27% of all births in Australia for that year; and 22.7% or 12,053 of the 53,039 mothers who gave birth in hospital in New Zealand were by caesarean section (MOHNZ 2004). Collectively this means that, each year, more than 80,000 women are having major surgery when they give birth to a baby in our two countries. This represents a very large rate of morbidity in an otherwise healthy and strong cohort of women. In fact, for the year 2002 in Australia, less than 2% of all women had risk markers for a medical condition during pregnancy, and less than 10% had a previous obstetric complication such as gestational

diabetes or gestational hypertension (Tracy et al 2006). This means that less than 12% of Australian childbearing women have risk markers that suggest an intervention may be required. Why, then, has the rate of caesarean delivery climbed so dramatically in the past 25 years?

The explanations include a lower tolerance for taking risks; fear of malpractice litigation; increased use of epidural anaesthesia; increased use of EFM, which has a high false-positive rate for the detection of fetal hypoxia or acidosis; and physicians' convenience. It can be quicker to do a caesarean delivery than a vaginal delivery during a difficult labour. A couple's expectation of a perfect baby, as well as a woman's previous experience of a difficult labour undoubtedly play a part in the decision to perform a caesarean delivery. Epidural anaesthesia has afforded women relatively effective and safe analgesia during labour, but it may increase the risk of dystocia and therefore the frequency of caesarean delivery in primiparous women. In the absence of previous caesarean delivery, the reasons for selecting caesarean delivery as the method of delivery are complex and are influenced by factors affecting women, obstetricians and midwives. The literature describes a diverse range of factors influencing this decision, from fear of childbirth, potential for perineal injury, incontinence, sexual dysfunction and fear of fetal injury, to convenience and control (Wax et al 2004).

The evidence to support the relative safety of different surgical modes of delivery is complex, often controversial, and remains conflicting. Other than one trial of vaginal compared with caesarean delivery for term breech presentation, little evidence from RCTs exists to compare the safety of caesarean with vaginal delivery (Bell et al 2001). With the growing trend toward 'patient choice' or 'purely elective' caesarean deliveries, there is a need for better understanding of the risks of all forms of delivery, to enable informed consent (Black et al 2005). In countries where the age of first-time motherhood has increased—in countries such as New Zealand and Australia—caesarean section rates have increased with maternal age. In New Zealand in 2002, 36.1% (640/1774) of women over 40 years had a caesarean section, whereas only 13.1% (467/3568) of women in the 16–19 years age group had a caesarean section.

A similar phenomenon has occurred in Australia, where older first-time mothers are much more likely to have intervention in labour and birth (including caesarean section) than first-time mothers between the ages of 25 and 29 years (Tracy et al 2006). Women having their first baby between the ages of 35 and 39 years are three times more likely to have an elective caesarean section, and women aged between 40 and 44 years and having their first baby are eight times more likely to have an elective caesarean section than women aged between 25 and 29 years (Tracy et al 2006).

Although caesarean section rates have increased over the past 10 to 15 years, the major clinical determinants of the caesarean section rate have not changed (NICE 2004).

Lowering caesarean rates

In Australia, caesarean rates rose from the rate of 18.0% in 1991 (Lancaster & Pedisich 1994) to 23.3% in 2000, and 27% in 2004. This is similar to the rate in the United States, 26.1%, the highest level ever reported in that country (Martin et al 2004). Similar alarming rates are reported in the United Kingdom.

New Zealand has a significantly lower national caesarean section rate than Australia, and in particular the primary units (where women are attended mainly by midwives) in both New Zealand and Australia are showing extraordinary gains in lowering the caesarean section rate. This is also noted worldwide, and the NICE guidelines (2004) have an entire section on the lowering of caesarean section rates through birth in primary units, birth centres or outside hospital with midwives at home.

TABLE 35.6 Type of birth among New Zealand women, 2002

Age group (years)	Normal birth (%)	Caesarean section			Operative vaginal birth				Total (%)
		Total (%)	Actute (%)	Elective (%)	Total (%)	Breech (%)	Forceps (%)	Vacuum (%)	
Under 16	77.5	11.6	10.9	0.8	10.9	0.8	3.1	7.0	100.0
16–19	78.0	13.1	11.2	1.9	8.9	0.6	3.4	4.9	100.0
20–24	76.6	15.0	11.2	3.7	8.5	0.6	3.2	4.7	100.0
25–29	69.8	20.4	13.7	6.6	9.8	0.6	3.8	5.5	100.0
30–34	63.8	25.4	15.5	10.0	10.8	0.6	4.5	5.7	100.0

Critical thinking exercise

Make a note of the neonatal and maternal outcomes from midwife-led units and primary level units that are documented in the literature so far. Draw a comparison table of the rates of intervention (caesarean section/instrumental birth in relation to the perinatal mortality of those countries. Report data from your own practice concerning caesarean birth rates and prevention, vaginal birth after caesarean, and elective caesarean.

Indications for caesarean section

The main indications for a caesarean delivery are:

- a prior caesarean delivery (accounting for 35% of all caesarean deliveries)
- dystocia or cephalo-pelvic disproportion (30%)
- breech presentation (12%)
- 'non-reassuring' fetal heart rate tracings (9%) (Black et al 2005).

The fifth most common reason given for performing a caesarean section has changed and is now reported to be 'maternal request' (7%) (NICE 2004).

Caesarean birth is the delivery of the infant through an abdominal and uterine incision. The method originated as a salvage procedure to rescue a child from a dying or dead mother. Technological and medical advancements have altered society's attitude towards caesarean birth from considering it a 'procedure of last resort' to an 'alternative birth method'. Nevertheless, it is a traumatic and often difficult decision for all concerned, and the risks and benefits of surgical birth should always be thoroughly discussed with each woman.

Shoe size, maternal height and estimations of fetal size (ultrasound or clinical examination) do not accurately predict CPD and should not be used to predict 'failure to progress' during labour. Although there are insufficient data on the morbidity of the mother and the baby to fully support the benefit of caesarean section over vaginal birth, the following reasons are usually given:

- Breech presentation—following the publication of the results of the term breech trial of Hannah et al (2000) in *The Lancet*, the rate of caesarean delivery for breech presentations has increased in all countries where this surgical option is available.
- Fetal distress—at some point during the progress of labour, a decision may be made to surgically intervene and deliver the baby to prevent the development of asphyxia.

Caesarean section 'on demand'

Michel Odent makes the observation, in his booklet on caesarean sections (Odent 2004, p 7), that at the end of the twentieth century, we were wondering whether it is ethical for women to 'demand' to have a caesarean section on request (without known medical indicators), and at the beginning of the twenty-first century, we are wondering whether all women should give birth by caesarean section! The phenomenon of elective caesarean section on demand began in Italy and in the largest Latin American cities (Behague et al 2002; Belizan et al 1999; Potter et al 2001) before the rest of the world (Odent 2004). There has been vigorous debate about the ethical and biological 'need' for women to have an elective caesarean section on demand. In Australia, several factors have influenced the prevalence of elective caesarean birth. These include the belief that caesarean section is protective of urinary and fecal incontinence, that elective caesarean section is safe, and that women's autonomy around birth translates into their right to choose an elective caesarean section regardless of clinical indication. (For further discussion of the concept of a woman's right to choose caesarean section, you are advised to read Bewley & Cockburn 2002, Clement 1995, O'Neill 2002 and Odent 2004.)

The following dot point summaries will give you an idea of how contentious the subject is:

- In 1998, Professor Philip Steer argued that as a race we are still evolving, and as our brains and (therefore craniums) are expected to become larger, there will be a time when the baby's head may no longer be able to squeeze out of the birth canal in the conventional way (Steer 1998).
- The American College of Obstetricians and Gynaecologists released a statement in 2003 that it considered elective caesarean section to be 'ethical' (ACOG 2003). It qualified this statement by saying that in the absence of a specific patient request for elective caesarean, the lack of hard data favouring this procedure does not obligate the obstetrician to initiate discussion regarding relative risks and benefits versus vaginal delivery. However, if a patient requesting a caesarean continues this request after informed counselling, and the physician believes that caesarean will promote the overall health of the patient and fetus more than vaginal delivery, then elective caesarean is ethically justified (ACOG 2003).

Reflective exercise

Ethical issues in elective caesarean birth force us to examine our obligations of justice (treating women fairly, and allocating heath resources fairly), respect for autonomy (self-governance, privacy and individual choice), non-malfeasance (only offering treatments that have a benefit, doing no harm), and beneficence (promoting good and preventing harm). A woman's autonomy in making decisions concerning mode of birth has displaced an outdated paternalistic model of care (McFarlin 2004). Research into the harms of childbirth and its interventions risks being distorted on both sides of the debate.

Can you make a 'case' for and against the right to have a caesarean section 'on demand'?

- The National Institute of Clinical Excellence (NICE) stated at the same time that in its considered opinion, doctors should not refuse a woman the right to have an elective caesarean section, but that the reasons for the request should be sought, recorded and discussed in depth (NICE 2004, p 38).
- The International Federation of Gynaecology and Obstetrics (FIGO) stated that it is unethical to perform a caesarean section without a medical reason because of inadequate evidence to support a net benefit (Schenker & Cain 1999).

To maintain objective decision-making in the face of a barrage of medico-legal, media and emotional concerns is difficult, and it would be easy for women and doctors to slip into a short-term approach of doing caesarean section as the easy way out: 'the belief that a caesarean delivery is the easy way does not appear to come from facts about caesarean birth itself but rather from deeply rooted fears about vaginal childbirth' (Clement 1995). Is it fear, or simply that obstetricians are rightly more relaxed about the dangers of caesarean section and focusing more on the recently and incompletely researched complications of vaginal delivery? (Bump 1998, cited in Bewley & Cockburn 2002).

The Canadian Association of Midwives (CAM) argued that presenting interventions such as caesarean section as 'options'

BOX 35.13 Lack of information for women

Even if doctors genuinely believe in fulfilling informed choices regardless of other ethical considerations, there is presently inadequate unbiased literature to help women. There are no standard evidence-based, or even uncertainly-based, leaflets (such as the MIDIRS Informed Choice leaflets) to help women make any postulated choice. Who knows what properly informed and assessed womean prefer?

Caesarean section rates, especially for request, are very variable, suggesting that currently women are not given fully unbiased information and so remain susceptible to cultural, media and medical fashion.

(Source: Bewley & Cockburn 2002)

BOX 35.15 CAM statement on caesarean section

Extract from statement by the Canadian Association of Midwives Board of Directors, June 2004

The debate around c-section on demand raises deep concerns for midwives about the persistent increase in obstetrical interventions and surveillance technologies used for pregnancy and birth. In many cases the increase is occurring without regard for substantiating data and despite efforts by professional organizations and consumer groups to curb rates of intervention which are not supported by evidence. This trend both reflects and serves to construct a mechanical and fragmented vision of the body and birth and also of the pregnant woman and her unborn baby. It is a product of our society's 'culture of fear' around childbirth and demonstrates the extent to which the 'epidemic of risk' is reflected in maternity care.

Presenting interventions such as c-section as 'options' puts maternity care providers and women in a consumerist relationship, and treats childbirth as a problem to be solved rather than a process to be respected. The importance of the social and cultural aspects of birth is supported by a broad humanistic discourse in the scholarly and public literature. Moreover, strong scientific evidence supports a low intervention approach. Vaginal birth is not 'an option'. It is a complex, highly developed physiologic process that deserves our fundamental respect. It is the role of midwifery and medicine to understand, promote and facilitate physiologic processes, and to intervene only when necessary.

The benefits of caesarean section and certain obstetrical interventions for specific problem situations are irrefutable. However, widespread use of intervention and technology creates fear and doubt about the adequacy of the female body, and reinforces distrust about the reproductive powers of women. When women request interventions that are not medically indicated, and when professionals offer unnecessary technology rather than support and reassurance, it may simply be an expression of those doubts. These requests can also be seen as a reflection of a system greatly in need of improving its ability to provide sensitive, supportive care in childbirth. The research on caesarean section by request clearly shows that anxiety and fear play a major role and that these factors can be addressed by more effective means than by surgery. Offering all women the choice of caesarean section is not safe and not ethical.

Midwives work in a model of care that supports the development of relationship. The potential for empowerment through 'informed choice' is much more than a neutral offer of choice. Midwifery care involves mutual trust, dialogue and acknowledgement of the fundamental uncertainy and complexity of pregnancy and birth. In that sense, empowerment comes through a process of shared decision making, not through a 'menu' of choices.

For women, families, midwives and for many other maternity care providers, childbirth is a deeply meaningful event. As a multidimensional life experience, its significance and symbolism touch the core of every society and every culture. Embedded in a historical and socio-cultural context, childbirth is far more than a medical event. As professionals, midwives consider the individual woman within her life context, and take into account factors that affect her overall health. Health policy must also take into account the societal implications affecting health as a common good. To build maternity care that is truly women-centred will require beginning with the fundamentals: trust in women and supporting their ability to trust themselves, their bodies and the birth process.

(Canadian Association of Midwives 2004)

BOX 35.14 Elective caesarean

We conclude that beneficence-based, justice-based, and autonomy-based considerations do not support routinely recommending or even offering elective caesarean delivery.

The physician should respond to questions with a thorough informed consent process and a suggestion that the woman reconsider her request in order to ensure that her autonomy is being meaningfully exercised.

In these cases, implementing her request is ethically permissible. The physician should beware of the potentially insidious influence of economic and other forms of conflict of interest. Acting on self-interest in increased income or convenience distorts clinical judgement and undermines the physician's fiduciary obligations to patients.

However, by neither dismissing a patient's informed desire regarding caesarean delivery, nor automatically acquiescing to it, the physician maintains both a responsibility to professional integrity and a respect for the patient's autonomy.

(Statement made by a group of physicians, obstetricians and medical ethicists in the United States and published by the ACOG (Minkoff et al 2004))

puts maternity care providers and women in a consumerist relationship, and treats childbirth as a problem to be solved rather than a process to be respected (CAM 2004). From an anonymous survey sent to all gynaecologists and registrars in the Netherlands in 1999, the researchers concluded that 'in The Netherlands, a woman can always find a gynaecologist willing to perform a caesarean section for non-medical reasons. This willingness increases with the age of the doctor. There is a need for guidelines when handling these cases' (Kwee et al 2004).

Preventing urinary incontinence

Many caesarean sections are performed in the belief that avoiding vaginal birth is a means of avoiding future urinary incontinence. However, the finding that prevalence of urinary incontinence in postmenopausal nuns who had never been pregnant is similar to rates reported in parous, postmenopausal women appears to be contrary to the conventional wisdom that nulliparity protects against stress urinary incontinence (Buchsbaum et al 2002). It is clear that our understanding of factors leading to pelvic floor disruption over a woman's lifetime is limited, and that the topic is extremely complex. Pregnancy itself, tissue rigidity, trauma, birth interventions, and mode of birth all probably influence the integrity of the pelvic floor (McFarlin 2004). Childbearing is an established risk factor for urinary incontinence among young and middle-aged women. It has been suggested that vaginal delivery is the main contributing factor, possibly because of damage to important muscle tissue or nerves.

However, pregnancy itself may predispose to mechanical changes, hormonal changes, or both, that can lead to urinary incontinence (Rortveit et al 2003). Studies showing the association between the mode of delivery and incontinence have so far been inconclusive. The mechanical strain during labour may add to the risk associated with pregnancy itself. In the EPINCONT study undertaken in Norway between 1995 and 1997, among 15,307 women aged between 20 years and 65 years, the prevalence of any incontinence was 10.1% in the women who had never had a pregnancy. Age-standardised prevalences were 15.9% in the caesarean-section group and 21.0% in the vaginal birth group (Rortveit et al 2003). The absolute difference of 5.7% in the prevalence between women who had never been pregnant and women who had had caesarean sections was significant. The researchers concluded that if 15% of women had caesarean sections, the population attributable risk, that is, the proportion of incontinence in the population that is attributable to vaginal birth, would be 30% for any incontinence and 41% for moderate or severe incontinence. These figures imply that attempts to prevent both any incontinence and moderate or severe incontinence in the population by encouraging the use of caesarean section would have limited effect, unless a very large proportion of women were to give birth by caesarean section only (Rortveit et al 2003). The individual woman's risk of moderate or severe incontinence would be decreased from about 10% to about 5% if she gave birth to all of her children by caesarean section, and this decrease would apply only until 50 years of age, since there was no association of incontinence with mode of birth in older age groups (Rortveit et al 2003). This study did not attempt to assess the greater risk of incontinence where women had an assisted instrumental birth. In addition, a previous report from the EPINCONT study (Rortveit et al 2001) did not show an association between parity and incontinence after 65 years of age. That study implies that the mode of birth is of minimal importance in elderly women, who have the highest prevalence of both any incontinence and moderate or severe incontinence. The EPINCONT researchers recommended that the risk of other conditions, the risk of death, or economic costs associated with the mode of birth should be considered in any policy decisions (Rortveit et al 2003).

A study comparing 184 first-time mothers who had caesarean sections with 100 controls who had a non-instrumental vaginal birth to determine incidence and severity of anal incontinence found that severe anal incontinence followed elective and pre-labour emergency caesarean, and that the risk after elective caesarean is comparable to that after non-instrumental vaginal delivery with an intact perineum (Lal et al 2003). Similar findings were reported from a large study undertaken in Australia (MacLennan et al 2000). In this study of 1546 women, in whom pelvic floor morbidity, including anal incontinence, occurred after caesarean delivery with a prevalence comparable to that after non-instrumental vaginal birth, the investigators concluded that pregnancy, not childbirth (unless compounded by instrumental vaginal birth), was responsible for the frequency of pelvic floor dysfunction. In an editorial on these Australian findings, the editor of the *British Journal of Obstetrics and Gynaecology* remarked on the fact that it is pregnancy itself, not childbirth that has the greater effect on the frequency of pelvic floor dysfunction in the population (Grant 2000). One in eight women who have never been pregnant had some form of pelvic floor dysfunction, compared with one-half of the women who

had a caesarean section or a spontaneous vaginal delivery and two-thirds of the women who underwent an instrumental vaginal delivery (Grant 2000). Meanwhile, in the United States, Diony Young, editor of *Birth*, lamented: 'What is a woman's chance of having a caesarean delivery? Certainly these days she's at high risk if she's too big or too small; too early or too late; too old or too fearful; too tired of being pregnant or too tired of being in labour; if she's having twins, if she's breech, if she's previously had a caesarean; or if she's due and so is the weekend, Christmas ...' (Young 2003).

Breech presentation at term

Breech presentation is now one of the major contributing factors to the rate of caesarean section in Australia. In 2002, 4.5% of Australian babies presented by the breech (Laws & Sullivan 2004). This means that among singleton pregnancies (and the first of twins), 1 in every 22 babies (11,309 babies) is breech. Breech presentation is now a primary indication for caesarean section.

External cephalic version

Interventions to promote cephalic version of babies in the breech position include external cephalic version (ECV), moxibustion and postural management. ECV involves applying pressure to the mother's abdomen to turn the fetus in either a forward or backward 'somersault' to achieve a vertex presentation. Recognised complications of ECV attributable to the procedure (and incidence) include:

- FHR abnormalities, the most commonest being transient bradycardia (1.1% to 16%)
- placental abruption (0.4% to 1%)
- painless vaginal bleeding (1.1%)
- admission for induction of labour (3%) (NICE 2004).

Maternal morbidity following caesarean section

In a study of all first-time mothers in Washington State 1987–1996, to determine the association between method of birth and maternal rehospitalisation within 60 days of birth, women who gave birth via caesarean or instrumental vaginal birth were twice as likely to be readmitted to hospital than those who gave birth spontaneously. Reasons for readmission were: uterine infection, gallbladder disease, genitourinary conditions, obstetric surgical wound complications, cardiopulmonary disorders, thromboembolic phenomena or appendicitis (Lydon Rochelle et al 2000). The study found an 80% increased risk among primiparous women who had a caesarean section and a 30% increased risk of hospitalisation at two months post partum for women who had an instrumental birth. The rates of admission to hospital for infection represented a 30-fold increase in surgical wound infection amont the primiparous women who had had a caesarean section. After caesarean, women were less likely to be readmitted for pelvic injury. Those women who had a forceps or vacuum birth were at increased risk for rehospitalisation for PPH, genitourinary conditions, obstetric surgical wound complications or pelvic injury compared with those having a spontaneous normal birth. Overall readmission rates were 17 per 1000 for caesarean, 12 per 1000 for operative vaginal, and 10 per 1000 for spontaneous vaginal birth (Lydon Rochelle et al 2000).

Abnormalities of placentation

Following a first caesarean section, women having their second or subsequent birth are at an increased risk of placental abruption and placenta praevia in their next pregnancy, compared with first-time mothers who give birth vaginally (Lydon-Rochelle et al 2001). The abruption risks in these groups are 13.7 per 1000 versus 10.9 per 1000 (relative risk (RR), 1.3; 95% CI 1.1–1.5) and the praevia risks are 6.9 per 1000 versus 4.7 per 1000 (RR 1.4; 95% CI 1.1–1.6), respectively (Lydon-Rochelle et al 2001). The risks appear to be a function of both parity and previous caesarean sections (Wax et al 2004). The rising caesarean section rate over the past 20 years has been accompanied by a 10-fold rise in the incidence of placenta accreta. The incidence is reported as anywhere between 1 per 1667 and 1 per 2510 births (Gilliam et al 2002; Hemminki & Merilainen 1996; Kastner et al 2002; Miller et al 1997; Wax 2004). The occurrence of abnormally implanted placentas appears to be directly related to the number of prior caesareans, mother's age either over 35 years or less than 35 years, and placental implantation over the prior uterine incision site. As early as 1997, researchers reported that a total of 3.7% of women less than 35 years of age with one prior caesarean and a placenta implanted away from the scar site had an accreta, in contrast to 38.1% of women over 35 with more than two previous caesareans and a placenta implanted over the previous uterine incision (Miller et al 1997). With the increased incidence of primary caesarean section worldwide, we can expect to see peripartum hysterectomy becoming a major morbidity among women who have had previous caesarean sections.

Neonatal outcomes

Neonatal outcomes following caesarean section vary in seriousness and long-term morbidity. Although birth asphyxia is the most worrying outcome both initially and because of the long-term sequelae (see cerebral palsy, above), serious morbidity is experienced in other forms of birth trauma. Serious trauma has been defined as subdural or cerebral haemorrhage, fractured clavicle, other injuries to skeleton, injury to spine or spinal cord, facial nerve palsy, brachial plexus injury, subarachnoid haemorrhage, convulsions, other and unspecified cerebral irritation, or cerebral depression/coma. Minor trauma may be defined as injuries to the scalp, other cranial or peripheral nerve injuries, other specified birth trauma, and birth trauma that is not otherwise specified (Baillit et al 2002). A study undertaken in Washington State from 1995 to 1996 evaluated the outcomes for all 158,177 births with no major anomalies (Baillit et al 2002) to determine the optimal caesarean delivery rate to balance quality care for

BOX 35.16 Abnormal placentation

Abnormal placental implantation with myometrial penetration can be a potentially life-threatening condition. Placenta accreta, increta and percreta represent a continuum under the broader category of placental implantation disorders. The mildest form of these is placenta accreta, which involves myometrial invasion. Placenta increta involves deep myometrial invasion. Placenta percreta is the most severe form of implantation anomaly and is defined as invasion through the serosal layer of the uterus with potential invasion of adjacent organs. Abnormal implantation of the placenta in or through the uterine wall can precipitate profuse haemorrhage, often at the time of delivery. The most common treatment for this is a hysterectomy performed immediately following birth. The incidence of emergency hysterectomy after childbirth is reported to range from 1.55 per 1000 deliveries in the United States to 0.2 per 1000 deliveries in Norway.

(Source: Engelsen et al 2001)

pregnant women and neonates. The researchers wanted to find out how low the caesarean birth rate could be before it would adversely affect babies. The study didn't set a number for caesarean sections per year but found that in hospitals where the caesarean section rate was above the average for the state, the neonatal outcomes were worse. This was also the case where the caesarean section rate was lower than the average (Baillit et al 2002). This finding suggests that the caesarean section rate can in fact become too high and cause more harm than good to babies.

The incidence of respiratory distress syndrome (RDS) and transient tachypnoea of the newborn (TTN) differs according to the method of birth of babies, whether by elective caesarean, caesarean following labour, or labour followed by vaginal birth. Studies in the United Kingdom undertaken by Morrison et al (1995) found that among term babies, the risk of neonatal respiratory distress necessitating oxygen therapy is higher if delivery is by caesarean (35.5 with pre-labour caesarean, vs 12.2 with caesarean during labour, vs 5.3 with vaginal delivery, per 1000 live births). This relationship is maintained week by week up to 40 weeks gestation, after which respiratory morbidity is statistically similar regardless of the birth delivery mode (Morrison et al 1995). Furthermore, after 35 weeks, infants delivered by elective caesarean exhibit a markedly increased risk of RDS, TTN and pulmonary hypertension relative to vaginally delivered neonates (Levine et al 2001; Wax et al 2004). The most recent study demonstrating risk associated with caesarean section found that delivery by caesarean section in the first pregnancy could increase the risk of unexplained stillbirth in the second (Smith et al 2003). In women with one previous caesarean delivery, the risk of unexplained antepartum stillbirth at or after 39 weeks gestation is about double the risk of stillbirth or neonatal death from intrapartum uterine rupture. Risk was not attenuated by adjustment for maternal characteristics or outcome of the first pregnancy (2.74, CI 1.74–4.30). The absolute risk of unexplained stillbirth at or after 39 weeks gestation was 1.1 per 1000 women who had had a previous caesarean section and 0.5 per 1000 in those who had not. The difference was due mostly to an excess of unexplained stillbirths among women previously delivered by caesarean section after 34 weeks (Smith et al 2003).

Prophylaxis for caesarean section

Both ampicillin and first-generation cephalosporins have similar efficacy in reducing postoperative endometritis. There does not appear to be added benefit in using a broad-spectrum agent or a multiple-dose regimen. There is need for an appropriately designed randomised trial to test the optimal timing of administration (immediately after the cord is clamped versus preoperative).

Preparing the woman for a caesarean section

These issues are discussed in full in the section above, on fluids and surveillance for epidural and spinal blocks. When the decision to move to caesarean section is made, there may not be much time to lose; however, it is of paramount importance that you are aware not only that the birth has become a major surgical procedure, but also that it is the beginning of a special relationship between a woman and her baby. As the midwife you will facilitate a discussion of the options surrounding caesarean section between the obstetrician and the woman, and the anaesthetist and the woman. It is important that the partner or husband is also included in the discussion and information-sharing session. Often you will be called upon to recount the events leading up to and including the caesarean birth of a baby. This is often crucial to the reconciliation of the fact that a caesarean section has had to be performed where the mother and her significant others were not planning for an emergency. Many women feel a sense of loss and grief when they have had a caesarean section. Some women feel guilty that they were unable to experience a normal, natural vaginal birth. For whatever reason women have a caesarean section, it is important to remember that this is a special event in a woman's life. There are ways of making it memorable for her, without succumbing to the depersonalising effect of technology.

Procedure for caesarean section

The procedure for an elective or emergency caesarean section is as follows:

1 Check that the woman has not had anything to eat or

Reflective exercise

What is the average number of caesarean sections in your country or state? What does the WHO recommend? Can you think of 10 ways to lower the caesarean section rate in your maternity unit or in your own practice?

BOX 35.17 Caesarean theatre staff

Theatre staff present for a caesarean include:

- obstetrician
- obstetrician's assistant (may be a student obstetric registrar or resident)
- anaesthetist
- anaesthetist's assistant (optional)
- 'scrub nurse/midwife'—the midwife or nurse who takes the sterile instruments and passes them to and from the obstetricain who is operating. She wears full theatre dress—sterile gown and gloves. The scrub nurse/midwife is responsible for the instrument and swab count at the end of surgery. She also documents the blood loss and records the observations regarding the placenta.
- paediatrician (optional)—if there is an emergency Caesarean section and fears are held for the health of the baby, a paediatrician should be present
- 'scout nurse/midwife'—the midwife or nurse who assists the others and runs errands out of the theatre if necessary. She will not be scrubbed or gowned and gloved.
- midwife—the midwife is not scrubbed or gowned and gloved. She remains with the woman and her partner at the head of the theatre table, to attend to the woman undergoing surgery. She will also help the women put the baby to the breast in theatre or in recovery immediately after theatre.

drink (not even water) for six hours prior to elective surgery.

2. On admission, follow the preoperative guidelines for your unit.
3. Maternal vital signs will be checked (BP, pulse and temperature).
4. An IV line for fluids is inserted (see above for epidural/spinal block).
5. Any hair on the incision site is removed.
6. A urinary catheter is inserted to keep the bladder empty during surgery.
7. Spend some time 'walking' the woman through the procedures that are about to take place. Inform her of the people who will be present in the theatre when the caesarean section is performed.
8. Make sure that her partner is either present at the bedside in theatre or is made comfortable outside the theatre
9. Anaesthetic guidelines concerning blood products and cross-matching will need to be adhered to.
10. The theatre should be prepared, instruments laid out and the wraps for the baby should be warmed.
11. Record all relevant details contemporaneously.
12. At the conclusion of the surgery, you may need to be vigilant in making sure the mother and baby are reunited as soon as possible, and that the baby is offered the mother's breast as soon as can be achieved. There is often no reason why babies cannot be tucked up with their mothers immediately after a caesarean birth as they would be after a vaginal birth, including in recovery rooms. Because the baby will not have had the added benefit of being squeezed through the pelvic canal of its mother, you may need to be vigilant for signs of respiratory effort. Sometimes babies born via caesarean section have 'wet lungs' that have not had the benefit of being 'squished' dry though the normal process of birth. (In fetal lambs it was observed that 75% of the fluid in their lungs at birth is squeezed out during the birth process (Berger et al 1998).)
13. Be aware that drugs such as fentanyl are very quick to cross the placenta and if they have been administered too close to birth, the baby may need to be observed for signs of respiratory arrest.

Caesarean section following previous C section

When caring for women who are attempting a vaginal birth after a caesarean section, the strongest indicator that all is not well is an abnormality in FHR. This is the most common sign of rupture, occurring in 55–87% of uterine rupture events (Guise et al 2004). Other signs may be vaginal bleeding, pain, and disturbances of uterine contractions.

Most of the information concerning the success or failure rate of vaginal birth after a caesarean (VBAC) has been forthcoming from tertiary institutions in the developed world. The set standards of practice that have resulted from these reports may well be out of reach of and irrelevant to non-academic institutions, especially in the developing world.

Of major concern is the possible maternal morbidity and mortality (mainly the risk of uterine rupture) resulting from a trial of labour after caesarean birth. In a study of births recorded in the population-based data from the Scottish birth registry, the risk of uterine rupture was a rare event, occurring in 3.5 per 1000 trials of labour (Smith et al 2004). This showed a higher rate of rupture than a systematic review of available studies, where the rate was reported to be 2.7/1000 trials of labour (Guise et al 2004). In the Scottish study, women who gave birth in a hospital with fewer than 3000 births per annum did not experience a significantly increased rate of uterine rupture; however, the risk of perinatal death following uterine rupture was increased threefold. The perinatal mortality rate was one per 1300 births in hospitals with fewer than 3000 births a year, and one per 4700 births in hospitals with more than 3000 births a year (Smith et al 2004).

There is mounting evidence that vaginal birth and uterine rupture are less likely for women with prior vaginal birth than for women without.

> The risk of perinatal death due to uterine rupture was also higher in women who had not previously given birth vaginally and in women who had been induced with prostaglandins but not with other methods of induction (Smith et al 2004, p 376).

> Among women who had not previously given birth vaginally,

> the risk of uterine rupture without induction of labour with prostaglandin was one in 210 and with induction of labour with prostaglandin was one in 71. Among women with a previous vaginal birth, the risk of uterine rupture without induction of labour with prostaglandin was one in 514 and with induction of labour with prostaglandin was one in 175 (Smith et al 2004, p 377).

Clearly the induction of labour is an intervention *not* without serious implications and risks. A large study from Washington State also found that use of prostaglandin was associated with uterine rupture (Lydon-Rochelle et al 2001a).

Guise and colleagues (2004), in their systematic review, set out to address the practice policy question: what additional risks does a woman who has had a caesarean birth assume if she chooses to attempt vaginal birth rather than have a repeat caesarean section? (Guise et al 2004). Most of the literature focuses on the risk of uterine rupture in those attempting a vaginal birth following caesarean section, with an implicit assumption that this risk would be eliminated by elective repeat caesarean birth. If this assumption were true, it would take 263 elective repeat caesareans to prevent one uterine rupture due to trial of labour (Guise et al 2004). However, elective repeat caesarean birth is not guaranteed to prevent uterine rupture. Studies to date have reported an additional risk posed by attempting a vaginal birth after caesarean birth up to 2.7 per 1000 births (McMahon et al 1996). This means that it would take 370 (213 to 1370) elective repeat caesareans to prevent one symptomatic uterine rupture due to trial of labour (Guise et al 2004).

Ideally, women should be informed of all the morbidity associated with caesarean sections and repeat caesarean sections, and this of course includes not only the rare event of a uterine rupture, but also the risk of the baby dying if such an event should happen; and also the risk of hysterectomy in a subsequent pregnancy following a first caesarean section. In the systematic review of studies to date, Guise et al (2004) report that about 5% of symptomatic uterine ruptures were associated with perinatal mortality and 13% with hysterectomy.

This translates to 7142 elective repeat caesareans to prevent one rupture-related perinatal death and 2941 to prevent one rupture-related hysterectomy. The authors of the systematic review urge caution with these results, stating that 'it would take only one misclassified case of symptomatic uterine rupture in the smaller study and five in the largest to entirely negate the observed difference in symptomatic uterine rupture between groups' (Guise et al 2004). Serious morbidity or mortality due to uterine rupture is rare, making it difficult to study. As a result, studies have focused on the occurrence of uterine rupture rather than how often bad outcomes result from it. The existing evidence is sufficient to conclude that there is an increased risk of symptomatic uterine rupture for trial of labour over elective repeat caesarean and that caesarean delivery is not completely protective. However, most uterine ruptures do not have serious consequences, and patients and clinicians may wish to base decisions on the likelihood of significant morbidity or mortality for the mother and baby rather than on the occurrence of uterine rupture itself. For every 10,000 women attempting trial of labour there would be 27 additional symptomatic uterine ruptures, 1.4 perinatal deaths related to rupture, and 3.4 hysterectomies related to rupture (Guise et al 2004, p 6).

A study released in December 2004 in the *New England Journal of Medicine*—the largest to date, involving almost 34,000 births at 19 academic hospitals from 2000 to 2003—confirms the VBAC's minimal risk. The study included 17,898 women who attempted to give birth vaginally and 15,801 women who elected a repeat caesarean (Landon et al 2004). Of note is the increased risk of uterine rupture associated with induction of labour or augmentation with both prostaglandin and Syntocinon. The risk was increased by two- to three-fold. Of those women who attempted a vaginal birth there were two perinatal deaths due to uterine rupture. There were 12 cases of hypoxic–ischaemic encephalopathy among the infants of the women attempting labour, and none among the women undergoing elective repeated caesarean birth. Combining these cases with cases of hypoxemic–ischaemic encephalopathy and neonatal deaths to represent 'poor perinatal outcomes' associated with the chosen method of delivery, there would need to be 588 elective repeated caesarean births to prevent one poor perinatal outcome. The corrected rates of perinatal death (after the exclusion of deaths associated with congenital malformations) were 4.0 per 10,000 in women undergoing a trial of labour and 1.4 per 10,000 in women undergoing elective repeated caesarean delivery. Demographic and perinatal characteristics of women and infants in the two groups show that, compared with women who underwent elective repeated caesarean delivery, women who underwent a trial of labour were more likely to be less than 30 years of age, black, unmarried, non-obese, and in receipt of government assistance (Medicaid or Medicare), and to have a preterm delivery (delivery before 37 weeks of gestation) or a delivery at 41 or more weeks of gestation. The elective caesarean following a previous caesarean group, meanwhile, saw twice as many maternal deaths (seven versus three). The three maternal deaths among women who underwent a trial of labour were due to severe pre-eclampsia with hepatic failure, sickle cell crisis with cardiac arrest, and postpartum haemorrhage. Of the seven maternal deaths among the women who had elective repeated caesarean delivery, two could be attributed to caesarean section (one resulted from haemorrhage and the other from anaesthetic complications). Of the five remaining deaths, four were caused by suspected amniotic-fluid embolism and one by aortic dissection.

Reflective exercise

What are the known risk factors that predispose women to the risk of uterine rupture? Where should these women give birth? Can we establish definitive risk criteria for women wanting to give birth vaginally following a previous caesarean section?

Overall, the data suggest a risk of an adverse perinatal outcome at term among women with a previous caesarean delivery of approximately 1 in 2000 trials of labour (0.46 per 1000), a risk that is quantitatively small but greater than that associated with elective repeated caesarean delivery (Landon et al 2004). Remaining issues of concern are the increased risks of placenta previa and placenta accreta for pregnancies subsequent to elective repeated caesarean delivery.

Summary: caesarean section

Caesarean section has become one of the most common surgical procedures in both Australia and New Zealand. (For current rates see the mothers and babies yearly report for your country—Australia's Institute of Health and Welfare and the New Zealand Ministry of Health publish yearly rates.) Decisions to deliver by caesarean can be made before the onset of labour (elective caesarean) or after the onset of labour (emergency caesarean). Delivery by caesarean may be appropriate in a range of circumstances related to the clinical characteristics of women where a vaginal birth is not possible. Some of the reasons for this may include breech or transverse presentation, cephalo-pelvic disproportion, placenta praevia, placental insufficiency, a prolapsed cord, multiple pregnancy, dangerously high blood pressure in the mother, and older women having a first baby. However, studies across the world have shown that non-clinical factors also contribute to the rising rates of caesarean section. These include women's requests for delivery by elective caesarean section when they perceive that the benefits of a planned elective caesarean outweigh the risks, elective induction of labour (with no obvious clinical indication), the different practice patterns of individual doctors, and the private health insurance status of women.

The escalation in the total caesarean rate is fuelled by both the rise in the primary caesarean rate and the steep decline in the rate of vaginal birth after caesarean (VBAC) delivery. In the United States, the primary rate rose 7% in 2002, and the rate of VBAC delivery plunged 23% (Martin et al 2003). In Australia, the rates have increased in both public and private hospitals, although they remain consistently higher in the private sector. Higher rates of electronic fetal monitoring, induction and epidural analgesia have been implicated in the rise in caesareans, but other factors are also contributing. Studies have shown that induction (including elective induction) may increase the risk of caesarean delivery in nulliparous women (Seyb et al 1999).

Randomised controlled trials and some multicentre trials (Hannah et al 1992, 2000) concluded that professional management guidelines should promote caesarean section for breech birth, and the latest data on birth following a previous caesarean section advises in favour of a repeat elective caesarean section (Landon et al 2004) in terms of perinatal risk. Greater access to private hospitals and changes in practice responding to the medical indemnity crisis have also contributed to rising rates (Laws & Sullivan 2004). Of the 21 OECD countries that reported caesarean section rates for 1999, Italy had the highest (32.4%), and the Netherlands had the lowest rate (11.3%). The median was Iceland (17.3%). Six countries were below 15%. Australia's rate of 21.7% of all live births was 25% higher than the OECD median and fourth-highest of the 21 OECD countries that reported that year (OECD 2002).

Implications

What are the risks of caesarean delivery? One of the most significant risks is the need for a subsequent caesarean birth (Bernstein 2002). Yet there is steady growth in the research evidence that illustrates the seriousness of the rising caesarean section phenomenon in terms of maternal and infant complications, and the importance of the debate about the appropriateness of caesarean delivery in maternity care.

Studies investigating whether caesarean section may prevent injury of the pelvic floor and the genesis of stress urinary incontinence are scarce and controversial. Contrary to popular belief, MacLennan et al (2000), in an Australian study, found that pregnancy, not childbirth (unless compounded by instrumental vaginal delivery), was responsible for the frequency of pelvic floor dysfunction. Grant (2000) added to the debate by noting that what is remarkable is the frequency of pelvic floor dysfunction in the population. One in eight women who have never been pregnant had some form of pelvic floor dysfunction, compared with one-half of the women who had a caesarean section or a spontaneous vaginal delivery and two-thirds of the women who underwent an instrumental vaginal delivery. However, Groutz et al (2004) in a urodynamic study of 300 women of similar maternal age, weight, and height, found that the prevalence of postpartum stress urinary incontinence was similar after spontaneous vaginal delivery (10.3%) and caesarean section performed for obstructed labour (12%), but stress urinary incontinence was

BOX 35.18 Framing risk

How should we frame risk in conditions of uncertainty?

In their Nobel Prize winning work, Tversky and Kahneman discovered that framing of outcomes, choices and contingencies influences decision-making (Kahneman & Tversky 1979; Tversky & Kahneman1981). The reference points and language chosen by providers and policy-making organisations influence public perceptions, policy formulation, and the climate for practice and research. Whether discussions highlight benefits or risks and whether the portrayal is relative or absolute can affect perceptions. Society often behaves as if the risk threshold is set at perfection and no risk is acceptable. Modern technology and superior medical care cannot remove all risk completely. Therefore, to decide on thresholds for risk for vaginal birth and repeat Caesarean section we need to look at rates for harms such as uterine rupture and benefits, and also to ensure consistency with other issues when we interpret the thresholds (Guise et al 2004).

significantly less common following elective caesarean section with no trial of labour (3.4%, $P < 0.05$) (Groutz et al 2004).

With regard to life-threatening risks of caesarean sections, Hall et al (1999) in their analysis of the maternal mortality report for 1994–96 in the United Kingdom found that the fatality rate for all caesarean sections was six times that for vaginal birth, and even for elective caesarean section the rate was almost three times as great. These differences are highly significant. The maternal mortality was higher than that associated with vaginal birth (5.9 for elective caesarean delivery versus 18.2 for emergency caesarean versus 2.1 for vaginal birth, per 100 000 completed pregnancies in the United Kingdom during 1994–96). In the absence of other evidence (e.g. from RCTs of different modes of birth), any decision to undertake major surgery with an associated mortality should be taken very seriously by all concerned (Hall et al 1999). Maternal mortality reports from both the United Kingdom and Australia consistently report death from direct causes related to surgical procedures.

Other morbidities associated with caesarean section include an increase in subsequent problems in placentation, including placenta praevia (Ananth et al 1997), placental abruption and ectopic pregnancies (Rasmussen et al 1999). In 2001, Lydon-Rochelle et al (2001b) found that there may be an increased risk of major bleeding in a subsequent pregnancy because of placenta praevia (5.2 per 1000 live births) and placental abruption (11.5 per 1000 live births). As yet, there are no significant studies demonstrating the risk of peripartum hysterectomy following a life-threatening postpartum haemorrhage from placenta accreta in pregnancies subsequent

BOX 35.19 Definitions: infant and maternal mortalities

1 WHO definitions

The World Health Organization (WHO) definition of fetal death is the absence of evidence of life after birth of babies of at least 500 grams birthweight or, if birthweight is not available, whose gestational age is at least 22 weeks.

WHO recommendations differ from the Australian Bureau of Statistics (ABS) standard for neonatal death and include only early neonatal deaths occurring in the first seven days, not all neonatal deaths up to 28 days, as reported by the ABS.

The WHO has also recommended that, for international comparisons, countries should report data based on lower limits of 1000 grams or, when birth weight is not available, a gestational age of at least 28 weeks, excluding births and fetal and neonatal deaths that do not meet these criteria.

2 Mortality rates / death rates (Australia and New Zealand)

- *Stillbirth rate (fetal death rate)*—the number of fetal deaths in 1000 total births.
- *Neonatal death rate*—the number of neonatal deaths in 1000 live births.
- *Perinatal death rate* (Australia)—the sum of fetal and early and late neonatal deaths in 1000 total births (both live and stillborn).
- *Perinatal death rate* (New Zealand)—the sum of fetal and early neonatal deaths in 1000 total births (both live and stillborn).
- *Infant mortality rate*—the number of infant deaths in a calendar year per 1000 live births in that year.

3 Births, perinatal and infant mortality (Australia and New Zealand)

- *Stillbirth* (fetal death)—death prior to the complete expulsion and extraction from its mother of the products of conception of 20 or more completed weeks of gestation or 400 grams or more birthweight: the death is indicated by the fact that after such separation the fetus does not breathe or show any other signs of life, such as heartbeat, pulsation of the umbilical cord or definite movement of voluntary muscles.
- *Neonatal death*—death of a live-born infant within 28 days of birth.
- *Early neonatal death*—death of a live-born infant within seven completed days after birth.
- *Late neonatal death*—death of a live-born infant after seven completed days and before 28 completed days after birth.
- *Post neonatal death*—death of a liveborn infant after the first completed 28 days after birth and before the end of the first year of birth.
- *Perinatal death* (Australia)—includes fetal and early and late neonatal deaths.
- *Perinatal death* (New Zealand)—includes fetal and early neonatal deaths
- *Infant death*—the death of a live infant born in the first year of life. This includes neonatal deaths, early and late, but does NOT include stillbirths (fetal deaths).

4 Maternal mortality (Australia)

The Australian definition of *maternal mortality* based on the WHO ICD-10 definition of a maternal death is the death of a woman who is pregnant or who dies within 42 days of a pregnancy being delivered or terminated. Maternal deaths are then classified as *direct*, *indirect* or *incidental*. These are defined as follows:

- *Direct deaths* arise from obstetric complications of the pregnancy state (pregnancy, labour and puerperium), from interventions, omissions or incorrect treatment from a chain of events resulting from any of the above.
- *Indirect deaths* result from pre-existing disease or disease that developed during pregnancy and was not due to direct obstetric causes, but which might have been aggravated by the physiological effects of pregnancy.
- *Incidental deaths* are those due to conditions occurring during pregnancy, where the pregnancy is unlikely to have contributed significantly to the death.

(Sources: 1,2, 3, above: Laws & Sullivan 2005; 4 above: Sullivan et al 2004)

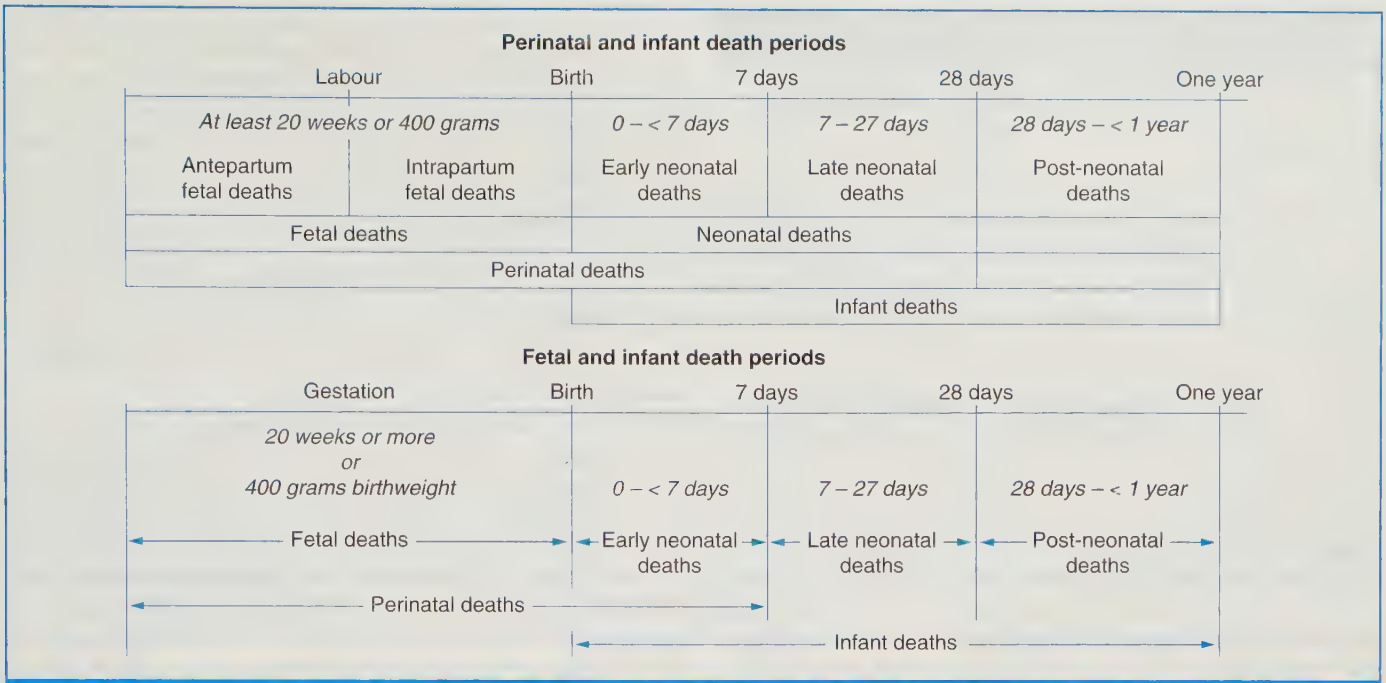

Figure 35.8 Perinatal and infant death periods, Australia (top) and fetal and infant death periods, New Zealand (bottom) (based on Laws & Sullivan 2004 and NZHIS 2004)

to a previous caesarean section. However, according to the American College of Obstetricians and Gynaecologists, the incidence of placenta accreta has increased ten-fold in the past 50 years and now occurs with a frequency of one per 2500 deliveries. Women who have had two or more caesarean deliveries with anterior or central placenta praevia have nearly a 40% risk of developing placenta accreta (ACOG 2002). Factors suggested as being associated with a higher incidence of placenta accreta include scarred uterus, multiparity and previous uterine surgery. Maternal complications in cases of placenta accreta usually occur in the third stage of labour and, rarely, in cases of placenta percreta during the pregnancy period. Women may present with a severe life-threatening hemorrhage requiring extensive surgical interventions, such as major pelvic vessel ligation and/or hysterectomy (Gielchinsky et al 2004).

Caesarean section also requires a longer recovery time, and operative complications such as lacerations and bleeding may occur, at rates varying from 6% for elective caesarean to 15% for emergency caesarean (Bergholt et al 2003; Hannah et al 2000). Babies are also implicated in risks associated with caesarean sections. Studies in the United Kingdom undertaken by Morrison et al (1995) found that among term babies, the risk of neonatal respiratory distress necessitating oxygen therapy is higher if birth is by caesarean (35.5 with a pre-labour caesarean vs 12.2 with a caesarean during labour vs 5.3 with vaginal delivery, per 1000 live births). Of potentially greater concern is data from a recent case-control study in Scotland. Over 120,000 second births from 1980 to 1998 were evaluated using linked maternal and stillbirth records. The investigators noted a 2.2-fold increased risk of unexplained stillbirth after 34 weeks gestation in association with a prior caesarean. This relationship was maintained weekly thereafter, including a risk of unexplained stillbirth after 39 weeks of 1.1 per 1000 versus 0.5 per 1000 for prior caesarean versus prior vaginal delivery (Smith et al 2003; Wax 2004). Pooled data from Sweden, Australia, Canada, Scotland, Denmark, England, the United States, Norway and Ireland reveal rising caesarean rates from the 1970s to the mid-1980s, after which rates remain stable or slightly increase.

Despite the marked increase in caesarean rate, cerebral palsy rates remained stable or slightly decreased. Therefore, caesarean is not neuroprotective for the fetus (Clark & Hankins 2003; Scheller & Nelson 1994; Wax 2004).

The Nordic countries remain lowest on the list for infant mortality rates reported by the CIA (2005). Australia, New Zealand and the United States, regardless of the rising intervention levels, remain woefully low on the rankings for resource-rich countries, especially compared to the Nordic countries and Europe (CIA 2005) (see Table 35.8).

Conclusion

Routine use of multiple childbirth procedures—that is, the over-treatment of normal childbirth—is not fiscally or medically defensible. Each procedure adds more costs to intrapartum care (Tracy & Tracy 2003), has potential adverse health effects for mother and baby, and necessitates use of still more technical care measures (Tracy et al 2006). No evidence supports routine use of electronic fetal monitoring, epidurals, oxytocin or episiotomies in low-risk women (Albers 2005).

TABLE 35.8 Infant mortality rates

Country	No. deaths / 1000 live births
United States	6.5
New Zealand	5.85
Australia	4.69
Denmark	4.56
Norway	3.7
Finland	3.57
Iceland	3.31
Sweden	2.77

(Source: CIA 2005)

In fact, the available evidence favours alternatives (Enkin et al 2000; WHO 1996) such as intermittent auscultation of the fetal heart, non-pharmacological measures for pain relief, low-technology strategies (ambulation, hydration) for labour stimulation, and no routine episiotomy. These care measures are both more pleasant for labouring women and feasible in the context of individualised care and intensive labour support. The short-sighted idea that a 'safe birth' is the only appropriate goal of maternity care fails to challenge the prevailing norm of over-treatment in hospital settings.

Ideally, a safe birth and optimal health of the new mother are both necessary goals, for which spontaneous vaginal birth and an intact genital tract are key elements. Such a mother will have the best postnatal health, including fewer hospital readmissions for post-delivery morbidity, less perineal pain and a stronger pelvic floor, better sexual function, and better overall physical functioning (Thompson et al 2002; Lydon-Rochelle 2001c). The mother's optimal health should be a high priority of caregivers, because newborn wellbeing depends so greatly on her health and functional status, which help equip her to undertake the complex and demanding task of mothering an infant with confidence (Albers 2005, p 68).

Common obstetric interventions are often for 'convenience' rather than for clinical indications. Before proceeding, it should be clear who the beneficiary of the convenience is. The midwife must make every effort to make sure that women and their partners have a full understanding of what is known about the associated risks, benefits and alternative approaches of the proposed intervention. Thorough and accurate information allows women to choose what is best for them and their infant on the basis of the individual clinical situation. Ideally, this discussion takes place during the antenatal time when there is ample opportunity to ask questions, reflect on the potential implications, and confer with partners and family members. While the interventions outlined above often are medically indicated for the wellbeing of mothers and infants, the evidence supporting their benefits when used electively may not be based on rigorous research and in many cases remains controversial.

Review questions

1. What are two points that midwives must consider when considering the use of interventions as routine practice?
2. What factors are associated with cerebral palsy in the antenatal period, during labour and in the postpartum period?
3. What is the evidence for the use of CTG assessment of fetal wellbeing in pregnancy?
4. What is the evidence for the use of routine CTG assessment on admission in labour?
5. What is the most appropriate form of fetal monitoring in an uncomplicated labour?
6. List six practices that should be performed whenever a CTG assessment is being undertaken.
7. List four characteristics of a non-reassuring CTG tracing.
8. What is the evidence in relation to the timing of induction of labour?
9. What interventions in labour are associated with the use of epidural anaesthesia?
10. List six possible reasons for the increasing caesarean section rate in Western health systems.

CHAPTER 36

Life-threatening emergencies

Carol Thorogood and Sue Hendy

Key terms

amniotic fluid embolism, artificial rupture of the membranes, decision-time to delivery, diagnostic peritoneal lavage, disseminated intravascular coagulation, eclampsia, external cephalic version, fetomaternal haemorrhage, fire drills, HELLP syndrome, inotropes, Kleihauer Betke, magnesium sulphate, placenta praevia, postpartum haemorrhage, seizures, severe pre-eclampsia, shoulder dystocia, symphysiotomy, tocolysis, umbilical cord (funic) presentation, umbilical cord prolapse, uterine inversion, vasa praevia

Chapter overview

For most women, childbirth is a healthy event. However, some women may develop complications requiring complex levels of medical and technological intervention, and it is these complications that are the focus of this chapter. Healthcare practitioners ensure that their practice is current, skilled and based on the best available evidence. This chapter is concerned with the most frequent life-threatening complications, which often transpire with little or no warning. It does not provide a definitive guide to the management of obstetric emergencies—this belongs to experts in obstetrics, midwifery or medicine, or trauma specialists. A thorough understanding of the biosciences and pathophysiology underpinning emergency conditions in obstetrics is crucial to best practice. Therefore, readers will need to supplement the information they gain from this chapter with other texts.

Learning outcomes

Learning outcomes for this chapter are:

1. To identify factors that indicate the potential for emergency situations for mother and baby in pregnancy, birth and the puerperium
2. To describe the aetiology and management of a range of emergency situations in pregnancy, birth and the puerperium
3. To apply best available evidence in the identification, assessment and collaborative management of: umbilical cord presentation and prolapsed cord; shoulder dystocia; postpartum haemorrhage; eclampsia; amniotic fluid embolism; uterine inversion; maternal trauma; stabilisation; cardiopulmonary resuscitation and transport; and neonatal resuscitation.

Introduction

Researchers have developed a number of screening tools to help clinicians make accurate predictions about which women are most at risk of complications in pregnancy and birth, with limited success. Birth is never 100% predictable, and hence the rationale underpinning the policy that there should be a skilled attendant at every birth. Worldwide, between 9% and 15% of all birthing women will experience potentially life-threatening complications, and at least 1–2% will need a major intervention to survive (Maine et al 1992). Midwifery is grounded by a primary health model of practice. For birth to be satisfying and safe, midwives have a statutory responsibility to adhere to the principles outlined by their professional and regulatory authorities. These are grounded in a primary health model of practice that is influenced by particular sociocultural, spiritual and politico-economic environments. The midwife 'respects and supports the needs of women and their families/whanau to be self-determining in promoting their own health and well-being' (NZMC 2004, p 1.7). The midwife 'accepts accountability and responsibility for her actions, whilst recognising her own knowledge base and scope of practice. She is able to identify complications with appropriate and timely consultation and referral as needed. She delegates when necessary, always providing the appropriate supervision' (ANMC 2006, p 2) and 'collaborates with other health care providers when care is outside the scope of practice' (ANMC 2006, p 2.1). While some complications can be prevented, and others predicted in time, the majority of severe complications can be neither prevented nor predicted. When these do occur it is crucial that the midwife consults the most appropriate care provider. The *Australian College of Midwives' National Guidelines for Consultation and Referral* (2004) provide an evidence-based framework for consultation and transfer of care between midwives and doctors. These guidelines inform decision-making by midwives about the care, consultation and referral of women at booking, during the antenatal period, throughout labour and birth, and in the postnatal period. They help the midwife and woman determine the most appropriate place of birth, and who should be the lead care provider.

Because some complications occur with little or no warning, it is crucial that midwives are able to recognise and then manage a range of obstetric emergencies until help comes or until the woman is transferred to an appropriate facility. When complications arise, a multidisciplinary approach is usually required and so there must be a system in place for access to consultation and referral to medical facilities, personnel and emergency transport. Effective communication is pivotal to best practice in maternity care but never more so than when emergencies occur.

Fire drills

Because an obstetric emergency is unpredictable, it is imperative for all midwives, including those in an out-of-hospital setting, to have 'crash' protocols or 'fire drills' in place to facilitate effective management of emergencies such as umbilical cord prolapse. The aims of these 'fire drills' (scenario-based training in emergencies) are to test local systems and protocols for responding to emergencies, and to facilitate interdisciplinary teamwork and the development of individual skills and knowledge. 'Fire drills' should include: the procedures to be taken in the event of activation, calls for help, first-level management, staff responses, and home/birth centre/labour ward/operating logistics.

Every maternity setting should have protocols in place for the management of obstetric emergencies such as postpartum haemorrhage, shoulder dystocia and eclampsia. They also need to ensure that the fire drills are feasible and reflect best practice. All members of staff, including those working in blood banks and laboratory services (e.g. to ensure that adequate quantities of cross-matched blood and blood products are available) and orderlies must know exactly what to do, how to do it and when it is to be done. In the hospital setting, the activation of such a fire drill is usually through the hospital main switchboard, which preferably has a dedicated 'hotline' and code for this purpose. Activation of an emergency fire drill should not compromise the level of care to the woman, as the most experienced person in each 'crash' team is directly responsible for the conduct of the emergency. This extends to the woman's right to be involved in decisions about her care. It is crucial that, as soon as possible, the woman and her family are provided with an explanation of the circumstances surrounding the emergency and the need for urgent action.

Decision to delivery

In an emergency, the time from the decision to deliver by caesarean section and the actual delivery of a baby is known as the 'decision to delivery' (D-D) interval. The accepted interval of 30 minutes was recommended in a Canadian consensus statement in 1986 (Hannah et al 1986) with little evidence to support it. Since then, several studies examining the association between D-D interval and maternal and baby outcomes have found little difference between babies born with a D-D interval of 15 mins and those with a D-D interval between 16 and 75 mins (Thomas et al 2004). Other researches found that 'fewer than 40% of intrapartum deliveries by caesarean section for fetal distress were achieved within 30 minutes of the decision' and 'no evidence to indicate that overall an interval up to 120 minutes was detrimental to the neonate unless the delivery was a "crash" caesarean section' (MacKenzie & Cook 2001, p 498). Although the D-D interval remains an important measure of quality of maternity care, very short D-D intervals have been associated with poorer baby outcomes and may harm the mother as a result of surgery or factors such as general anesthesia (RCOG 2001).

Cord presentation and prolapse

Umbilical cord prolapse constitutes an obstetric emergency with potential for fetal death. With up to a 50% perinatal mortality rate, umbilical cord prolapse is one of the most catastrophic events in the intrapartum period (Curran 2003). It occurs in about 1 in 1000 births and is associated with significant perinatal morbidity and mortality. In many cases it is iatrogenic and thus a preventable condition. The risks increase whenever the presenting part does not fit snugly into the pelvis. Although a prolapsed cord poses no immediate physical threat for the woman, interventions to save the fetus, such as an emergency operative birth, will threaten her safety and wellbeing. An unexpected emergency situation combined with fear for the wellbeing of her child causes immense stress for the woman and her family.

Umbilical cord presentation

An umbilical cord presentation (Fig 36.1) is a condition in which the umbilical cord is interposed between the leading part of the fetus and the internal os of the uterine cervix but the amniotic membranes remain intact. Once the membranes break, the risk that the cord will prolapse through the cervix into the vagina increases significantly. In an occult cord presentation, a loop of cord lies alongside, instead of in front of, the presenting part and may not be felt on vaginal examination. A non-reassuring fetal heart rate (FHR) trace with deep, early decelerations may be an early sign of this complication. As labour establishes, umbilical cord compression associated with contractions causes variable FHR decelerations. If the umbilical cord prolapses through the cervix when the membranes break, it is compressed with every contraction and so severe variable FHR decelerations and/or profound fetal bradycardia may become apparent. If an umbilical cord presentation is diagnosed before the cervix is completely dilated, perhaps during ultrasonography, an obstetrician may, after obtaining informed consent from the woman, choose to perform a 'controlled' artificial rupture of the membranes (ARM) and at the same time push the cord away from the presenting part. Alternatively, once the cervix is fully dilated but before the fetal head reaches the pelvic floor, it is often possible to gently lift the fetal head up and push the umbilical cord upwards and away from it. If this is unsuccessful or if the umbilical cord prolapses, an immediate emergency Caesarean section is often necessary.

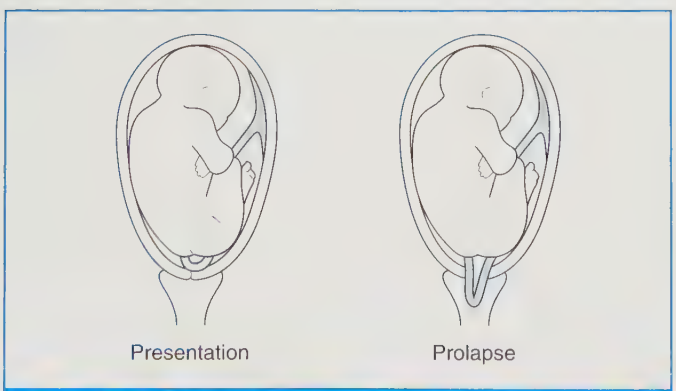

Figure 36.1 Cord presentation and cord prolapse (based on Henderson & MacDonald 2004)

Umbilical cord prolapse

Prolapse of the umbilical cord is a rare obstetric emergency requiring immediate, skilled action on the part of the clinician who first recognises the problem. In many cases this is the midwife. An umbilical cord that, in the presence of ruptured membranes, lies in front of or beside the presenting part is said to be prolapsed (Fig 36.1). It occurs when the cord falls or is washed down through the cervix into the vagina when the membranes break and becomes trapped between the presenting part and the maternal pelvis. Thus, it is most likely to occur if the pelvic inlet is not completely filled by the presenting part.

Much more is known about umbilical cord prolapse than cord presentation, because the former is dramatically apparent and the latter is usually diagnosed by sonography or during a 'routine' vaginal examination of a clinically asymptomatic woman. If the umbilical cord prolapses through the cervix or even lies between the presenting part and the pelvis, during uterine contractions the umbilical cord will be exposed to intermittent compression, which compromises the fetal circulation. Depending on its duration and the degree of compression fetal hypoxia, brain damage and fetal death may occur. Dramatic changes in the fetal heart rate are often the first signs of a cord prolapse.

Risk factors

The risks of umbilical cord presentation and prolapse increase in frequency with malpresentations and with poorly fitting presenting parts such as in a transverse lie, shoulder and breech presentation. A flexed or footling breech poses the most risk for cord prolapse due to the increased space through which the umbilical cord can fall into the vagina. Prematurity also increases the risk of cord prolapse because these babies are more likely to present as a malpresentation and their small size in relation to the pelvis means there is more room for loops of cord to escape through the cervix. There is also more liquor volume in relation to fetal size than for a term infant.

Any structural abnormalities of the placenta, uterus or pelvis may also stop the presenting part from fitting snugly into the pelvis and thus increase the risk of prolapse (e.g. succenturiate placental lobe or contracted pelvis). A low-lying placenta (placenta praevia) can prevent the presenting part from entering the brim of the pelvis and it too increases the risk of cord prolapse. Repeated pregnancies interfere with the integrity of the abdominal musculature, which means that some multiparous woman may have lax abdominal muscles, which also increases the likelihood of an ill-fitting presenting

BOX 36.1 Diagnosis of cord presentation and prolapse

Clinical diagnosis of umbilical cord presentation and prolapse

- *Cord presentation*—loops of cord are palpated through the membranes. The presence of umbilical cord lying in front of the presenting part can also be visualised using colour Doppler studies.
- *Cord prolapse*—diagnosis is made by visual inspection or palpation of a pulsing umbilical cord during a vaginal examination. The umbilical cord is felt below or beside the presenting part.
- *Occult prolapsed cord*—is rarely felt on vaginal examination and the only indication may be FHR changes.
- *Overt prolapse*—the umbilical cord can be seen protruding from the introitus or loops of cord palpated within the vaginal canal.

part at term. Finally, the use of external cephalic version (ECV) to prevent breech presentation at birth is occasionally associated with cord prolapse, so it must be conducted in an environment where fetal wellbeing can be assessed and resources available to proceed to an emergency Caesarean section.

Whenever the presenting part is not engaged, an amniotomy—especially in the presence of polyhydramnios—poses a real risk of an iatrogenic cord prolapse. Of course, spontaneous rupture of the membranes can also trigger cord prolapse and so it is important for the midwife to auscultate the fetal heart prior to amniotomy and immediately after spontaneous or artificial breaking of the membranes.

Incidence

Gabbe and colleagues (2002) state that the rate of umbilical cord prolapse is much lower in fetuses presenting by the vertex than in fetuses with breech presentation or transverse lie.

The precise incidence of occult cord prolapse is unknown, but half of electronically monitored labours show fetal heart rate (FHR) changes suggestive of umbilical cord compression, which is usually transitory and relieved by changing the maternal position. Approximately 50% of prolapsed cords occur in the second stage of labour. An additional 47% result from some obstetric intervention such as amniotomy or ECV (Usta et al 1999).

TABLE 36.1 Incidence of cord prolapse

Overall risk in vertex presentation	0.2–0.5%
Overall risk in breech presentations	3.5%
Complete breech	2–5%
Footling breech	15%
Transverse lie	20%
Multiple pregnancies	4%
Preterm labours and birth	5–10%

(Source: Gabbe et al 2002)

The presence of repetitive, early FHR decelerations may be indicative of umbilical cord compression or occult cord presentation, especially in the presence of oligohydramnios. This occurs because the umbilical vein is thinner than the arterial walls and therefore more susceptible to compression. Usually these apparently dramatic heart rate decelerations resolve rapidly after the contraction is finished. Unresolved cord compression will result in further fetal hypoxia, an increase in the severity of the decelerations and, eventually, prolonged fetal bradycardia. Cord prolapse is usually associated with profound fetal bradycardia.

If the cord is presenting and the amniotic membranes are still intact, during a vaginal examination the midwife may palpate a pulsating membrane, at the same rhythm and rate as the fetal heart. It is important to differentiate this rate from the maternal pulse, which may also be felt through the vaginal fornices. When the umbilical cord has prolapsed through the cervix or vagina, the midwife may palpate a 'rope-like pulsing, soft structure' in the vagina. Sometimes the cord is visible at the introitus. The midwife may also diagnose vasa praevia during a vaginal examination. This is a very rare condition where the umbilical cord vessels covered only by chorion and amnion lie across the cervical os and ahead of the fetus. This means that the cord has very little protection and the vessels often tear as the membranes break, causing asphyxia, exsanguination and death.

Management

Cord presentation

If the midwife suspects a cord presentation she must immediately and gently withdraw her fingers from the vagina to reduce the risk of rupturing the membranes. Medical assistance is summoned immediately. The aim is to relieve pressure on the cord to ensure an adequate oxygen supply to the fetus. A full explanation is given to the woman, and she is placed in an exaggerated Sim's position (left lateral, right knee to chest, resting on bed in front of left, hips supported by wedges/pillows or turned over face down with knees to nipples (see Fig 36.2).

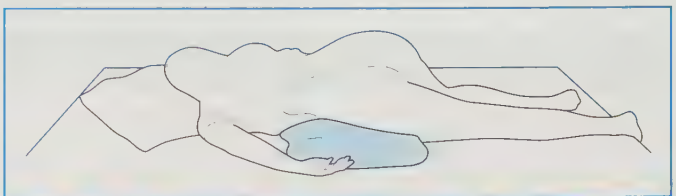

Figure 36.2 Exaggerated Sims' position (based on Henderson & MacDonald 2004)

Changing maternal position may resolve a cord presentation by enabling the presenting part to engage in the pelvis after the cord has moved away. Administering oxygen at 6–8 L/min may help to prevent fetal hypoxia. Unless the cord can be pushed away from the fetal head during an ARM, an emergency caesarean section is warranted.

Cord prolapse

As already noted, if the umbilical cord prolapses through the cervix or even lies between the presenting part and the pelvis, during uterine contractions the umbilical cord will be exposed to intermittent compression, compromising the fetal circulation. Exposure of the umbilical cord to air in an overt prolapse causes irritation and cooling of the cord, which produces vasospasm of the cord vessels. Delays in recognition and management are associated with significant perinatal morbidity and mortality. Therefore, cord prolapse requires urgent intervention and assistance.

In brief, if the fetus is alive and the cervix is not completely dilated, prompt delivery via caesarean section offers the best chance for a favourable fetal outcome. However, effective elevation of the presenting part, and tocolysis where necessary, removes the urgency of immediate caesarean section. Even with a prolapsed cord, a vaginal birth may still be possible if the birth is imminent—that is, the cervix is completely dilated, the presenting part is well down and there are no contraindications that will slow immediate delivery. If the fetus is not viable, labour should proceed to a vaginal birth.

First-level strategies (until help arrives)

Strategies to improve oxygen delivery to the fetus include:

- changing the mother's position
- techniques to stop compression of the cord against the fetal head and the pelvis
- administering oxygen.

If the fetus is viable and birth is not imminent, the woman is asked to assume an exaggerated Sim's position (her hips can be elevated on pillows) and the midwife inserts two fingers into the vagina to push the presenting part up and away from the cord to relieve compression during contractions. This manoeuvre is maintained until help arrives or the baby is born. If the cord is visible at the introitus it is carefully replaced in the vagina, to minimise chilling and vasospasm. The midwife then makes a rapid assessment to determine the degree of cervical dilatation, fetal position and descent of the presenting part, as management now depends on the viability of the fetus, the stage of labour and whether or not birth is imminent. This assessment guides strategies for the ongoing management of this emergency.

Second-level strategies

Before moving on to the next steps in the management of cord prolapse, it is vital to assess fetal wellbeing. Fetal demise is a complication of cord prolapse and should be excluded before proceeding to operative delivery. Continuous electronic FHR monitoring is a useful adjunct in assessing fetal wellbeing and if the techniques to eliminate cord compression are successful. Maternal oxygen therapy at 6–8 L/min may have a positive impact on fetal blood arterial levels but only in the presence of a functioning gaseous interchange between the maternal and fetal circulation. This is why it is critical that the midwife's first action must be to minimise compression of the umbilical cord.

Umbilical cord compression may also be relieved by first pushing the fetal head out of the pelvis and then inserting a Foleys catheter into the maternal bladder and filling it with 500–700 mL of normal saline (Griese & Prickett 1993; Runnebaum & Katz 1999). This procedure is of most use if

Clinical point

Repetitive variable decelerations (see Fig 36.3) suggest umbilical cord compression, especially in the presence of oligohydramnios or amniotomy.

Clinical point

Prolapse of the umbilical cord is an obstetric emergency demanding immediate attention. Delay in management is associated with significant perinatal morbidity and mortality, due mainly to complications associated with preterm birth and birth asphyxia.

Clinical point

Faced with a cord prolapse, the main aims of management are: prevention, early diagnosis and temporising care through alleviation of compression on the prolapsed cord until emergency delivery of the baby can be effected.

Critical thinking exercise

Given that cord prolapse often has catastrophic consequences, think of strategies that you as a midwife can use to prevent or minimise this complication. You may like to consider:

- how to identify risk factors for umbilical cord prolapse
- how to recognise a cord presentation in a timely way
- why an ARM should not be performed without a clinical indication
- what you can do if a clinician tells you he or she wishes to perform an amniotomy when the fetal head is still 4/5 above the brim of the pelvis.

the woman needs to be transferred from an outlying facility without operative delivery capabilities to hospital, and a D-D interval of more than one hour is expected.

If vaginal birth is not possible, it is important to inhibit uterine contractions. Syntocinon® infusions are turned off and, if it is already in place, the rate of an IV infusion of Hartmann's solution is increased. Tocolysis with a drug such as terbutaline (Bricanyl®) has been used successfully to inhibit uterine contractions and thus further reduce compression on the umbilical cord. Even in a critical situation such as cord

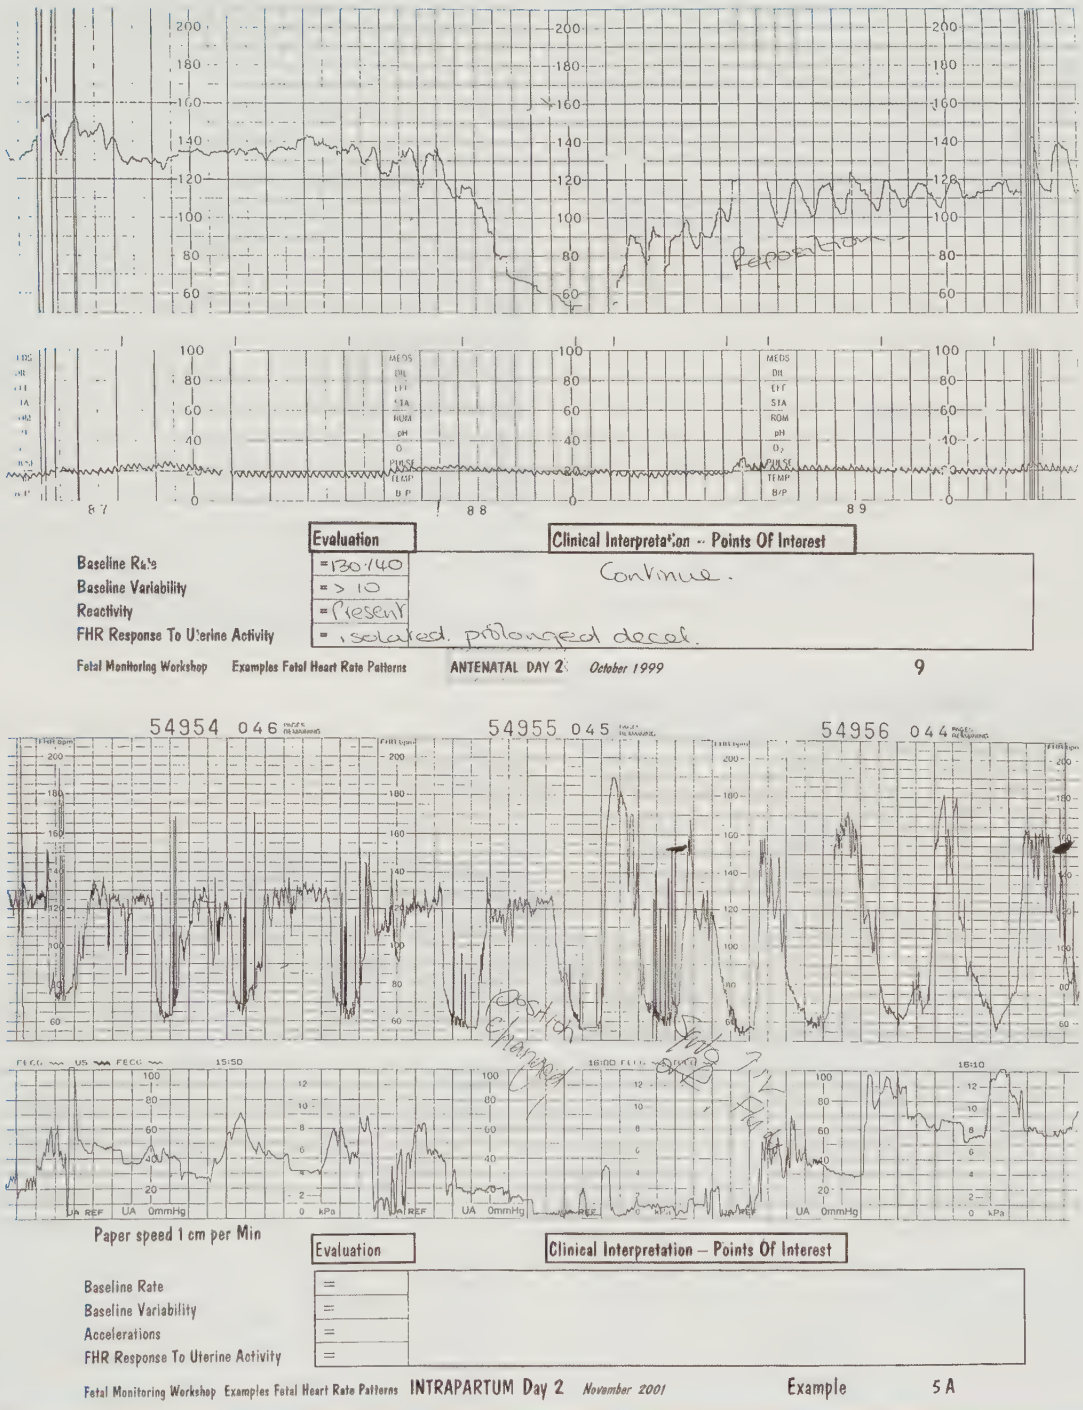

Figure 36.3 Variable decelerations on a CTG trace suggest umbilical cord compression, especially in the presence of oligohydramnios or amniotomy.

Critical thinking exercise

Jane Smith has been in labour for six hours, her cervix is 4 cm dilated and the fetal head is 3/5 above the pelvic brim.

Jane's membranes break spontaneously; the umbilical cord prolapses and the FHR is 70 bpm. The fire drill for a cord prolapse is activated.

The senior midwife present asks you to remain with Jane and to relay to Jane and her husband what is happening and what needs to be done.

1 Role play what you would say to them right now.

Jane's baby dies.

2 What will you say to her the following day?

prolapse, the midwife must still ensure that the woman gives her consent for the planned interventions.

Summary: cord prolapse

Umbilical cord prolapse is an infrequent obstetric emergency with a well-documented poor fetal prognosis. A high index of suspicion and recognition of predisposing factors may allow for early detection and timely delivery, thereby minimising perinatal morbidity and mortality. A multidisciplinary approach to management of this complication is essential to minimise maternal and fetal risks in such an emergency.

BOX 36.2 Clinical review

The 'cardinal movements of labour' for a vertex presentation

- The bisacromial diameter of a term fetus is greater than the biparietal diameter.
- The pelvic inlet is wider in the oblique diameter than the anteroposterior diameter.
- Unless it has occurred already, during labour uterine contractions lead to flexion, descent of the fetal head and engagement.
- Usually the fetal head enters the pelvic inlet in the occipitolateral position, with the shoulders lying in the anteroposterior diameter.
- Internal rotation of the head occurs as the head reaches the level of the ischial spines and the shoulders rotate to the oblique position.
- The fetal head crowns and extends as it passes through the pelvic outlet.
- The shoulders now pass through the pelvic inlet in the oblique diameter of the pelvis. The posterior shoulder enters first, coming to rest in the sacral hollow or over the sacrosciatic notch, while the anterior shoulder follows it to lie over the obturator foramen.
- As further descent occurs, the anterior shoulder emerges from under the pubic ramus, and the shoulder girdle rotates to allow delivery in the anteroposterior position.
- The baby's body is born by lateral flexion.

Shoulder dystocia

Shoulder dystocia is one of the most dramatic, anxiety-provoking emergencies encountered by midwives. It is unpredictable and has potentially catastrophic consequences for the neonate and often causes significant morbidity for the mother. This section discusses known risk factors, and provides guidance to the midwife regarding management in the antenatal and intrapartum periods. When shoulder dystocia occurs, it is best to have an action plan in place to guide clinicians as they manage this complication, and so one plan of action is described here.

Definition

Shoulder dystocia is best defined as a birth in which additional manoeuvres are required to deliver the fetal shoulders after normal gentle downward traction has failed.

Applied anatomy and physiology

Shoulder dystocia occurs as a result of disproportion between the bisacromial diameter of the fetus and the anteroposterior diameter of the pelvic inlet (11 cm) compared to the roomier oblique diameter of 13 cm. Usually the posterior shoulder has descended past the sacral promontory and entered the true pelvis. The fetal anterior shoulder begins its descent into the pelvis but becomes impacted behind the symphysis pubis. Rarely, the posterior shoulder is also impacted above the sacral promontory. It is important to remember that the point of obstruction occurs at the inlet of the pelvis. Therefore no amount of tugging on the baby's head or cutting large episiotomies will release this bony obstruction.

Shoulder dystocia, 'bed' dystocia and 'mild' dystocia

Some clinicians confuse 'bed' dystocia or 'snug shoulders' with 'mild' shoulder dystocia. In none of these cases has the anterior fetal shoulder impacted behind the mother's symphysis pubis. Bed dystocia occurs when the woman is propped up in a semi-Fowler's position and the baby's head is born down into the mattress. There may be insufficient room for lateral (downward) flexion for delivery of the fetal anterior shoulder. In addition, because the weight of the mother is in part taken on the sacrum, it is pushed upwards, thus decreasing the anteroposterior diameter of the pelvic outlet. This problem is compounded if the woman has an epidural block and cannot assist the birth process. In most cases asking the woman to change her position—all fours, standing or rolling into a left lateral position—allows lateral flexion and easy birth.

Others fall into the trap of calling snug shoulders 'mild dystocia'—it is not. Delivery of 'snug' or tight fetal shoulders

is more common in women who are obese. The fetal head may be larger than expected but the 'turtle' sign (slow extension of the head with the chin remaining tight against the maternal perineum) after delivery does not occur and the head still restitutes and goes through external rotation. Although the shoulders are 'tight', there is no need for the midwife to implement the steps used to manage shoulder dystocia, although sometimes supra-pubic pressure or asking the woman to birth in an 'all fours' position, standing or squatting, may prevent or alleviate the problem.

Incidence and risk factors

The incidence of 'true' shoulder dystocia is 0.2–2.8% of all births (Hope et al 1998). Most cases occur in fetuses of normal birthweight and are unanticipated, limiting the clinical usefulness of risk-factor identification. Approximately half occur without warning and in the absence of any known risk factors. However, most texts and hospital protocols list a number of antenatal and intrapartum factors believed to be associated with this complication. Box 36.3 lists these risk factors.

About half of all shoulder dystocias occur in macrosomic babies (Haram et al 2002; Rouse 1999). As birthweight increases, so does the occurrence of shoulder dystocia. However, even in the presence of macrosomia, the incidence of shoulder dystocia is approximately 8–20%, which means the majority occur in non-macrosomic babies.

Anecdotal, but not research-based, evidence suggests that women are increasingly choosing to have a caesarean section because they have been told by their lead caregiver that their baby is so big that they are at significant risk of shoulder dystocia. As yet medical science is unable to predict fetal weight with any certainty. Gonen and colleagues (1996) published the findings of a study aimed at testing the ability to detect macrosomic fetuses, and examining the relationships between antenatal diagnosis of macrosomia diagnosed by clinical assessment and by ultrasonography, and the incidence of shoulder dystocia and birth trauma. The authors (Gonen et al 1996) reported an overall frequency of shoulder dystocia of 2%, the majority (93%) occurring in infants weighing less than 4500 g. Moreover, the ability to predict macrosomia via clinical assessment and/or ultrasonography was limited. They concluded that because most cases of shoulder dystocia and birth trauma occur in non-macrosomic infants, this condition is almost impossible to prevent.

Box 36.3 Risk factors

Risk factors for shoulder dystocia

Maternal:

- increasing maternal age
- maternal obesity
- maternal birthweight
- abnormal pelvic anatomy
- gestational diabetes
- prolonged pregnancy
- previous shoulder dystocia
- short stature.

Fetal:

- suspected macrosomia
- labour-related
- assisted vaginal delivery (forceps or vacuum)
- epidural block
- protracted active phase of first-stage labour
- protracted second-stage labour
- epidural analgesia—relaxes pelvic floor.

Clinical point

True shoulder dystocia occurs when there is disproportion between the bisacromial diameter of the fetus and the anteroposterior diameter of the pelvic inlet. The anterior shoulder is impacted behind the symphysis pubis.

Maternal diabetes, macrosomia and shoulder dystocia

Currently, prevention of shoulder dystocia in diabetic women is based on quality antenatal care. Control of blood sugar levels reduces the incidence of fetal macrosomia (Wiznizer 1995). A review of the Cochrane Database (Boulvain et al 2000) reveals no firm evidence to support elective delivery, by induction of labour or by elective caesarean section, over expectant management at term for insulin-requiring diabetics. While induction of labour in women with gestational diabetes who require insulin may reduce the risk of macrosomia and shoulder dystocia, the actual risk of maternal or neonatal injury is not modified.

Research

Haram and colleagues (2002) conducted a literature search to explore the problems associated with diagnosing macrosomia and its relationship to shoulder dystocia. Approximately half of all cases of shoulder dystocia occurred in macrosomic babies when using 4000 g as the cut-off point, but only in about 25% of cases when 4500 g was used as the cut-off point. Further, the incidence of shoulder dystocia was only 8–20% of all macrosomic babies. Thus, most shoulder dystocias occurred in non-macrosomic babies, and contrary to popular medical opinion, most macrosomic babies do not suffer shoulder dystocia at birth.

Warning signs of shoulder dystocia

The single most common risk factor for shoulder dystocia is the use of a vacuum extractor or forceps during delivery (Sokol et al 2003). Instrumental vaginal deliveries carry a significant risk of shoulder dystocia due to the elongation of the head, extension of the neck and abduction of the shoulders. This increases the bisacromial diameter of the fetal shoulders, making entrapment of the fetal shoulder behind the symphysis more likely. A prolonged second stage of labour and 'bobbing' (recoil of the fetal head) up and down in second stage when the fetal head is in the vagina may be an indication that the fetal shoulders have not rotated and that the anterior shoulder is impacted behind the symphysis pubis. This is often followed by the appearance of the 'turtle' sign.

Management

Because most shoulder dystocias are unpredictable, birth attendants need to be skilled in the management of this condition when it occurs (Enkin et al 2000). Irrespective of the precise management plan, it is vital that each facility has a policy and training system so that all staff skilled in the manoeuvres are employed effectively and efficiently. The management of shoulder dystocia requires a focused and calm environment, with the midwife taking the lead to direct the team to ensure a coordinated approach. This section outlines one systematic set of manoeuvres (and a mnemonic) known to assist delivery of a baby with shoulder dystocia. While nomenclature of these manoeuvres (and mnemonics) may change within various textbooks, the principles of management remain the same. The HELPERR (ALSO©) mnemonic is a clinical tool that offers a structured framework for coping with shoulder dystocia.

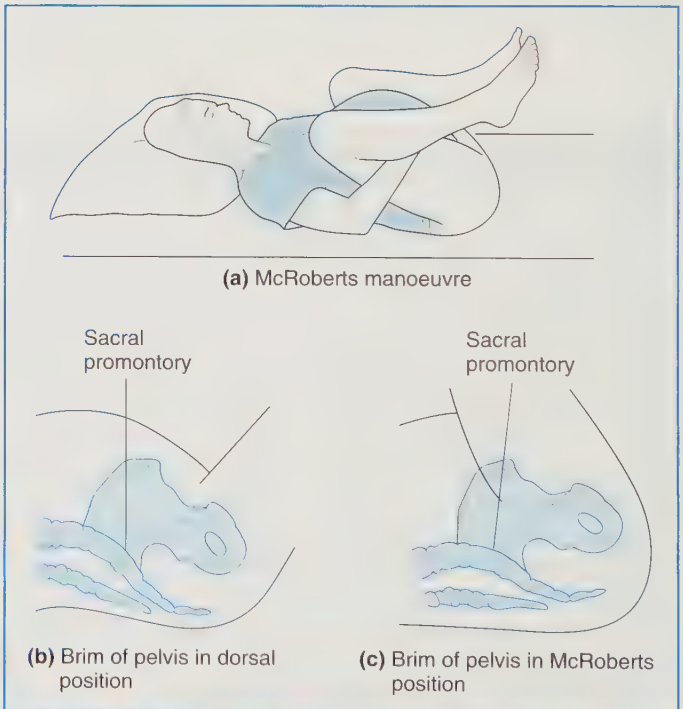
Emergency manoeuvres for the management of shoulder dystocia are designed to do one of three things:

- increase the functional size of the bony pelvis through flattening of the lumbar lordosis and cephalad rotation of the symphysis. The McRoberts manoeuvre (Fig 36.4) is thought to alleviate approximately 40–50% of all shoulder dystocias (Gherman et al 1997). The woman lies in a supine position and her knees are lifted up to her nipples. This exaggerated knee–chest position can also be achieved by rolling the woman into an all fours position.
- decrease the bisacromial diameter of the fetus (i.e. the breadth of the shoulders) of the fetus through application of suprapubic pressure (i.e. internal pressure on the posterior aspect of the impacted shoulder)
- change the relationship of the bisacromial diameter within the bony pelvis through internal manoeuvres.

Whatever the resources available, it is vital that the midwife summons help. In a hospital, additional midwives, an obstetrician, neonatologist or other clinicians available to resuscitate the baby should be called. Allocating someone to document times and manoeuvres employed is very helpful. Managing shoulder dystocia is an extremely anxiety-provoking time, and if it is to be managed well, it needs cool minds and clear thinking. It is important to remember to talk to the mother and her support people and to explain what is happening, especially since their cooperation and assistance are required.

The HELPERR mnemonic

The HELPER® mnemonic has been developed by ALSO© (Advanced Life Support in Obstetrics). Each step of the mnemonic involves rotation of the shoulders using pressure on the scapula or clavicle, not the fetal head. Internal manoeuvres are more successful if combined with suprapubic pressure in a direction that facilitates rotation within the vagina.



The HELPERR mnemonic (ALSO©) works as follows:

H Call for help

Activate a prearranged protocol that summons the appropriate personnel to respond with necessary equipment to the birthing room.

Clinical point

Whenever the normal events and progress of labour are disturbed by obstetric intervention—epidural block, induction of labour or interfering with the normal progress of the second stage of labour with forceps and vacuum extraction—*think* about the increased risk of shoulder dystocia.

(a) McRoberts manoeuvre

(b) Brim of pelvis in dorsal position

(c) Brim of pelvis in McRoberts position

Figure 36.4 Shoulder dystocia (based on Henderson & Macdonald 2004)

BOX 36.4 HELPERR

The HELPERR mnemonic (ALSO©):

- **H** Call for help
- **E** Evaluate for episiotomy
- **L** Legs (McRoberts manoeuvre)
- **P** Suprapubic pressure
- **E** Enter manoeuvres (internal rotation)
- **R** Remove the posterior arm
- **R** Roll the woman on to all fours (Gaskin manoeuvre)

E Evaluate for episiotomy

Episiotomy should be considered throughout the management of shoulder dystocia but only because it makes more room if rotation manoeuvres are required. Shoulder dystocia is a bony impaction that occurs at the pelvic inlet, so episiotomy alone will not release the shoulder.

L Legs (McRoberts manoeuvre)

This procedure involves flexing and abducting the maternal hips, positioning the maternal thighs up onto the maternal abdomen (knees to nipples). This position flattens the sacral promontory and results in cephalad rotation of the pubic symphysis. The woman is placed in a recumbent position. Remove or lower the bottom of the bed and manipulate the woman's buttocks to the extreme edge of the bed. With an assistant on either side of the woman, the thighs are abducted and hyper-flexed onto the abdomen, while the midwife applies gentle traction to the baby's head.

P Suprapubic pressure

The hand of an assistant is placed suprapubically over the fetal anterior shoulder, applying continuous pressure in a cardiopulmonary resuscitation style with a downward and lateral motion on the posterior aspect of the anterior fetal shoulder, to disimpact the shoulder. It is important to identify the plane of the fetal back because the midwife is attempting to adduct the shoulders to decrease the bisacromial diameter. This manoeuvre should be attempted while continuing downward traction. If delivery is unsuccessful, a rocking motion may be applied. Initially the procedure should be continuous for 30 seconds, followed by a rocking motion for another 30 seconds. If delivery is still not possible, the midwife's hand must now enter the vagina in an attempt to expedite delivery.

E Enter manoeuvres (internal rotation)

The Rubin manoeuvre (Fig 36.7 (a)) attempts to manipulate the fetus to rotate the anterior shoulder into an oblique plane and under the maternal symphysis. They can be difficult to perform when the anterior shoulder is wedged beneath the symphysis. All internal manoeuvres must be effected with insertion of two fingers into the vagina posteriorly. They are then moved upwards to apply digital pressure to the posterior aspect of the anterior shoulder in a clockwise direction, pushing it towards the fetal chest for another 30 seconds. This motion will adduct the fetal shoulder girdle, reducing its diameter and rotating the shoulders forward into the oblique diameter. The midwife again attempts delivery.

Wood screw manoeuvre (the only manoeuvre using two hands) (Fig 36.7 (b))

While maintaining pressure on the posterior aspect of the anterior shoulder, the midwife now introduces two fingers of her second hand into the vagina, locating the anterior aspect of the posterior shoulder. Both hands apply pressure in an effort to rotate the posterior shoulder in the same direction as before. The midwife again attempts delivery once the shoulders move into the oblique diameter. If this does not work, the midwife moves to the next manoeuvre.

Reverse Wood screw manoeuvre

The fingers on the posterior shoulder (Fig 36.7 (c)) are removed from the vagina and the two fingers on the anterior shoulder moved down and along the fetal back to the posterior aspect of the posterior shoulder. The midwife attempts to rotate the shoulder in the opposite direction to the Wood screw manoeuvre for 30–60 seconds.

If these manoeuvres have not resulted in delivery of the baby, removal of the posterior arm may be possible.

R Remove the posterior arm

Removing the posterior arm from the birth canal (Figs 36.6, 36.7 (d)) aims to shorten the bisacromial diameter, allowing the fetus to drop into the sacral hollow, freeing the impaction. If the woman is not in the all-fours position, it may be helpful to do this first before attempting to remove the posterior arm. Repositioning the woman means the posterior arm is now lying anteriorly. Two fingers are inserted into the

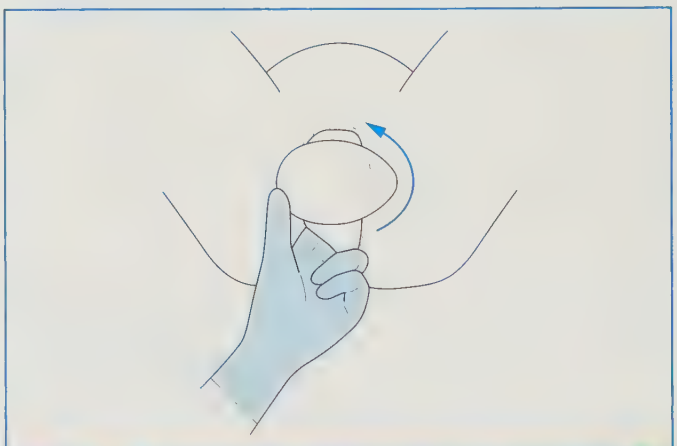


Figure 36.5 Shoulder dystocia: in the Rubin manoeuvre, the shoulders are adducted as the shoulder is rotated anteriorly (based on Henderson & Macdonald 2004)

vagina and passed down the front of the posterior arm as far as possible to flex the arm at the baby's elbow and the forearm delivered in a sweeping motion over the fetal anterior chest wall ('cat lick' manoeuvre). Grasping and pulling directly on the fetal arm may fracture the humerus.

R **Roll the woman onto all fours (Gaskin manoeuvre)**
The woman is rolled from her existing position to the all-fours position. Often, the shoulder will dislodge during the act of turning, so this movement alone may be sufficient to dislodge the impaction. Rotation of the woman may facilitate delivery by increasing the pelvic diameters and allowing better access to the posterior shoulder. In addition, the position change may affect gravitational forces, which further aid in the disimpaction of the fetal shoulders.

Some clinicians use this as their first-line management by asking the woman to move her knees to her nipples while in the all-fours position. The only manoeuvre that cannot be done in this position is the application of suprapubic pressure.

If at any time the midwife feels the shoulders move, delivery should be attempted without delay. Maternal effort is advisable but the midwife should not wait for contractions before proceeding through the steps. If, on the rare occasion that all these manoeuvres have been attempted, and birth has not been successful, the process is started again.

The complications associated with shoulder dystocia are listed in Box 36.5.

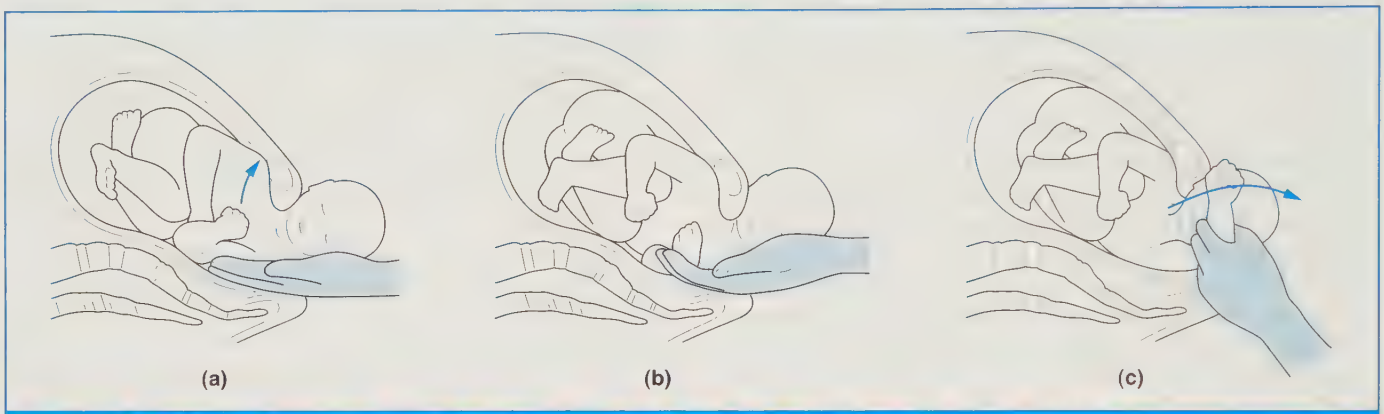

Figure 36.6 Shoulder dystocia: delivery of the posterior arm (based on Henderson & Macdonald 2004)

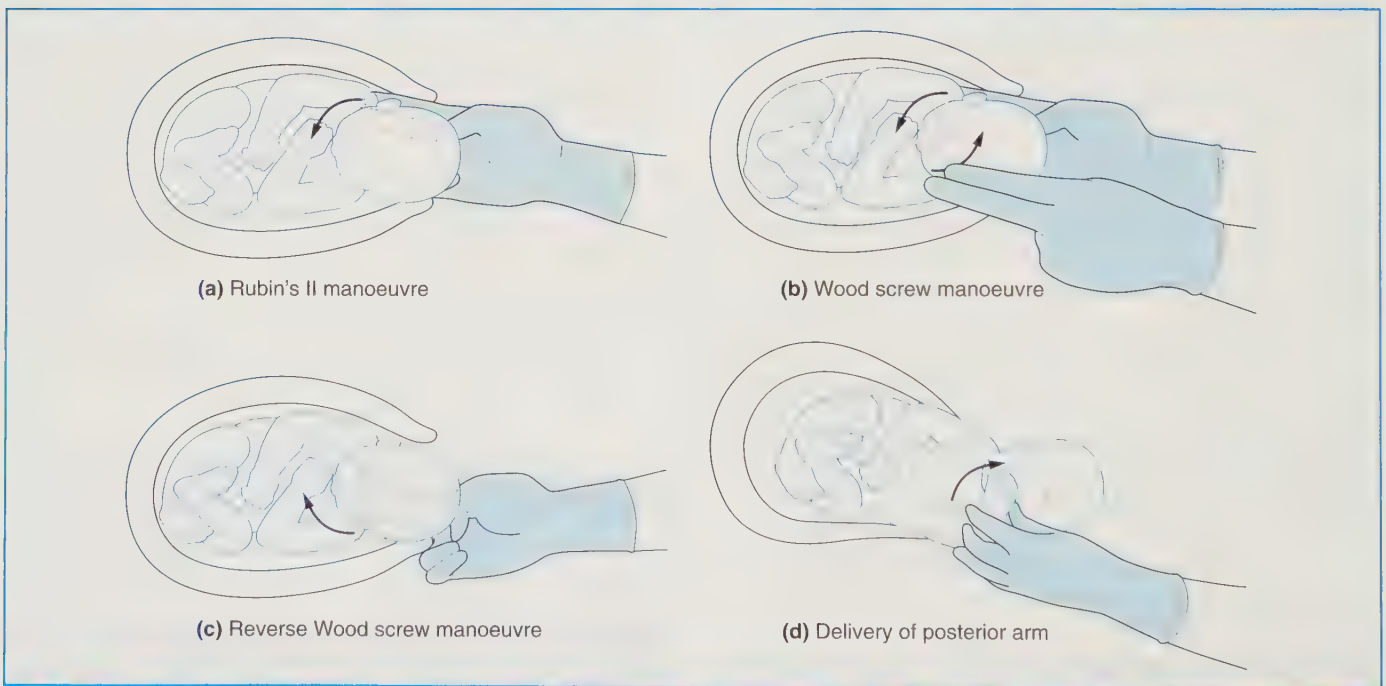

Figure 36.7 HELPPER© manouvres for shoulder dystocia (based on Oats & Abraham 2004)

BOX 36.5 Complications of dystocia

Maternal:
- postpartum haemorrhage
- rectovaginal fistula
- symphyseal separation or diastasis, with or without transient femoral neuropathy
- third or fourth degree episiotomy or tear
- uterine rupture.

Fetal:
- brachial plexus palsy
- clavicle fracture
- death
- hypoxia, with or without permanent neurological damage
- fracture of the humerus.

Manoeuvres of last resort

A number of authors, such as Gobbo and Baxley (2000), Sandberg (1999) and Gherman et al (1998), describe a number of 'last-resort' manoeuvres. There is little or no evidence to support their use, except perhaps as a desperate last measure; they are briefly summarised below.

- *Deliberate clavicle fracture*—direct upward pressure on the mid-portion of the anterior fetal clavicle reduces the shoulder-to-shoulder distance. The danger of this procedure is that bone fragments may pierce the underlying lung or the subclavian blood vessels.
- *Zavanelli manoeuvre*—cephalic replacement is followed by caesarean delivery; it involves rotating the fetal head into a direct occiput anterior position, then flexing and pushing the fetal head back into the birth canal, while holding continuous upward pressure.
- *General anaesthesia*—musculoskeletal or uterine relaxation with halothane or another general anaesthetic may bring about enough uterine relaxation to effect delivery. Oral or intravenous nitroglycerine may be used as an alternative to general anaesthesia.
- *Symphysiotomy*—intentional division of the fibrous cartilage of the symphysis pubis under local anaesthesia is used more widely in developing than developed countries. It should be used only when all other manoeuvres have failed and caesarean delivery is unavailable.

Documentation

It is vital that the midwife attending a shoulder dystocia thoroughly document the manoeuvres employed and the time taken to deliver the baby. Midwives need to differentiate between 'difficult shoulders' and shoulder dystocia, to ensure that subsequent pregnancies are managed appropriately. Imprecise, subjective language such as 'mild or moderate' shoulder dystocia should never be used. Instead, documentation should clearly outline what procedures were used to expedite delivery, how long each one took and their effect. The woman should also be fully informed about what happened and de-briefing or counselling offered.

Summary: shoulder dystocia

Sooner or later every midwife is confronted with a life-threatening and frightening complication such as shoulder dystocia. The key to management is that the team knows exactly what to do and, at a time of great tension, works calmly and without panic, and proceeds through a logical series of steps designed to disimpact the anterior shoulder from behind the symphysis pubis. Over-zealous techniques used to deliver the anterior shoulder frequently do more damage to the fetus than that caused by manoeuvres such as those described in the HELPERR© mnemonic.

Uterine inversion

Uterine inversion is a potentially life-threatening complication of childbirth in which, as Varney (2004, p 915) says, the uterus literally turns inside out (Fig 36.8), so that the inside of the fundus protrudes through the cervical os (incomplete), descends to the vaginal introitus (complete) or extrudes beyond the vulva (prolapsed). Uterine inversion may occur with the third stage of labour or, less frequently, post partum. Inversions are described as acute if they occur within the first 24 hours of birth, while those occurring more than 24 hours after birth are subacute. Mothers' survival rate is about 85%. The most frequent cause of death is intractable haemorrhage and associated shock. These complications are minimised by prompt recognition and management.

Incidence

The rate of uterine inversion is estimated at 1: 2000 to 1:23,000 labours. This wide range reflects differences in recording methods and client populations.

Pathophysiology

Occasionally inversion is idiopathic, and it rarely occurs spontaneously, but most often it is due to 'mismanagement' of the third stage of labour. Nevertheless, for it to occur, a portion of the uterine wall either indents toward or prolapses through the dilated cervix. Thus, uterine relaxation combined with simultaneous downward additional traction force on the fundus of the uterus and/or with additional traction applied to the umbilical cord before it has separated, causes the fundus of the uterus to prolapse. Telling the mother to push to help expel the unseparated placenta increases the risk of uterine inversion.

Associated factors

According to Varney (2004, p 915), there are three circumstances that when combined create a situation favourable to uterine inversion:

- uterine atony, or flaccidity of the myometrium around the implantation site

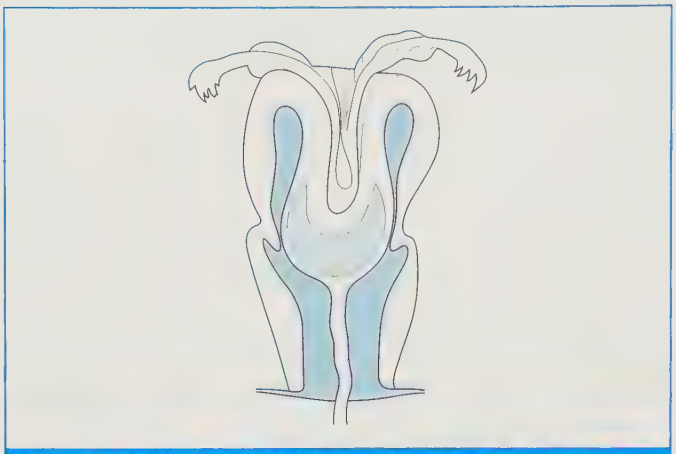

Figure 36.8 Inversion of the gravid uterus (based on Henderson & Macdonald 2004)

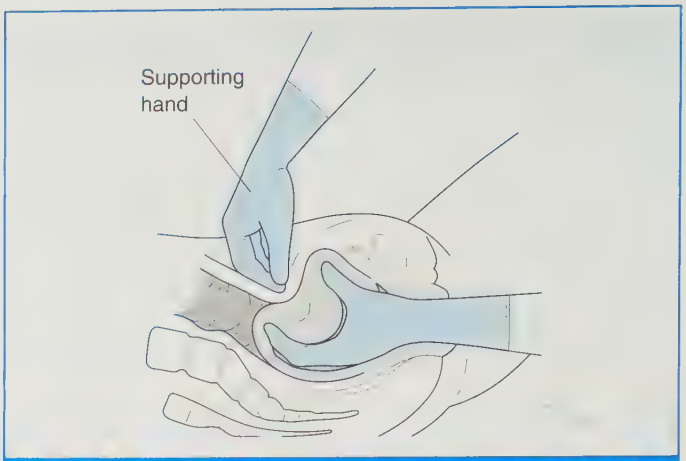

Figure 36.9 Correcting uterine inversion (based on WHO n.d.)

- patulous dilated cervix
- fundal pressure (Credé's manoeuvre) or excessive traction on the umbilical cord, especially when the placenta has not separated from the uterine wall.

There are a number of other reported associations (not causations) with uterine inversion. In all likelihood, a number of common factors act in concert to result in an inversion. These include:

- a short umbilical cord
- multiparity
- sudden increase in abdominal pressure, as in coughing
- placenta accreta/increta/percreta
- fundal implantation of the placenta
- chronic endometritis
- fetal macrosomia
- use of $MgSO_4$
- 'trials' of vaginal birth following caesarean section
- myometrial weakness/uterine sacculation
- precipitate labour
- acute tocolysis with nitroglycerine or other potent agents.

Clinical presentation

The diagnosis of uterine inversion is usually established clinically when the midwife observes the uterus lying outside the vulva immediately after birth, or following vaginal examination—perhaps when the fundus of the uterus cannot be palpated after the delivery of the placenta. Uterine inversion should always be suspected if the woman becomes shocked immediately after birth without an obvious reason. However, if the inversion is not complete, PPH is usually the most striking sign that draws the attention of the clinician to suspect uterine inversion.

Management

Successful management of this rare but potentially life-threatening condition requires a collaborative effort. Skilled midwifery assistance, an accomplished obstetrician and anaesthetist, and immediate access to the operating room are important components of success. Treatment for inversion employs parenteral tocolytics to permit immediate uterine replacement, treatment of shock, fluid replacement and oxytocic drugs to maintain normal uterine positioning. The optimal technique for rapid uterine replacement is contentious. Theoretically, in the presence of neurological shock, further stretching of the pelvic viscera as the uterus is replaced has the potential to exacerbate shock. In practice, however, once the diagnosis is recognised, the best management is still immediate replacement, because the longer the delay, the more firmly contracted the lower uterine segment/cervix becomes, making the replacement increasingly difficult. In summary, reduction of the uterine inversion may be accomplished either by a conservative non-surgical approach or by a surgical procedure.

Non-surgical techniques

In 1945, O'Sullivan described a method for the correction of partial uterine inversion using hydrostatic pressure. Warm saline is rapidly instilled into the vagina via a Foley's catheter. The fluid pushes the uterine fundus upwards until it resumes its correct position. An oxytocic infusion is used to maintain uterine contraction.

Tocolytics, such as terbutaline or glyceryl trinitrate, make manual replacement less difficult. During this procedure, the clinician inserts a hand into the vagina and holds the inverted uterus so that the fundus is positioned in the palm of the hand (Fig 36.9). Pressure is then applied to lift the uterus upward and anteriorly through the pelvis into the abdominal cavity to the level of the umbilicus. If two or more attempts at this very painful procedure fail, surgery is indicated.

In most cases, as the placenta will not have separated before manual or surgical replacement is attempted, the best plan is not to try and remove it but to wait until the woman is transferred to the operating theatre with adequate personnel and resources to deal with the problem. Immediate placental removal without replacement simply increases blood loss. Furthermore, in the increasingly common event of a

Clinical point

Uterine inversion is a rare obstetric catastrophe often involving haemorrhage, major surgery to replace the uterus, and sometimes hysterectomy. There is no place for fundal pressure during the third stage of labour. A report on a series of 358 cases found that third-stage fundal pressure was a factor in a third of cases (Morini et al 1994). A more recent French survey found that fundal pressure or umbilical cord traction was a factor in 60% of uterine inversions (Miras et al 2002).

placenta accreta/increta/percreta, separation is very difficult, or impossible.

Surgical approaches

Occasionally, abdominal surgery is required to reposition the uterus. General anaesthesia, followed by laparotomy or incision of the contracted cervix may be necessary. Regardless of the procedure employed, after replacement, uterine atony and PPH is common. The prompt administration of 15-methyl prostaglandin $F_{2\alpha}$ (Hemabate®), high-dose oxytocin infusions and perhaps ergometrine (provided there are no contraindications), or misoprostol per rectum is recommended to control PPH. Many clinicians still prefer to administer a single prophylactic dose of a broad-spectrum first-generation cephalosporin or a similar drug at the time of repositioning. Reinversion may also occur.

Summary: uterine inversion

Puerperal uterine inversion is a rare but potentially life-threatening complication of the third stage of labour. It is often accompanied by massive haemorrhage and shock. Timely diagnosis, replacement of the inverted uterus, and prompt, expert management are mandatory. Judicious replacement of the inverted uterus by vaginal manipulation is recommended. Careful clinical observation following replacement and the administration of oxytocic drugs prevents most reinversions. In the rare case when the inversion is long-standing or if manual replacement fails, surgical replacement is required. The risk of recurrence of inversion in subsequent births is unknown.

Amniotic fluid embolism

Amniotic fluid embolism (AFE) is a poorly understood phenomenon usually occurring without warning, and perhaps because it is so rare its consequences are often catastrophic. It is unpredictable, unpreventable and rapidly progressive. AFE occurs in about 1:8000 to 1:30,000 pregnancies, with high maternal and fetal mortality and frequently permanent neurological damage in survivors. Women with AFE are critically ill and, if they survive the initial phase of this disorder, will require admission to an intensive care unit (ICU). Most maternity hospitals in Australia and New Zealand do not have dedicated obstetric ICU units, so it is crucial that all maternity service providers are prepared to provide emergency care for these women until referral to an ICU can be effected.

Historical context

Steiner and Lushbaugh (1941) were the first researchers to use the term 'amniotic fluid embolism' to describe the signs and symptoms associated with sustained tachycardia, cardiovascular collapse, pulmonary oedema and shock that developed during labour in the absence of other illnesses. The authors postulated that powerful or tetanic uterine contractions caused an embolism of squamous cells, mucin and/or other amorphous debris, from the fetus, to lodge in the woman's pulmonary vessels. Benson (1993) was one of the first investigators to cast doubt on the belief that amniotic fluid leakage into the maternal circulation was the primary cause of AFE. He argued that the disease was probably associated with an immune response to a pregnancy-associated antigen, in part because the clinical features of AFE were more similar to anaphylaxis than to embolism. In the United States, Clark et al (1995) commenced a national registry of women with AFE. They reported a significant association between AFE and a male fetus. Moreover, 41% of women with this syndrome had a history of allergy or atopy (Clarke et al 1995). He and others recommended a new clinical definition, anaphylactoid syndrome of pregnancy, to describe the condition. More recently, Benson et al (2001) postulated that complement activation rather than anaphylaxis might play a role in the pathophysiology of AFE. Whatever the initial precipitating factor, there is little doubt that mechanical obstruction caused by emboli lodging in maternal blood vessels is a major feature in determining the severity of the condition and maternal and fetal outcomes.

Mortality/morbidity

Death rates from AFE vary between 26.4% and 61% (Clarke et al 1995). Most mortality occurs in the first few hours—50% within the first hour. More than half of those who develop AFE will experience coagulopathy, including disseminated intravascular coagulopathy (DIC). Less than 15% of women experiencing AFE survive without neurological impairment. Although 79% of neonates survive, 50% are neurologically impaired (Clarke et al 1995).

Pathophysiology

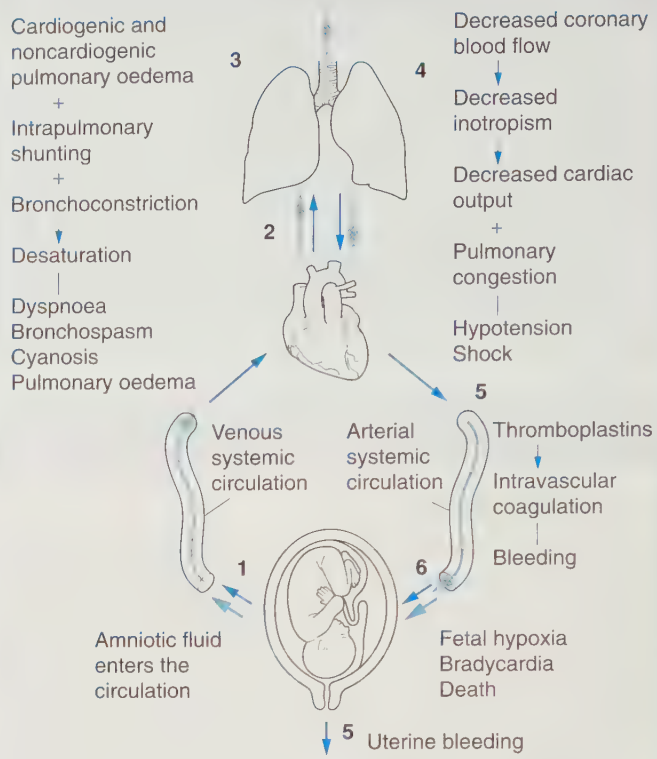
According to the *Maternal Deaths in Australia 1997–1999* report (Slaytor et al 2004), AFE was responsible for seven direct maternal deaths in Australia in the 1997–1999 triennium. In five of these cases, labour was induced. The authors note that drawing conclusions from analysis of such small numbers is problematic, but all clinicians should be aware that there may be an association between AFE and the induction of labour with Syntocinon® and/or ARM. However, it has been

suggested that the uterine hypertonus sometimes observed prior to the onset of clinical signs of AFE occur because of an amniotic fluid embolism.

The precise pathophysiological pathway by which AFE occurs is still unknown. Under certain conditions, when amniotic fluid and its fetal components enter the maternal circulation, endogenous mediators (e.g. prostaglandins, leukotrienes, histamine, bradykinin, cytokines, thromboxane, complement-activating factors, and platelet-activating factor) are released and these trigger a two-phase response. In phase one, pulmonary artery vasospasm, pulmonary hypertension and elevated right ventricular pressure result in hypoxia, and myocardial and pulmonary capillary damage, resulting in left heart failure and adult respiratory distress syndrome. Phase two is characterised by haemodynamic instability and/or DIC.

Maternal clinical presentation

The onset of signs and symptoms associated with AFE are related to pulmonary vasospasm, pulmonary hypertension and ventricular dysfunction. According to Gei and Hankins (2000), the initial signs and symptoms have a typical chronology. Once the amniotic fluid enters the maternal systemic circulation:



- the amniotic fluid enters the pulmonary circulation, leading to respiratory distress and cyanosis occuring within 60 seconds
- pulmonary venous pressure increases, with a concomitant drop in cardiac output, pulmonary oedema, hypotension and shock
- neurological manifestations such as confusion, loss of consciousness and seizures occur
- the exposure of the circulatory system to amniotic fluid thromboplastin and other mediators induces DIC
- systemic hypotension and decreased uterine perfusion develop. Abnormalities of the FHR are apparent.
- more than 80% of cases end in cardiac arrest.

Fetal signs and symptoms

Profound fetal respiratory acidosis and associated FHR changes occur in response to maternal hypoxia and hypertonic uterine contractions. Prolonged late decelerations followed by baseline fetal bradycardia can result in neurological injury. A rate of 60 bpm or less for more than three minutes may indicate a terminal bradycardia. A short interval between cardiac arrest and delivery correlates positively with neonatal survival.

Diagnosis

The classic scenario of AFE involves an older multiparous woman in advanced labour who suddenly collapses, although it can occur following termination of pregnancy, amniocentesis, placental abruption and trauma, during caesarean section and without known risk factors within 30 minutes after birth (Box 36.6). There may be CTG abnormalities, uterine hypertonus and an obstetric intervention such as ARM. The

Sequence of events:

(1) For reasons not completely understood, amniotic fluid reaches the maternal intravascular compartment (systemic venous system).

(2) The amniotic fluid enters pulmonary circulation via the pulmonary artery. This contaminated blood crosses to the left atrium through a patent foramen and probably through intra-pulmonary shunts once the embolism is significant, as shown in cases of massive amniotic fluid embolism at autopsy.

(3) The exposure of the pulmonary vasculature to both soluble (leucotrines, surfactant, thromboxane A_2, endothelin, etc.) and insoluble components (squames, vernix, hair, mucin, etc.) of the amniotic fluid and possibly other mediators released locally induces capillary leak, negative inotropism, and bronchospasm. This results in sudden onset of respiratory distress and cyanosis.

(4) Within minutes, the negative inotropic effect becomes prevalent (probably due to myocardial ischaemia). Pulmonary venous pressure (congestion) increases and a drop in cardiac output are manifested by pulmonary oedema and hypotension to the point of shock.

(5) The exposure of the intravascular compartment to amniotic fluid thromboplastin and to other mediators freed in the circulation by the presence of amniotic fluid induces a consumptive coagulopathy in a large proportion of the first-phase survivors. This disseminated intravascular coagulation often results in severe uterine bleeding.

(6) The resultant systemic hypotension decreases the uterine perfusion. Abnormalities of the fetal heart tracing will rapidly follow and may result in fetal death.

Figure 36.10 Pathophysiology of amniotic fluid embolism (based on Perozzi & Englert 2004)

BOX 36.6 Diagnosis of AFE

The National Registry's criteria for diagnosis of Amniotic Fluid Embolism (Clarke et al 1995):

- acute hypotension or cardiac arrest
- acute hypoxia, defined as dyspnoea, cyanosis or respiratory arrest
- coagulopathy, defined as laboratory evidence of intravascular consumption or fibrinolysis (or severe clinical haemorrhage in the absence of other explanations)
- onset during cervical dilatation and curettage, labour, birth and caesarean delivery, or within 30 minutes post partum
- absence of any other significant confounding condition or potential explanation of symptoms and signs just listed.

initial pulmonary symptoms may be minor but acute left ventricular failure usually develops and leads to cardiovascular collapse. This is followed by haemorrhage and DIC. Clarke and colleagues (1995) reported that 83% of cases documented in the national registry had either clinical or laboratory evidence of DIC. The remaining 17% died before clotting status could be determined. For a clinical diagnosis of AFE to be made, there needs to be evidence of:

- acute hypotension or cardiac arrest
- acute hypoxia (dyspnoea, cyanosis or respiratory arrest)
- coagulopathy (laboratory evidence of DIC or severe haemorrhage)
- onset of all of the above during labour or within 30 minutes of birth
- no other clinical conditions or potential explanations for the symptoms and signs.

There is no specific diagnostic test to confirm the diagnosis of AFE. The diagnosis is by exclusion. Any pregnant or labouring woman who exhibits signs associated with pulmonary embolus, septic shock, acute myocardial infarction, cardiomyopathy, anaphylaxis, cardiorespiratory collapse or intractable haemorrhage must be systematically evaluated to exclude the diagnosis of AFE. Laboratory investigations include:

- complete blood count
- coagulation parameters (FDP, fibrinogen)
- arterial blood gases
- chest X-ray
- ECG
- V/Q scan
- echocardiogram.

Management

Management of AFE depends on the following:

- oxygenation and ventilatory support:
  - supplemental oxygen
  - intubation
  - ventilation
  - diuretics

Clinical point

Several clinical conditions (abruption, hydramnios, multiparity) are associated with AFE. There are no consistent clues, warning signs or associated complications to indicate an increased risk of AFE.

- correction of cardiovascular collapse and maintenance of normal cardiovascular function:
  - CPR protocol
  - delivery of the fetus
  - volume
  - inotropes
  - after-load fluid reduction
- treatment of DIC with blood transfusion and replacement of clotting factors:
  - fresh frozen plasma
  - packed red blood cells
  - platelets
  - cryoprecipitate.

Additional measures may include:

- high-dose corticosteroids
- adrenaline
- cardiopulmonary bypass
- nitric oxide
- inhaled prostacyclin.

Recognition of the condition followed by prompt and aggressive treatment of AFE is necessary to achieve better outcomes. All the cases described in the report on maternal deaths in Australia involved resuscitation and advanced life support (Slaytor et al 2004). Therefore it is crucial that all healthcare providers, irrespective of where they work, keep their basic and advanced life support skills up to date and be encouraged to attend appropriate courses, such as Advanced Life Support in Obstetrics (ALSO©) and Managing Obstetric Emergencies and Trauma (MOET©).

Dr Alex Tuffnell provides a valuable summary on the five maternal deaths caused by AFE in the *Report on Confidential Enquiries into Maternal Deaths in the United Kingdom* (CEMCH 2004). This summary helps us to understand this rare but often fatal complication and highlights the effects of treatment. Box 36.7 is derived from that analysis.

Summary: amniotic fluid embolism

Amniotic fluid embolism is not universally fatal but it is one of the most feared and devastating complications of pregnancy. It can be neither predicted nor prevented. Its presentation is variable and may mimic other embolic phenomena (pulmonary embolus). Medical management is essentially supportive. The primary goals of management are to provide oxygen, maintain cardiac output and organ perfusion, correct coagulopathy, and provide adjunctive therapies. Women with symptoms suspicious of AFE should be transferred to

an ICU as soon as possible, as these women often have better outcomes.

BOX 36.7 AFE findings

Analysis of five cases of AFE

There were five cases of amniotic fluid embolism in the United Kingdom reported during the triennium 2000–2002, eight in 1997–99 and 17 in 1994–95. The youngest woman was in her mid-twenties, two were nulliparous and all had reached term. Labour was spontaneous for two women and induced with prostaglandins for a further two, and the fifth received oxytocin augmentation. At the time of embolism, one woman still had her membranes intact, in two cases they had spontaneously ruptured (in one, a few minutes before collapse) and they were artificially ruptured for the other two women.

Speed of collapse

Three women experienced premonitory symptoms before their collapse. In one case, the woman complained of feeling cold and developed stertorous breathing and cyanosis for an unspecified time before collapse. Another woman developed respiratory distress, restlessness and cyanosis, and the third experienced extreme distress and was said to have behaved in an abnormal manner. These symptoms appeared to have developed within the half an hour preceding their collapse. The time taken to deliver the baby from first symptoms ranged from 15 minutes to 45 minutes.

Outcomes

Three women died within one hour of collapse and two between five and seven hours later. Only one woman was admitted to ICU but died shortly after admission, and the other four women died before transfer to ICU.

Two women required hysterectomies after caesarean section because of continued heavy bleeding, with one requiring a subsequent laparotomy. A third woman underwent a laparotomy without hysterectomy.

For four women, the diagnosis was confirmed at autopsy and one diagnosis made clinically as no autopsy was held. All the women were delivered by caesarean section, four being peri-mortem during maternal resuscitation and one performed before the woman collapsed. Four of the babies were born alive but two died in the early neonatal period. One was stillborn.

Dr Tuffnell concluded that maternal death was inevitable in all of the cases he reviewed. There was no substandard care in two cases and, although there were general lessons around the provision of anaesthesia in the other three, these would not, in all probability, have affected the outcome. However, it was disconcerting that, in one case, the arrival of the cardiac arrest team was delayed because it was unable to find the obstetric operating theatre.

(Source: CEMCH 2004)

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is not a disease but a complex syndrome that is always secondary to an underlying disorder such as AFE. DIC occurs when the clotting cascade goes awry. It is characterised by systemic activation of the blood coagulation system, leading to the generation of intravascular fibrin, widespread fibrin deposition in the microcirculation, which contributes to the development of multi-organ failure. Consumption and subsequent exhaustion of coagulation proteins and platelets because of ongoing activation of the coagulation cascade may induce severe bleeding complications.

In obstetrics, DIC usually results from entrance into or generation within the blood of material with tissue factor activity (TFA), which initiates coagulation pathways. DIC usually arises in one of four clinical circumstances:

- obstetric calamities—where uterine material with TFA gains access to the maternal circulation (e.g. in abruptio placentae, retained dead fetus syndrome and following amniotic fluid embolism)
- shock—from any cause including PPH, probably because of the generation of TFA on monocytes and endothelial cells
- bacterial infection—particularly with Gram-negative organisms. Gram-negative endotoxins cause generation of TFA on the plasma membrane of monocytes and endothelial cells.
- malignancy—particularly mucin-secreting adenocarcinomas in which hypergranular, leucaemic cells are thought to release material from their granules with TFA.

Pathophysiology

The mechanisms by which DIC is triggered are not entirely understood and are too complex to be considered in detail in this chapter. In brief, several simultaneously occurring mechanisms play a role in the pathogenesis of DIC (Fig 36.11). For some reason, maternal blood is exposed to large amounts of the tissue factor FVIIa system. Two proteolytic enzymes, thrombin and plasmin, are activated and released into the systemic circulation. In normal circumstances the balance between these two substances determines a bleeding or thrombotic tendency. Thrombin cleaves fibrinogen to form fibrin monomers. The fibrin deposition is a result of tissue factor-mediated thrombin generation that is insufficiently balanced by physiological anticoagulant mechanisms such as the antithrombin system and the protein C system. In addition to enhanced fibrin formation, fibrin removal is impaired as a result of depression of the fibrinolytic system. This leads to small and large vessel thrombosis, with the end-result of multi-organ failure. As a result, large amounts of thrombin are

Clinical point

Warning signs of DIC:

- Profound haemorrhage
- Blood fails to clot.
- Petechiae appear.
- Bleeding from the woman's eyes, nose, gums or vagina and from venipuncture, surgical and episiotomy sites occurs.
- Haematomas, flank pain, abdominal distension, swollen extremities, neurological abnormalities, hypotension, tachycardia, cool skin temperature, pallour and diaphoresis may indicate profuse internal bleeding.

generated, leading to a hypercoagulable state. In the normal physiological state, plasmin is responsible for breaking fibrin into fibrin split products, thereby limiting the formation of fibrin clots. In DIC, the quantity of plasmin is significantly increased, leading to the generation of significant quantities of fibrin degradation products. This results in the catastrophic bleeding seen in DIC.

Incidence and management

It is difficult to determine the exact incidence of DIC in obstetrics. If there is any suspicion of DIC arising from either clinical or laboratory findings, it is imperative to monitor the woman carefully with clinical and laboratory tests in order to identify the progression of the coagulopathy. In most cases the disease can be ameliorated in the early stages, for example in cases of DIC induced by abruptio placentae. Management

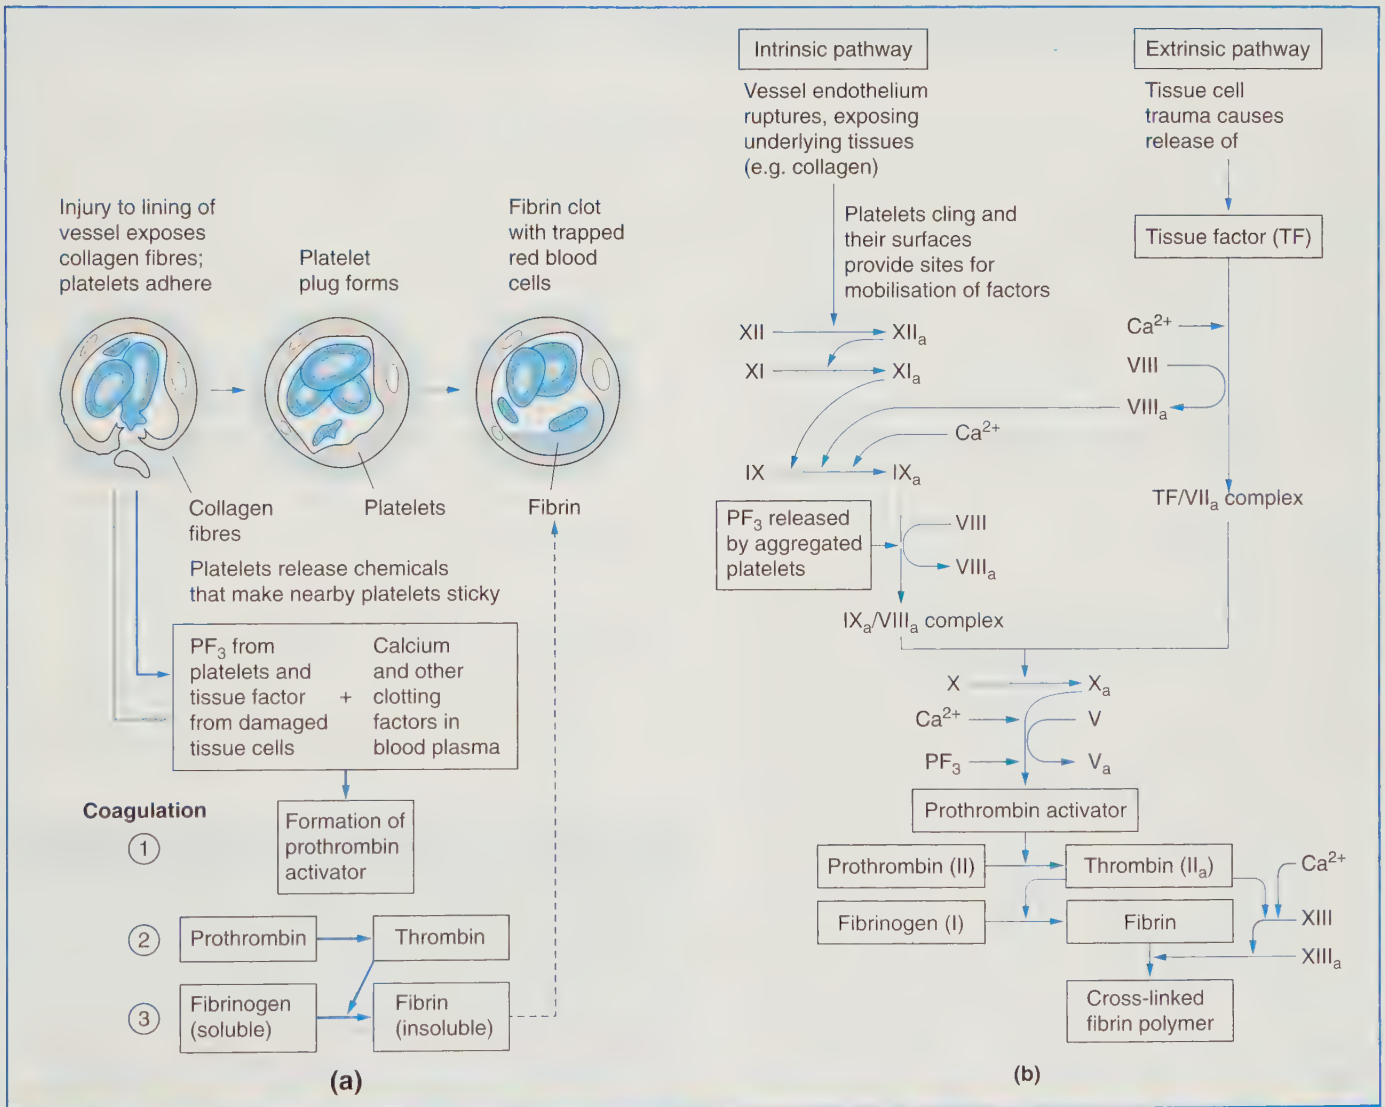


Figure 36.11 Platelet formation and blood clotting **(a)** Simplified overview of events. Steps 1 to 3 are the major events. **(b)** Detailed flow chart indicating intermediates and events involved in platelet plug formation and the intrinsic and extrinsic mechanisms of clotting (Note: subscript a: activated procoagulant) (based on Marien 2004)

is always individualised and supportive, and centred on treatment of the underlying disorder. Treatment includes:

- plasma and platelet substitution therapy
- anticoagulants
- restoration of anticoagulant pathways.

Eclampsia

Pre-eclampsia (PE) is a pregnancy-specific, multi-organ disorder usually associated with hypertension, thrombocytopenia and proteinuria. PE may progress to eclamptic seizures. Eclampsia, meaning literally to 'shine forth', complicates about 1:2000 pregnancies. In *Maternal Deaths in Australia 1997–1999*, Slaytor et al (2004) report six direct deaths where hypertension and/or eclampsia were identified. Seizures can occur before, during or after labour in roughly equal proportions (i.e. 30% antenatal, birth and postnatal). Women are at risk of eclampsia for about 48 to 72 hours after birth.

The Australasian Society for the Study of Hypertension in Pregnancy published its consensus statement on the detection, investigation and management of hypertension in pregnancy in 2000 (Brown et al 2000). The authors are unequivocal that prompt detection and treatment of eclampsia are the key to maternal and perinatal survival. Best practice recommendations are based on two international, multicentred trails. Both have shown that magnesium sulfate ($MgSO_4$) is the anticonvulsant agent of choice for the prevention and treatment of eclamptic seizures (Eclampsia Trial Collaborative Group 1995; Magpie Trial Collaborative Group 2002). This section focuses on identification and current management according to these recommendations.

Pathophysiology

Pre-eclampsia/eclampsia is part of a multi-system disorder of unknown aetiology characterised by vasoconstriction and hypercoagulability. Possible causes include a defect in placentation leading to uteroplacental hypoperfusion, immunological intolerance between mother and fetus, and genetic factors. Although the exact mechanism that leads to PE is not clear, several known factors are associated with the onset of the disease. Major pathological changes occur in the placental vascular bed, and trophoblastic implantation is abnormal, with reduced placental perfusion. An alteration in the ratio of prostacyclin and thromboxane occurs, along with platelet aggregation, thrombin activation and fibrin deposition in maternal vascular beds. Increased capillary permeability and hypoalbuminaemia also occur. The combination of profound vasospasm with consequent reduction of plasma volume and thrombosis causes dysfunction in almost all body systems. The latter triggers the coagulation cascade. Clotting times are often elevated in severe PE, although standard tests such as prothrombin time and partial thromboplastin time may be normal. The natural progression of the disease is from severe PE to eclampsia. Most women with eclampsia present with a history of hypertension and seizures, although in about 20% of cases eclampsia may occur without warning in women who have no history of hypertension. It is believed that eclamptic seizures occur as the result of cerebral vasospasm and endothelial damage, which lead to cerebral ischaemia, microinfarcts and oedema.

Imminent eclampsia: signs and symptoms

Most women report premonitory symptoms of eclampsia:

- severe frontal headache—cerebral oedema
- diminished urinary output—renal failure: most important clinical feature
- visual disturbances—retinal oedema
- epigastric pain—haemorrhage of the subcapsular parts of the liver
- vomiting and nausea—related to cerebral oedema and liver damage
- hyper-reflexia—can signal impending eclampsia.

Management of severe pre-eclampsia and prevention of eclampsia

Early detection and prevention of severe PE is the key to prevention of eclampsia. The main aims of therapy centre on prevention or treatment of seizures, resuscitation, control of hypertension, treatment of complications, prompt consultation, and timely delivery of the infant and placenta. The only 'cure' for P-E/eclampsia is delivery of the placenta. The suppression of eclamptic seizures does not solve the underlying multi-system disease. It helps to protect the mother and baby from complications such as cerebral haemorrhage, antepartum haemorrhage, fetal asphyxia and death while the maternal condition is stabilised, and enables a multidisciplinary team to plan future care, including referral to a Level III hospital and the mode of delivery.

Prevention and control of seizures

Magnesium sulfate ($MgSO_4$) infusions for eclamptic seizure prophylaxis is now accepted as the gold standard of treatment of seizure-related complications of eclampsia and PE (Brown

Case study

Samantha, a primigravida at 38 weeks, attends a rural maternity centre with a severe headache. On assessment her BP is found to be 170/120. She has diminished urine output, a urine analysis of 3+ protein, epigastric pain and hyperreflexia. The FHR is within normal limits. Her lead carer is out of town and you are the only midwife on duty. You call the Emergency Retrieval Team for advice. They are now en route with an ETA of 45 mins. What will be your management of Samantha until the retrieval team arrives?

et al 2000; NSW Health Department 2002). Although the exact mechanism is unknown, $MgSO_4$ is thought to act as a physiological calcium antagonist, and may act by blocking calcium channels in smooth muscle, resulting in the reversal of cerebral vasospasm. Continuous infusion improves the maintenance of serum levels compared with intermittent bolus doses. Table 36.2 provides one example of a typical protocol for $MgSO_4$ used in the management of severe PE or eclampsia.

Side-effects of $MgSO_4$ (Magpie and Collaborative Eclampsia trials)

About 25% of women will experience one or more side-effects from the $MgSO_4$ infusion. The woman should be monitored carefully for clinical signs of magnesium toxicity, particularly:

- sensation of pain and warmth in arms
- disruption to sensation, particularly in extremities
- flushing of face, neck and hands
- thirst, headache, dizziness, itching
- nausea, vomiting
- loss of patellar reflexes—absent well before toxic serum levels are reached
- respiratory depression (rate < 10/min)
- slurring of speech, muscle weakness, drowsiness and double vision
- respiratory/cardiac arrest (Eclampsia Trial Collaborative Group 1995; Magpie Trial Collaborative Group 2002).

If toxicity is suspected, the infusion should be discontinued. If required, the antidote for maternal toxicity is an IV injection of calcium chloride or calcium gluconate (10 mL of 10% solution at a rate not exceeding 5 mL/min) over three minutes.

TABLE 36.2 Example of a protocol for $MgSO_4$ management of severe PE or eclampsia

Loading dose
Presentation is usually 50% solution in 5 mL H_2O
Undiluted, this = 10 mmol/5 mL = 2 mmol/mL
Ampoules: 2.47 g in 5 mL / 0.49 g in 1mL / 3.92 g in 8 mL
Recommended loading dose: 4 g (16 mmol) $MgSO_4$ over 15–30 mins

Infusion pump	Syringe pump
Loading dose	
4 g $MgSO_4$ (50% solution) diluted in normal saline via infusion pump over 20–30 min: • Using 500 mL flask normal saline, run 100 mL into burette. • Add 8 mL (4 g) $MgSO_4$ (50% solution) to 100 mL normal saline in burette. • Infuse over 20–30 min via infusion pump.	4 g $MgSO_4$ (50% solution) not diluted is given via syringe pump over 15 min: • Using 20 mL syringe, draw up 9 mL undiluted $MgSO_4$ (50% solution). • Prime line with 1 mL of solution. • Run the remaining 8 mL of 2 mmol/mL solution at 32 mL/hr for 15 min.
Maintenance infusion	
1 g $MgSO_4$ (50% solution) per hour via infusion pump: • Remove 20 mL normal saline from the remaining flask and discard. Add 20 mL (10 g) of $MgSO_4$ (50% solution) to the remaining 380 mL flask of normal saline. • Infuse at 40 mL/hr via infusion pump. • Run maintenance for at least 24 hrs.	1 g $MgSO_4$ per hour via syringe pump: • Using a 50 mL syringe, draw up 49 mL of undiluted $MgSO_4$ (50% solution). • Prime line with 1 mL of solution. • Run the remaining 48 mL of 2 mmol/mL at 2 mL/hr for at least 24 hrs.

Key points:
- Use an infusion pump or syringe.
- Do not use IV line to inject other drugs.
- Check serum levels 1 hour after administration and 6-hourly thereafter.

Contraindications include:
- renal failure—$MgSO_4$ is eliminated in the renal system, so can reach toxicity in the presence of oliguria
- hypocalcaemic states
- cardiac condition, e.g. conduction or myocardial damage.

Should be used cautiously with other drugs that cause respiratory depression, e.g. diazepam, narcotics.
Considerations:
- May lower BP due to vasodilatory effects.
- May have tocolytic effect.
- May decrease FHR variability as decompression of CNS.
- May cause loss of reflexes.

(Source: NSW Health Department 2002)

Reflective exercise

Review the adult advanced life support skills in relation to altered maternal physiology.

1 Do you know how to elicit reflexes?
2 When did you last review the adult resuscitation trolley in your clinical practice time?

Control of hypertension

Anti-hypertensive therapy is an essential component in the treatment of severe PE/eclampsia. It controls severe hypertension and helps to protect the mother from cerebral haemorrhage. However, it is important not to decrease the blood pressure (BP) too quickly or by too much, as this may further reduce placental perfusion. Once the systolic BP reaches ≥ 170 mmHg and the diastolic BP ≥ 110 mmHg, antihypertensive therapy is begun. The aim is to decrease the systolic BP by about 20–30 mmHg and the diastolic BP by 10–15 mmHg. A rapid and precipitous decrease in the BP as result of antihypertensive drugs should be avoided because of the risks of further fetal compromise in babies that are often already growth-restricted. Hydralazine is known to be effective in controlling hypertension in severe PE/eclampsia. After an IV bolus dose of 10 mg over 20 minutes by slow IV infusion to a maximum of 60 mg, effects are seen by 10 minutes and reach maximum levels within a further 10 minutes. Its duration is six to eight hours. Side-effects include hypotension, tachycardia, tremor, headache, nausea and vomiting (often signs that herald the onset of eclampsia). In some countries, including New Zealand, labetalol is being used more frequently in the management of hypertension in pregnancy (the drug is not available for IV use in Australia). Its onset of action is more rapid than hydralazine, and reflex tachycardia does not occur. The typical regimen is: an initial dose of 50 mg IV (over two minutes). If necessary it is repeated every 10–20 minutes to a maximum of 300 mg. It can also be administered as an infusion at 2.0 mg/hr, increasing by 0.5 mg/hr as required (2–20 mg/hr is usually necessary).

Fluid balance

Severe PE/eclampsia is associated with high peripheral resistance, haemoconcentration, reduction and central distribution of plasma volume and oliguria. However, routine volume expansion is not recommended because of the danger of precipitating pulmonary oedema. Iatrogenic fluid overload is a common cause of maternal death in severe PE/eclampsia. Maintenance fluids should be given to prevent maternal hypotension and fetal compromise, especially in the presence of oliguria. Nevertheless, severe hypotension and fetal compromise have been reported in eclamptic women given epidural analgesia or hydralazine without prior infusion of solutions. The Australasian Society for the Study of Hypertension in Pregnancy (ASSHP 2000) recommends a 500 mL fluid load for severe pre-eclamptics prior to antihypertensive therapy, epidural therapy or immediate delivery, or as part of the initial management of oliguria.

Delivery

The timing and place of delivery depend on the maternal and fetal condition. Referral to a regional centre for advice and/or assistance is crucial in all cases of severe PE or eclampsia, but each case should be considered on its clinical merits. Delivery by caesarean section or induction of labour may be appropriate. In eclampsia the definitive 'cure' is delivery. Nevertheless, it is inappropriate to deliver a physiologically unstable mother even if there is evidence of severe fetal compromise. Once the seizures have been controlled and hypertension treated, delivery can be expedited. It is often necessary to admit the woman to an ICU. Best practice demands that a collaborative, multidisciplinary team, including obstetricians, midwives, anaesthetists and paediatrician, work with all women who have eclampsia.

Management of eclampsia

More than 50% of eclamptic seizures occur outside the hospital environment. It is therefore essential for all clinicians to be competent to deal with severe PE and eclampsia. The principles of management include the following:

- **ABCs—airway, breathing, circulation**
  - Do not leave the woman alone.
  - Protect from harm.
  - Obtain help.
  - Assess, maintain patency of airway.
  - Apply oxygen via Hudson mask (8 L/min).
  - Evaluate pulse and BP.
  - If absent, initiate CPR and call arrest team.
  - Secure IV access as soon as possible.
- **Control seizures**
  - $MgSO_4$—loading and maintenance dose
  - Monitor
    - urinary output
    - respiratory rate, oxygen saturation and patellar reflexes, initially every 10 mins, then 30 mins
    - Check serum magnesium levels at least daily if infusion is continued for > 24 hrs
  - Stop infusion: check $MgSO_4$ levels and review with specialist team if:
    - urine output < 100 mL in 4 hrs
    - *or* patellar reflexes are absent
    - *or* respiratory rate < 16 bpm
    - *or* oxygen saturation < 90%
    - Antidote 10% calcium gluconate 10 mL IV over 10 mins.
- **Control hypertension**
  - Treat hypertension if systolic BP ≥ 170 mmHg or diastolic BP ≥ 110 mmHg
    - hydralazine
    - labetalol
- **Deliver**
  - 'Stabilise' the mother before delivery.

Critical thinking exercise

Significant findings from midwifery assessments

Midwives are in a good position to detect the early signs of obstetric risks. What might be the significance of the following findings from a midwifery assessment?

- oliguria < 30 mL/hr
- significant change in maternal vital signs
- diastolic BP 110 mmHg or higher
- seizure activity
- severe epigastric or upper right quadrant pain
- altered mental status
- signs of pulmonary oedema
- abnormal laboratory results.

- Delivery is a team effort.
- Ergometrine should not be used in the presence of PE or eclampsia.
- Consider prophylaxis against thromboembolism.
- Maintain vigilance, as most seizures occur after birth.

- **Ongoing care**
  - **Observations**
    - pulse oximeter, BP, respirations, temperature
    - ECG
    - test urine for protein
    - hourly urine output
    - strict fluid balance chart
    - continuous EFM
  - **Investigations**
    - FBP, platelets and urea and electrolytes
    - urate, liver function tests
    - coagulation screen
    - group, hold and serum
    - MSSU
    - 24-hour urine collection for total protein and creatinine clearance and catecholamines.

Further study

1. Visit sites designed for women with complications in pregnancy, such as:
   - Pre-eclampsia site, http://www.pre-eclampsia.co.uk/
   - Action On Pre-eclampsia http://www.apec.org.uk
2. Use a search engine such as PubMed, HighWire at: http://highwire.stanford.edu/ or Ovid, to study pre-eclampsia and eclampsia in more depth.
3. Compare and contrast clinical guidelines on management of pregnant women with hypertensive disorders.

Summary: eclampsia

Eclampsia remains a major, albeit rare, cause of maternal and perinatal morbidity and mortality in Australia and New Zealand. It is often associated with other morbidity, such as preterm birth. The relationship between the onset of pre-eclampsia and eclampsia is not fully understood. Despite successful identification of women at risk of PE or eclampsia during pregnancy, it is clear that not all cases can be prevented. Optimal emergency management of seizures, hypertension, fluid balance and subsequent safe transfer is essential to minimise morbidity and mortality. It is essential that midwives ensure that, irrespective of the place of birth, they are competent and confident to manage an eclamptic seizure until help arrives.

Rupture of the uterus

Rupture of the uterus is one of the most serious complications of pregnancy, and can be fatal for the fetus. The incidence of uterine rupture is 1:1148 to 1:2250 deliveries (DeCherney & Nathan 2003). The term 'uterine rupture' is used to describe trauma to the uterus in a continuum of events, from a 'weak' spot in the uterine wall noticed by the obstetrician at the time of a caesarean section to the catastrophe of the uterus rupturing so that the fetus and placenta are expelled into the peritoneal cavity.

Classification

There are two types of uterine rupture, complete and incomplete, distinguished by whether or not the serosa is involved. In a complete rupture, the entire thickness of the uterine wall and usually the overlying broad ligament rupture, so the uterine contents, including fetus and occasionally the placenta, extrude into the peritoneal cavity. Occult or incomplete rupture refers to dehiscence of a surgical wound, where the visceral peritoneum stays intact and the fetus and placenta remain inside the uterine cavity. The complete variety is the rarer and more dangerous of the two. Uterine rupture most often occurs in the lower uterine segment, with the most common site of rupture being the anterior uterine wall. Longitudinal rupture of the lateral wall is also relatively common and may extend upwards into the fundus of the uterus or downwards into the vagina. Posterior ruptures are the least common and are usually transverse. Rupture of the uterus during labour is more dangerous than that occurring in pregnancy, because shock is greater and infection is almost inevitable.

Risk factors

Uterine rupture may develop as a result of pre-existing injury such as a scar from uterine surgery, perforation or anomaly. It is also associated with trauma, or it may complicate labour in a previously unscarred uterus. In developing countries, uterine rupture is most often caused by obstructed labour related to CPD, grandmultiparity and malpresentation. In

contrast, in developed countries the most common cause of uterine rupture is dehiscence of a previous caesarean section scar. Injudicious use of oxytocin and traumatic rupture from obstetric manipulative procedures such as internal podalic version are also contributing factors.

Other associations include:

- caesarean section
- induction of labour
- uterine anomalies
- trauma (e.g. MVA)
- use of rotational forceps
- cervical laceration
- manual removal of the placenta (placenta percreta and increta)
- conditions causing overdistension of uterus:
  - hydramnios
  - macrosomia
  - multiple pregnancy
  - choriocarcinoma.

Presentation

In developing countries, where spontaneous rupture usually follows an obstructed labour, the clinical presentation is characterised by sudden, severe pain and vaginal bleeding (Ola & Olamijulo 1998). Cardiovascular collapse often occurs if the rupture involves major blood vessels. Cessation of uterine contractions accompanies the rupture. On clinical examination the contours of the uterus may change, especially if the fetus is only partially extruded. If it is completely extruded into the peritoneal cavity, the fetal parts are easily palpable but the fetal heart tones cannot be heard. Haematuria suggests that the bladder is also involved in the rupture.

In developed countries, the presentation may not be so dramatic because the rupture usually occurs during labour along a previous uterine scar. Moreover, it is most unlikely that the woman has had to endure many hours of obstructed labour before her uterus ruptures. There may, however, be no signs and symptoms associated with a rupture of a low cervical scar during labour.

When the uterus spontaneously ruptures during labour, the typical features are suprapubic pain and tenderness, cessation of uterine contractions, absence of fetal heart sounds, recession of presenting parts and vaginal haemorrhage. This may be followed by signs and symptoms of hypovolaemic shock and haemoperitoneum. In some cases labour may progress to vaginal birth with a live neonate. Ultrasound may show abnormal fetal position or extension of fetal extremities or haemoperitoneum. If there is any doubt about the diagnosis, a laparotomy is essential, especially in the presence of persistent haemorrhage and shock that cannot be attributed to other causes and does not abate following the administration of oxytocics drugs and treatment for shock.

Clinical point

Following uterine rupture, in more than 75% of cases, signs of fetal distress will appear before pain or bleeding. Prolonged, late or variable decelerations and bradycardia seen on FHR monitoring are the most common—and often the only—manifestation of uterine rupture.

Clinical point

Intrapartum or postpartum collapse can occur because of uterine rupture, sepsis, uterine inversion and amniotic fluid embolism.

Management

In all cases of operative delivery, especially where there are significant risk factors for uterine rupture, there should be a careful examination of the uterus and birth canal for evidence of trauma. Once the diagnosis of a rupture is made, resuscitation following the guidelines described later in this chapter is the first priority. Provided the woman gives her consent, hysterectomy is the preferred treatment, especially if the rupture is extensive or in the presence of infection. However, where future childbearing is important, and depending on the facilities available, the skill of the surgeon and the extent of the rupture, a laparotomy and attempted rupture repair may be feasible. There is an increased risk of a repeat rupture in subsequent pregnancies.

Trauma in pregnancy

Major trauma in pregnancy is a relatively uncommon event. Management of the pregnant woman in trauma poses specific challenges often beyond the realm of midwifery or obstetric care. In part this is because it is such an uncommon experience for most midwives and obstetricians. Similarly, Emergency Department staff may not be aware of the normal maternal and fetal physiology and the woman's anatomical and physiological adaptations to pregnancy. These may mask or mimic injury or mean that physical signs are misinterpreted.

Normal clinical and laboratory findings in pregnant women may be suggestive of pathology in non-pregnant women. It is crucial for clinicians (trauma specialists, obstetric staff and midwives) to work collaboratively to establish safe and effective protocols for monitoring and treating the mother and the fetus. The following section provides an overview of the risks of trauma in pregnancy, its effects on the mother and fetus, and the management of trauma in pregnant women. It concludes with an overview of the skills required in cardiopulmonary resuscitation of pregnant women.

Trauma and maternal and neonatal mortality

Although it is a relatively uncommon event, occurring in less than 1% of all trauma admissions to Australian hospitals, trauma remains a leading cause of morbidity and mortality in young pregnant women and their babies (Sugrue et al 2004). According to the 2004 AIHW report, *Maternal Deaths in Australia 1997–1999* (Slaytor et al 2004), of the 90 deaths reported to the National Advisory Committee on maternal mortality, 28 deaths were classified as being from incidental causes. These are maternal deaths that result from a condition occurring during pregnancy, where the pregnancy is unlikely to have contributed significantly to the death, although it may be possible to postulate a distant association. Seven of these involved traffic accidents and two were the result of homicide (p 52). Of particular concern for midwives because of their role in parent education is that of the five deaths involving motor vehicles, alcohol and cannabis were contributing factors in three accidents; and three women were not wearing seatbelts at the time of the accident.

Fetal death associated with trauma in pregnancy affects about 0.03% to 0.09% of pregnancies (Warner et al 2004, p 125). Few studies provide data on pregnant women with trauma that can be used to direct management decisions. A 1991 US retrospective study (Esposito et al 1991) found that of 79 pregnant women who were admitted to a trauma centre during a nine-year period, the maternal mortality was 10%, which was similar to the rate for non-pregnant females. Overall, the rate of fetal death was 34%. These rates were no different between women with or without evidence of shock and/or hypoxia, or between women who were or were not wearing seat belts in motor vehicle accidents.

Trauma in pregnant women: morbidity, incidence and causes

In the United States (as in Australia and probably New Zealand), although less than 1% of admissions to hospital for trauma are pregnant, trauma complicates about 7% of all pregnancies and is the leading non-obstetric cause of maternal and fetal morbidity and death. Motor vehicle accidents, family violence and falls are the most common causes of blunt trauma in pregnancy (Shah et al 1998). Almost 60% of trauma in pregnant women is intentional (Shah et al 1998). It is difficult to ascertain precise rates of pregnant women who present to emergency departments following trauma. In Western Australia, Royal Perth Hospital, a tertiary-level hospital, maintains an electronic trauma registry (Warner et al 2004, p 126). From July 1994 until August 2002, 3383 women of reproductive age were entered in the register and 34 were known to be pregnant. The baseline characteristics of these women are listed in Table 36.3.

The clinical outcomes are listed in Table 36.4. None of the women had a ruptured uterus. The four women admitted following a motor vehicle accident and experiencing uterine contractions did not go on to have a preterm birth.

Risk of trauma in pregnancy

The pattern of major injuries in pregnant women is different from that in non-pregnant women: trauma to the abdomen is more common than injuries to the head and chest. Given that up to 24% of all pregnant women experience family violence (Commonwealth Fund 1999), the likelihood of domestic

assault should always be borne in mind, especially when the observed injuries are inconsistent with their alleged cause. The rate of fetal mortality after blunt trauma is 3.8–38%, mostly from abruption, maternal shock and maternal death (Grossman 2004, p 1303). The risk to pregnancy in 'minor' or non-catastrophic trauma is still significant, with preterm labour occurring in 8%, placental abruption in 1%, and fetal death in 1%. For those with major trauma, maternal mortality is about 9% and the fetal death rate is 20% or greater (Sugrue et al 2004).

Fetal injury or death can still happen even if the mother has incurred no apparent abdominal injury. About 5% of fetal injuries occur without apparent trauma to the mother, often from complications associated with maternal hypoxia and shock. Irrespective of the apparent severity of the injury, all pregnant women should be evaluated in a medical setting.

Physiological changes in pregnancy

See Table 36.5. The non-pregnant uterus is thick-walled but loses this protection as it expands out of the pelvis during pregnancy from about 12 weeks gestation. By the second trimester the growing fetus is protected somewhat by amniotic fluid. By the third trimester the uterus is thin-walled, and by the 36th week of pregnancy the head may engage in the pelvis. When full, the bladder also becomes an abdominal organ. An increase in heart rate and stroke volume leads to an increase in cardiac output by about 50% in pregnancy. Blood volume has increased by as much as 50% by the 28th week of gestation. The protective effects of hypervolaemia allow the woman to lose up to 30% (1500 mL) of her circulating blood volume before signs associated with hypotension appear. However, it is not uncommon for a pregnant woman to have what is often called 'low blood pressure'—perhaps 80/40 mmHg in early pregnancy, although late in the second trimester the blood pressure returns to 'normal levels'.

BOX 36.6 Trauma in pregnancy

Unique problems of the pregnant woman with trauma

- The placenta is devoid of elastic tissue but the myometrium is very elastic, predisposing to shearing.
- From 16 weeks gestation, abruptio placenta is the most common result of blunt injury.
- Following trauma, the most common cause of preterm labour is abruptio placentae.
- Fetal skull injury is the most common fetal injury, with a mortality rate of 42%.
- After 12 weeks gestation, the bladder is displaced upward and forward by the enlarging uterus, leading to an increased risk of bladder injury from blunt or penetrating trauma.
- Because of the enlarging uterus, the diaphragm rises by about 4 cm and the diameter of the chest enlarges by about 2%. The trachea is displaced to the right. Upward displacement of the diaphragm and viscera decreases chest compliance and ventilation and makes chest compression in CPR more difficult.
- As pregnancy progresses, there is a decrease in the functional residual capacity of the lungs, coupled with a 20% increase in oxygen consumption, making women more prone to hypoxia. Further, 30% of pregnant women have airway closure during normal tidal ventilation if they are placed in a supine position. All these alterations predispose pregnant women to a rapid decrease in maternal PaO_2 during periods of apnoea or airway obstruction.
- Changes in the gastrointestinal tract and increased levels of progesterone make pregnant women more prone to regurgitation of gastric contents and Mendelson's syndrome.
- Enlarged breast tissue also makes chest compression more difficult.

Maternal posture and haemodynamics

In the third trimester, the heavy gravid uterus compresses the descending aorta and the inferior vena cava. This results in a greater tendency for pooling of venous blood in the lower limbs, decreasing venous return from the heart, a fall in cardiac output and hypotension. One of the first signs of supine hypotension is often a non-reassuring FHR caused by decreased uteroplacental perfusion. If the woman is supine, cardiac return may be reduced by as much as 30% (Fig 36.12). This affects the mother's cardiac output. It is therefore important to tilt the pregnant woman to the left by about 30 degrees and it may be necessary to manually displace

TABLE 36.5 Physiological changes in pregnancy

	Non-pregnant	Pregnant
Cardiovascular		
Pulse	70–80 bpm	up by 10–15 bpm
Cardiac output	4.5 L/min	up to 6.7 L/min
Systolic blood pressure	110 mmHg	down by 5–15 mmHg
Haematological		
Blood volume	4000 mL	up by 30–50%
Plasma	2400 mL	up to 3700 mL
RBC volume	1600 mL	up to 1900 mL
Haemoglobin	120–160 g/L	down to 100–140 g/L
Respiratory		
Tidal volume	500 mL	up by 25%
Functional residual volume	1200 mL	down by 25%
Gastrointestinal		
Intra-abdominal pressure	normal	increased
Gastric emptying	normal	decreased

(Source: Sugrue et al 2004)

the uterine fundus to the woman's left. However, it should be remembered that airway control and efforts to reduce the risk of supine hypotension must be balanced against the need to stabilise the cervical spine. The woman should be tilted as an entire unit, maintaining stabilisation of the cervical spine (Sugrue et al 2004).

Management

When confronted with an injured pregnant woman, the mother is always attended to first. There are two patients with separate needs. The goals of management are to:

- identify and meet the needs of the pregnant woman
- identify and meet the needs of the fetus.

The important rule to remember is: 'What is good for the mother is good for the fetus'. Optimal care of the mother optimises fetal outcomes. However, an apparently stable mother may be compensating at the expense of the fetus.

Assessment

The following plan for maternal assessment follows guidelines set out by the Early Management of Severe Trauma (EMST®) / Advanced Trauma Life Support (ATLS®) approach to trauma, with detailed primary and secondary survey (assessments) (Fig 36.13). It outlines a systematic approach to initial stabilisation.

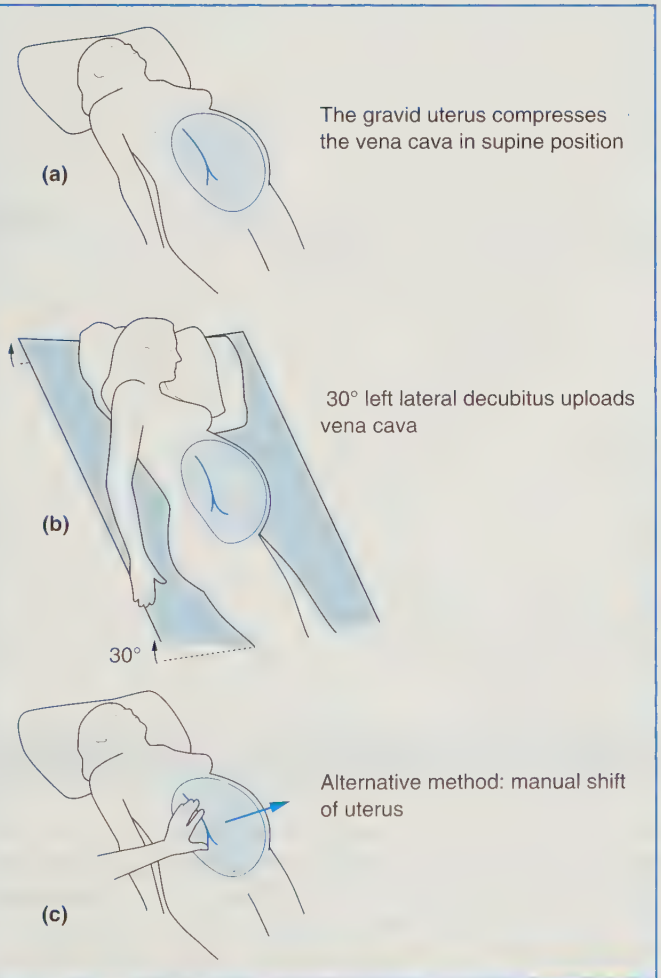

Figure 36.12 Management of supine hypotension

Primary survey

The purpose of the primary survey is to diagnose immediate life-threatening conditions. These should be treated as soon as they are discovered, before continuing the survey. As with any other injured person, the primary survey addresses the airway, cervical spine control, breathing and circulation, volume replacement/haemorrhage control, as well as assessment of conscious state and environmental injury. Once the ABCs have been achieved, an assessment of fetal wellbeing is conducted. An electronic trace of the FHR is usually started if the woman is more than 24 weeks pregnant, to detect fetal compromise and thus reduce the risk of unexpected fetal demise.

The survey is planned as follows:

- **A**irway control with cervical spine protection
- **B**reathing
- **C**irculation and control of haemorrhage
- **D**isorders of the central nervous system
- **E**xposure of the whole body.

During the course of the primary survey, any deterioration in the woman's clinical condition should be managed by reassessing from the start of the protocol, as a previously undiagnosed injury may become apparent. Supplemental oxygen is essential to prevent and treat maternal and fetal hypoxia. Severe trauma stimulates maternal catecholamine release, which causes uteroplacental vasoconstriction and compromised fetal circulation. Prevention of aortocaval compression (supine hypotension) optimises maternal and fetal haemodynamics. Hypovolaemia should be suspected before it becomes apparent, because relative pregnancy-induced hypervolaemia and haemodilution may mask significant blood loss. Aggressive volume resuscitation is encouraged even for normotensive women; however, care needs to be taken to ensure that the woman does not develop pulmonary oedema. A pneumatic anti-shock garment (PASG) may be used to stabilise lower extremity fractures and perhaps control

Clinical point

If the mother is haemodynamically compromised, so is the blood supply to the fetus, which rapidly becomes hypoxic and acidotic. Return of blood to the mother's heart may be impaired by the uterus pressing against the inferior vena cava and so circulation must be restored. Consequently, the key to resuscitation of the fetus is resuscitation of the mother. The mother cannot be resuscitated until blood flow to her right ventricle is restored, and therefore prevention of supine hypotension caused by the gravid uterus pressing on the mother's major blood vessels must be prevented.

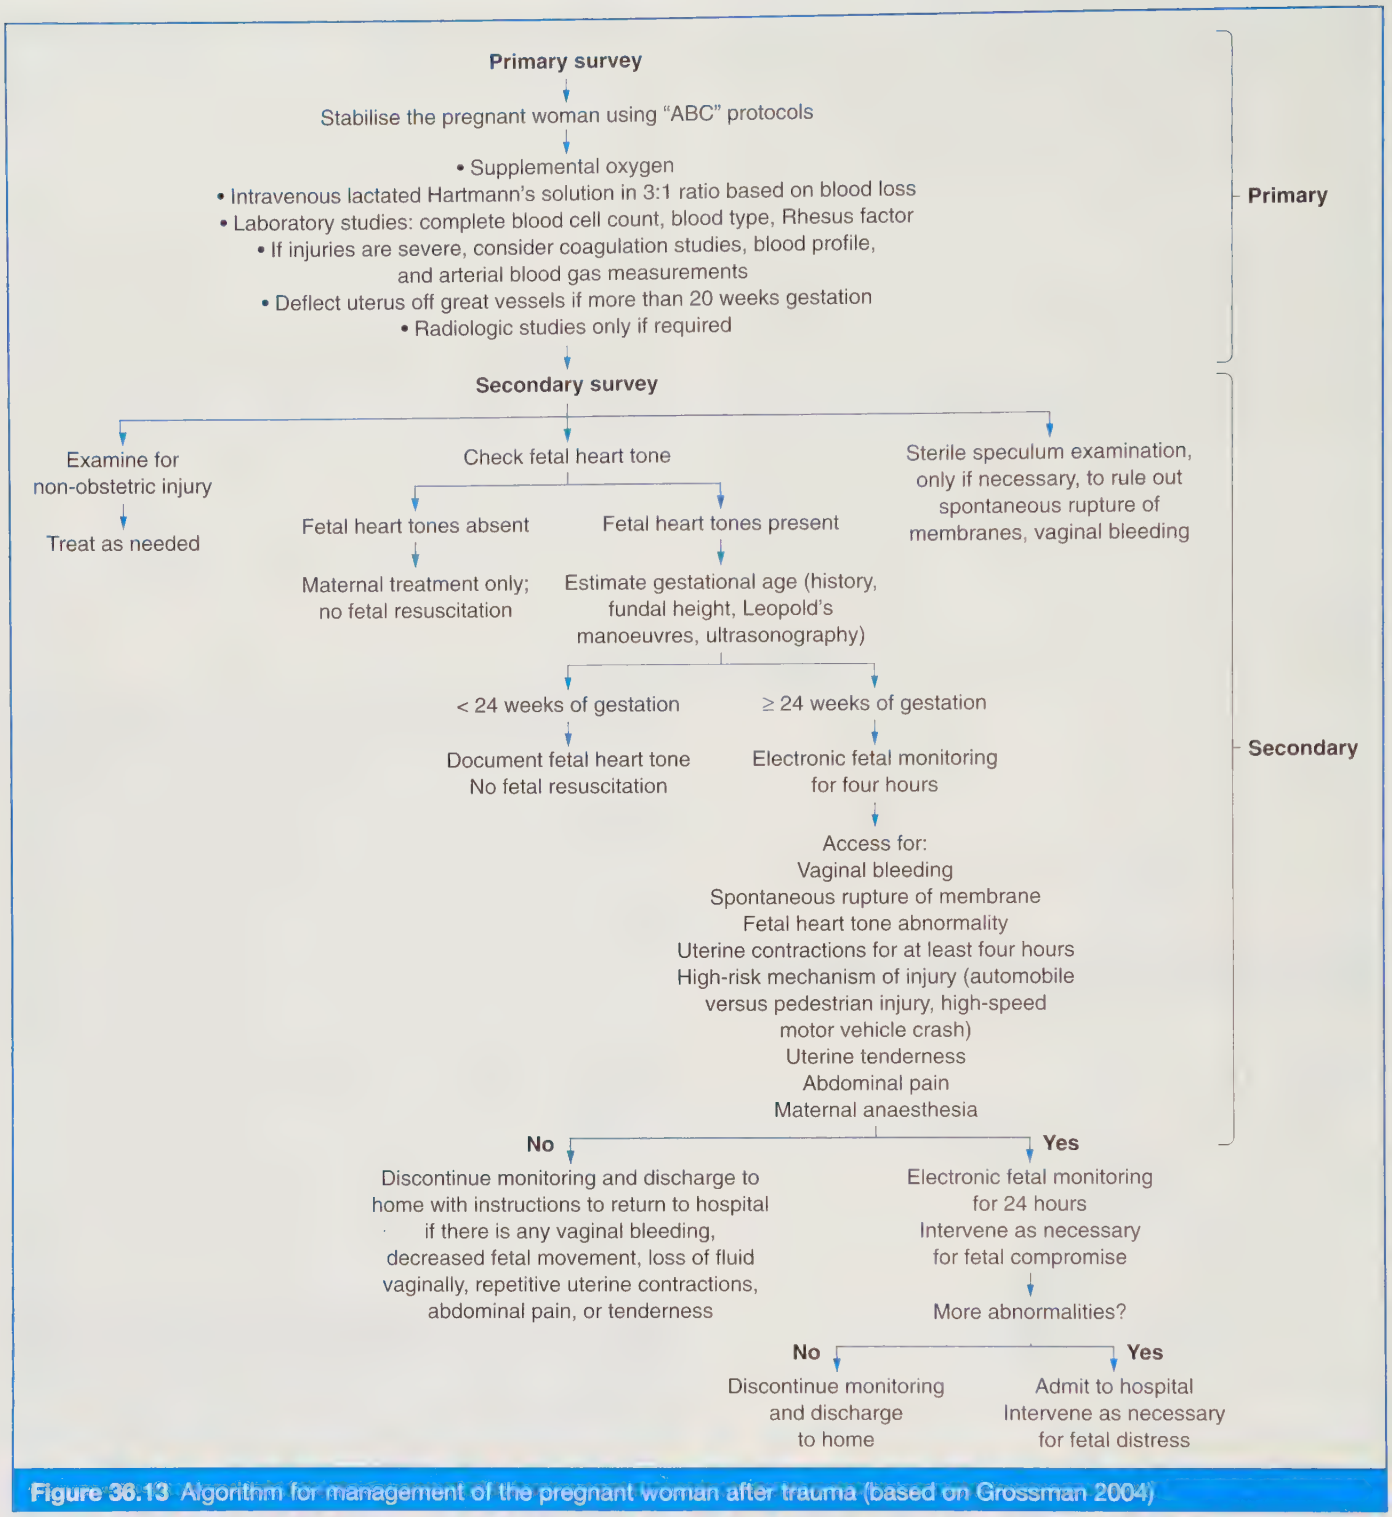

Figure 38.13 Algorithm for management of the pregnant woman after trauma (based on Grossman 2004)

haemorrhage; however, in the pregnant woman, inflation of the abdominal compartment of the PASG should be avoided because it compromises uteroplacental blood flow.

Secondary survey

The secondary survey—detailed assessment—only begins when the primary survey has been completed and immediate life-threatening injuries addressed. Following the initial survey and resuscitation, the woman should undergo a thorough secondary survey with the aim of documenting any other injuries. At the same time, the basics of the primary survey (airway, breathing and circulation) are continually reassessed to detect any unexpected deterioration. The secondary survey consists of obtaining a complete history, including

an obstetric history, performing a physical examination, and evaluating and monitoring the fetus. It may be necessary at this stage to place the woman on her back for a short time to assess hidden injuries. The obstetric history is important because co-morbidities such as threatened preterm labour or antepartum haemorrhage predispose the woman to a recurrence of these complications. The obstetric history includes the date of the last menstruation, expected date of birth and any problems or complications of the current and previous pregnancies. Determination of the uterine size provides an approximation of gestational age—measurement of fundal height is a rapid method for estimating fetal age.

Determination of fetal viability, age and fetal maturity are important factors in decisions regarding the need for early delivery. Decisions about fetal viability are made on the basis of the best estimate of gestational age available. When estimating the fetal age in the resuscitation area or a non-obstetric setting, a rough guide might be that when the fundus of the uterus extends beyond the umbilicus, the fetus is potentially viable. Ultrasonography is the most accurate way of determining gestational age.

Aside from the usual secondary survey, assessment of the injured pregnant woman are performed to rule out vaginal bleeding, ruptured membranes and the presence of contractions or other signs of the onset of labour, and identify the FHR and rhythm. The physical examination includes assessment and reassessment of uterine size and tone. Provided there is no evidence of placenta praevia, a vaginal examination is performed to detect the presence of blood, liquor, cervical changes and the station of the fetus in the pelvis.

The AMPLE history is a good way to remember to ask the right questions during the secondary survey:

A History of allergies
M Medication history
P Past medical, surgical and obstetric history (including the current pregnancy)
L Time of the last meal
E Events leading up to injury and hospital admission.

Cardiotocographic monitoring

Controversy still exists about the ideal duration of fetal monitoring following a traumatic event needed to identify trauma-related fetal problems. A CTG is, however, the current standard of post-trauma care for all viable fetuses. The objectives of the monitoring period are to look for the onset of labour, placental abruption and fetal compromise. A combination of high-resolution real-time ultrasonography and CTG monitoring has the highest sensitivity and specificity. Both should be instituted as soon as possible without interfering with maternal resuscitative efforts. Fetal evaluation begins with checking FHR and noting fetal movement. This should be done late in the primary survey or early in the secondary survey and repeated regularly. CTG enables prompt identification of the fetus at greater risk for asphyxia and fetal death. A non-reassuring FHR pattern may be the first sign of maternal haemodynamic compromise.

Any viable fetus of 24 or more weeks gestation requires monitoring after a trauma event. This includes women with no obvious signs of abdominal injury, because direct impact is not necessary for feto-placental pathology to be present. Monitoring is commenced as soon as possible after initial stabilisation because most placental abruptions occur shortly after trauma. Continuous electronic fetal monitoring is more sensitive in detecting a placental abruption than ultrasonography, intermittent monitoring, Kleihauer Betke test or physical examination. The midwife assesses:

- FHR (baseline rate, pattern, variability, accelerations, decelerations)
- Uterine activity (tone, contractions). If after four hours of monitoring there is less than one contraction in 10 minutes, the risk of further complications drops to baseline. The occurrence of more than eight uterine contractions per hour over four hours is associated with a 20% increase in the risk of an APH.
  - A minimum of four hours monitoring is recommended, even after minor abdominal trauma. This is because clinical signs and symptoms of abruption, such as vaginal bleeding, abdominal pain and tenderness, and uterine tenderness, are often absent.
  - Monitoring for 24 hours is suggested following major trauma or signs of obstetric decompensation, such as regular uterine contractions, vaginal bleeding, premature rupture of the membranes, or a non-reassuring FHR pattern.

Procedures for evaluating abdominal trauma

The preferred diagnostic procedures for evaluating abdominal trauma are, in order of priority:

1 ultrasound
2 DPL (diagnostic peritoneal lavage)
3 CT scan
4 laparoscopy
5 laparotomy.

Diagnostic peritoneal lavage is a procedure most midwives will not be familiar with. During DPL, the peritoneum is visualised directly; it is safe and accurate in pregnancy, especially if a supraumbilical, open technique is used to avoid injury to the gravid uterus. If CT scan is necessary, both oral and IV contrast media should be administered. Ultrasound is also a useful method of assessing the abdomen. However, it misses 50–80% of placental abruptions but, as Grossman points out, it rapidly and safely determines fetal heart tones, placental location, gestational age and amniotic fluid index (Grossman 2004, p 1307).

Radiation exposure

Following maternal stabilisation and assessment, and fetal evaluation, the extent of maternal and fetal injury is further evaluated with the help of specific diagnostic modalities. With good reason, physicians and midwives are concerned about the risks to a pregnant woman and her fetus from radiation exposure. It may, however, be necessary

to undertake comprehensive radiological assessment even though sensitivity to radiation is greater during intrauterine development than at any other time of life. The greatest risk to the fetus from radiation exposure (central nervous systems defects, microcephaly, growth restriction and childhood neoplasia, and death) is during the fourth and eighth weeks of gestation, a time of major organogenesis. Organs are less sensitive to radiation teratogenesis after the fifteenth week of gestation but growth restriction, central nervous system dysfunction and postnatal neoplasias may still occur.

Nevertheless, studies show that exposure of the fetus to less than 5–10 rad (radiation absorbed doses) causes no significant increase in the risk of congenital malformations, intrauterine growth restriction or miscarriage. Adverse effects from radiation exposure are unlikely at less than 5–10 rad. Grossman (2004, p 1308) quotes reports from some studies that indicate that the radiation dose from a plain AP chest X-ray is in general below 0.005 rad; a pelvic film < 0.2 rad, CT scan of the head < 0.05 rad; CT scan of the upper abdomen < 3.5 rad; and CT scan of the entire upper abdomen < 5.0 rad (depending on the trimester). Moreover, less than 1% of trauma patients are exposed to more than 3 rads (Grossman 2004).

Complications of trauma

The most common complication of trauma in pregnancy is uterine contractions and the onset of labour. Myometrial and decidual cells, damaged by contusion or placental separation, release prostaglandins, which stimulate uterine contractions. These may or may not be painful. Occasional uterine contractions are very common after trauma and in the vast majority of cases will resolve in a few hours, and therefore are not associated with adverse perinatal outcomes. Progression to true labour depends on the extent of uterine trauma, the amount of prostaglandins released, and the gestational age of the fetus.

Placental abruption

Grossman (2004, p 1309) comments that despite advances in trauma management, fetal and maternal mortality rates from traumatic injury have not declined. Prevention is therefore the key to increasing maternal and fetal survival. Both motor vehicle accidents and domestic assault are preventable causes of trauma in pregnancy. Even in countries where seatbelt use is compulsory, pregnant women have lower rates of seatbelt use than non-pregnant women.

Placental abruption after trauma occurs in 1% to 4% of 'minor' accidents and in up to 50% of 'major' injuries. Abruption can occur with little or no external signs of injury. Maternal mortality from abruption is less than 1%, but fetal death ranges from 20% to 35%. When present after trauma, vaginal bleeding is an ominous sign that is strongly suggestive of an abruption. The first-line test to confirm the presence of abruption is a transabdominal ultrasound, although it is less than 50% accurate. In general, CTG monitoring is more sensitive in picking up placental abruption by non-reassuring FHR pattern than ultrasound is by visualisation. Most cases of abruption become evident within several hours after trauma.

Feto-maternal haemorrhage

Feto-maternal haemorrhage (FMH), the transplacental haemorrhage of fetal blood into the normally separate maternal circulation, is a complication of trauma during pregnancy. The reported incidence of FMH after trauma is 8–30%. There is no real correlation between severity of trauma, gestational age and frequency and volume of FMH. Complications of FMH include Rh sensitisation in the mother, fetal anaemia, fetal atrial tachycardia and fetal death from exsanguination. FMH is most likely to occur after 12 weeks gestation, when the uterus rises above the pelvis and becomes more susceptible to direct trauma. FMH is detected by the Kleihauer Betke (KB) test. Estimation of the ratio of fetal to maternal cells enables calculation of the volume of fetal blood leaked into the maternal circulation. Unfortunately, the sensitivity of all the KB tests is relatively low. Therefore, all Rh-negative mothers who present with a history of abdominal trauma should receive one 300 μg prophylactic dose of Rh immunoglobulin within 72 hours of the trauma. As a general rule, 300 μg of Rh immunoglobulin should be given for every 30 mL of fetal blood found in the maternal circulation.

Clinical point

In an emergency, the simplest action may be the most often ignored. Many cardiovascular problems associated with pregnancy are due to nothing more than anatomy interacting with gravity. The pregnant woman's uterus may press down against the inferior vena cava, reducing or blocking blood flow. The ensuing failure of venous blood return can produce hypotension and even shock. These potentially catastrophic complications are often preventable or easily remedied by tilting the woman to the left (see Fig 36.12) (American Heart Association 2000).

Perimortem caesarean delivery

If standard application of basic life support (BLS) and advanced cardiac life support (ACLS) fail and there is some chance that the fetus is viable, the goal is to deliver the fetus within four to five minutes after the onset of cardiac arrest. Perimortem caesarean delivery is rarely required, but is performed on the woman who has a viable fetus where maternal resuscitation is unsucessful. A few cases of maternal survival after delivery of the fetus during unsuccessful cardiopulmonary resuscitation (CPR) have been reported, probably because delivery of the fetus increases maternal perfusion. It is also possible to commence trans-abdominal cardiac massage or, if the chest wall is opened, open-chest cardiac massage (OCM). Delivery improves thoracic compliance, which improves the efficacy

Reflective exercise

The following phrases are all in common use in the literature and in many accident and emergency units and maternity hospitals:

'postmortem caesarean section'
'perimortem delivery'
'sacrifice mother/child' or 'save mother/child'
'harvest the fetus'
'empty the uterus'.

1 Think about what they mean to us (as healthcare professionals) and to women and their loved ones. Imagine how it would be for you if a doctor asked you to consent to a perimortem caesarean on your baby.
2 Can you think of any other phrases that will ensure that everyone understands the meaning but do not demean or diminish women and their grief over the death of their baby?

of chest compressions and the ability to ventilate the lungs. According to the 'four-minute rule', if maternal resuscitation is unsuccessful after four minutes of CPR, the fetus should be delivered by the fifth minute. CPR is continued throughout the procedure and afterwards, in a final effort to improve the maternal and perinatal survival rate.

Resuscitation in pregnancy

Cardiac arrest occurs about once in every 30,000 pregnancies, and maternal and fetal survival from this catastrophic event is rare. The anatomical and physiological changes of pregnancy described earlier in this chapter militate against successful maternal resuscitation. Every maternity care provider, irrespective of their place of work, has a duty of care to the woman in need of resuscitation and should therefore be competent in BLS and ACLS.

Table 36.6 lists the recommendations for advanced life support from the American Heart Association (2000). The AHA paper states unequivocally that there are no changes to

TABLE 36.6 Recommendations for advanced life support in obstetrics

ACLS approach	Modifications to standard BLS and ACLS guidelines
Primary ABCD survey	***A**irway* No modifications ***B**reathing* No modifications ***C**irculation* Chest compressions are ineffective when a woman in her last trimester lies on her back because the gravid uterus blocks the return of blood from the inferior vena cava. Start chest compressions after placing the woman on her left side with her back angled 30° to 45° from the floor. *or* Start chest compressions after placing a wedge under the woman's right side (so that she lies on her left side). *or* Have one rescuer kneel next to the woman on her left side and gently pull the gravid uterus laterally to relieve pressure on the inferior vena cava. ***D**efibrillation* No modifications. Defibrillatory shocks transfer no significant current to the fetus in utero.
Secondary ABCD survey	***A**irway* No modifications to intubation techniques ***B**reathing* No modifications to secondary confirmation of successful intubation. A gravid uterus is known to push up the diaphragm and therefore decrease ventilatory volumes and make positive-pressure ventilation difficult. ***C**irculation* Follow standard ACLS recommendations for administration of all resuscitation medications. ***D**ifferential diagnosis and decisions* Decide whether to perform emergency caesarean section.

(Source: American Heart Association 2000)

Clinical scenario

At 0300 the ambulance brings a 35-year-old pregnant woman into the resuscitation room of the Emergency Department at your Level II hospital following cardiac arrest of almost four minutes duration. Full basic life support has been present since arrest; initial application of advanced protocols has not re-established circulation. You are the most experienced person on duty. You know that a perimortem emergency caesarean section could be life-saving for either fetus or mother. What are you going to do, when and why? What if you are unable to obtain consent from the next of kin in time?

the standard ACLS algorithms for medications, intubation and defibrillation. A pregnant woman in cardiac arrest is assessed and treated by using the Primary and Secondary ABCD Surveys of ACLS as modified for the pregnant woman. It is important that clinicians consider a wide variety of possible causes of arrest, such as amniotic fluid embolism, magnesium sulfate toxicity, and mishap in patients who have received spinal anaesthesia, as well as drug overdose, drug abuse, medication toxicity and iatrogenic events (American Heart Association 2000).

Postpartum haemorrhage

Postpartum haemorrhage (PPH) is defined as excessive blood loss occurring after the birth of the baby and is a potentially life-threatening emergency. Until recently, in Western countries, the incidence of maternal mortality caused by PPH has decreased due to improvements in early detection and treatment. In most cases PPH occurs in the immediate postpartum period (within 24 hours after birth and known as a primary PPH) and is due to uterine atony. Without immediate and proper medical attention, a woman with PPH may die.

Definition

There are numerous definitions of PPH in the literature. The most widely recognised is blood loss after childbirth in excess of 500 mL. Because it is often difficult to accurately measure blood loss, the true incidence of PPH may be underestimated by up to 50%. Consequently, the usefulness of 'traditional' definitions of PPH is now being questioned. Careful quantification of blood loss shows that many women bleed more than 500 mL and the blood loss following a caesarean section often exceeds 1000 mL (Shevell & Malone 2003). Clinical estimation of blood loss at childbirth is difficult because the blood mixes with amniotic fluid, urine and, if they are used, the solutions used to wash the vulval area before birth. In contrast to bleeding occurring after surgery, many clinicians in maternity settings do not routinely weigh pads, drapes and bed clothes in order to obtain an accurate estimation of blood loss. Further, the immediate post-birth period is a time when the parents want to be alone with their newly born infant and so it is difficult for the midwife to continue vigilant assessments without being intrusive. Analysis of 'avoidable factors' in reports such as *Maternal Deaths in Australia* (Slaytor et al 2004) and the UK *Confidential Enquiries into Maternal and Child Health* (RCOG 2002) show that midwives sometimes fail to appreciate the significance of slow, steady, blood loss over some hours until a massive PPH has occurred. When estimating the amount of postpartum blood loss, it is not sufficient to check the perineal pad; it is important that the midwife ask the woman to move or roll onto her side so that she can check for pooling of blood. As the amount of blood loss increases, estimates of the extent of the haemorrhage tend to be even less accurate. Given the relative hypervolaemia of pregnancy, the clinical signs of haemorrhage and shock, such as hypotension, tachycardia and oliguria, may not appear until the woman has lost over 1500 mL—that is, just before she becomes haemodynamically unstable.

BOX 36.9 Maternal death and PPH

The truth about maternal death and PPH

Worldwide:

- 515,000 women die during pregnancy and childbirth every year.
- 99% of maternal deaths occur in developing countries.
- 130,000 women bleed to death each year while giving birth.
- two-thirds of women with PPH have no identifiable risk factors.
- 90% of cases of PPH are due to uterine atony.

The majority of these deaths occur in:

- Sub-Saharan Africa (25%)
- West Africa (27%)
- Indonesia (45%).

BOX 36.10 Definition of PPH

Definition of postpartum haemorrhage:

- Blood loss of ≥ 500 mL during and after childbirth.
- A primary PPH occurs within the first 24 hours after birth.
- A secondary (late) PPH occurs from 24 hours to the first six weeks after birth.
- A severe PPH is defined as blood loss of ≥ 1000 mL or more.

A more clinically useful definition is that a PPH is any amount of blood loss post partum that causes haemodynamic compromise.

Incidence

The incidence of PPH worldwide ranges from 5% to 15% of all births. However, there is evidence that the incidence of PPH

is increasing, with both the United Kingdom and Australian reports on maternal deaths identifying a significant increase in direct maternal mortality from PPH, which is currently the leading cause of maternal deaths in Australia (CEMCH 2004; Slaytor et al 2004). According to Haynes et al (2004), in 2002 in Victoria, approximately 9.2% of women experienced a PPH. These rates are similar to those reported in published studies across Australia, in New Zealand, British Columbia and Nova Scotia. It is, however, higher than many North American centres (Haynes et al 2004).

In developed and developing countries, maternal mortality due to PPH is highest where there is inadequate access to skilled healthcare providers and transport and emergency services. Twenty-five per cent of all maternal deaths are caused by maternal haemorrhage. This is not surprising, considering that, on average, a woman will die within two hours after the onset of PPH if she does not receive proper treatment (e.g. appropriate drugs, blood transfusion or surgical intervention).

In 2004 the Victorian Government in Australia (Haynes et al 2004) initiated a review of morbidity caused by obstetric haemorrhage because it was so concerned about an alarming rise in the incidence of PPH (from 6.2% of all births in 1992–98 to 9.5% in 1999–2002). Between 1992 and 2002, nine Victorian women died as a direct result of obstetric haemorrhage and 132 women (0.05%) required hysterectomy as a life-saving measure (Haynes et al 2004).

Recently some possible risk factors have begun to emerge to explain the increase in PPH. These include the increased mean age of women in childbirth, advances in technology that enable women with complex medical problems to give birth, increasing multiple pregnancies with assisted reproductive technologies, and increased rates of Caesarean section leading to placenta praevia or accreta (CEMCH 2004). Nevertheless, as Haynes et al (2004) report, despite the identification of risk factors, PPH still occurs unpredictably in low-risk women. More than a quarter of women who experience an obstetric haemorrhage significant enough to require hysterectomy did not have any known risk factors (Haynes et al 2004).

The inclusion of haemodynamic compromise or shock is an important factor to consider in any definition of PPH, as some women will become compromised with a relatively small blood loss—for instance, women with pre-eclampsia or anaemia, women of small stature and those with socioeconomic disadvantage (Alexander et al 2002).

Haemorrhagic shock

Haemorrhagic shock can result in a combination of anaemic and ischaemic tissue hypoxia. Tissue hypoxia causes a progressive failure of cellular metabolism. Compensatory mechanisms and different oxygen requirements in various tissue beds cause a range of complications including organ damage, which may result in early or late multiple-organ dysfunction and death. Haemorrhagic shock may coexist with other types of shock; for example, after trauma septic shock (most often from wound contamination or genital infection) may occur.

Prevention

Prevention of PPH is a key component of risk minimisation for women. Antenatal screening of previous history and risk is important so that a plan of care can be discussed with the woman before birth. Antepartum anaemia should be checked and corrected during pregnancy. The authors recommend that in the antenatal period, all women be fully informed of the current evidence related to the benefits and risks of physiological versus active management of the third stage of labour.

Causes of PPH

The four major causes of primary PPH are commonly known as the 4Ts:

- Tone—uterine atony
- Tissue—retained placental tissue
- Trauma—genital tract trauma
- Thrombin—coagulopathies.

Table 36.7 lists the aetiology and clinical risk factors associated with each of the 4Ts.

Early recognition of PPH

Once the placenta and membranes are delivered, they should be checked carefully for completeness. Even if vaginal blood loss is minimal, the vaginal vault and perineum must be thoroughly inspected for bleeding points, and sutured if necessary. Haematomas should be evaluated and treated. All women must be closely observed post birth, particularly in the first hour, when PPH is most likely to occur. Uterine tone and position are monitored frequently and maternal pulse and blood pressure recorded and documented. Mild shock is usually preceded by tachycardia and a fall in BP. However, the

Clinical point

An empty and contracted uterus will not bleed (except where coagulopathy occurs). The finding of a 'boggy' uterus indicates that it is not well contracted and the blood vessels or 'living ligatures' are not compressed, resulting in excessive postpartum bleeding. The midwife's first action is to massage or 'rub up the fundus' until it is firm and contracted and pooled blood or clots are expelled.

A uterus that is not centrally located suggests that a full bladder has pushed the uterus to one side.

If the woman continues to bleed vaginally even though the uterus is contracted and centrally located, the cause of the haemorrhage is due to other factors—trauma, retained placental fragments or coagulopathy.

TABLE 36.7 Antenatal and intrapartum risk factors for PPH

Cause	Process	Clinical risk factors
Abnormalities of uterine contraction (TONE) 70%	Atonic uterus	Prolonged 3rd stage (> 30 mins)
	Over distended uterus	Polyhydramnios Multiple gestation Macrosomia
	Uterine muscle exhaustion	Rapid labour Prolonged labour (1st/2nd stage) or augmented labour Labour dystocia or incoordinate labour High parity
	Intra amniotic infection	Pyrexia Prolonged ROM > 24 hrs
	Drug-induced hypertonia	Magnesium sulphate, nifedipine, Salbutamol, general anaesthetic
	Functional or anatomical distortion of the uterus	Fibroids Uterine anomalies
Genital tract trauma (TRAUMA) 20%	Episiotomy or lacerations (cervix, vagina or perineum)	Labour induced or augmented Labour dystocia Malposition Precipitous delivery Operative delivery (vacuum or forceps)
	Extensions, lacerations at caesarean section	Malposition Deep engagement
	Uterine rupture	Previous caesarean section
	Uterine inversion	Strong cord traction in 3rd stage, especially with fundal position Short umbilical cord High parity Relaxed uterus, lower segment and cervix Placental accreta, especially fundal insertion Congenital uterine weakness or anomalies Antepartum use of magnesium sulphate or oxytocin
Retained product of conception (TISSUE) 10%	Retained products of conception Abnormal placenta Retained cotyledon or succenturiate lobe	Incomplete placenta at birth Placenta accreta or percreta Previous caesarean section or uterine surgery High parity Abnormal placenta (succenturiate lobe)
Abnormalities of coagulation (THROMBIN) 1%	Retained blood clots	Atonic uterus
	Coagulation disorders acquired in pregnancy Idiopathic thrombocytopenic purpura (ITP) Von Willebrand's disease Haemophilia or carrier Thrombocytopenia with pre-eclampsia Disseminated Intravascular Coagulation (DIC) Pre-eclampsia Dead fetus in utero	Bruising Elevated BP, HELLP Fetal death Pyrexia, WBC Antepartum haemorrhage (previous or current) Sudden collapse

TABLE 36.7 Antenatal and intrapartum risk factors for PPH—cont'd

Cause	Process	Clinical risk factors
Abnormalities of coagulation (THROMBIN) 1%—cont'd	Severe infection Abruption Amniotic fluid embolism	
	Therapeutic anti-coagulation	History of blood clot such as DVT

Research

Active versus expectant management in the third stage of labour (Cochrane Review, Prendiville et al 2000)

In 2000, Prendiville et al conducted a systematic review to assess the effects of active versus expectant management on blood loss, PPH and other maternal and perinatal complications of the third stage of labour. Expectant (physiological) management of the third stage of labour involves allowing the placenta to deliver spontaneously, or aiding it by gravity or nipple stimulation. Active management involves administration of a prophylactic oxytocic before delivery of the placenta, and usually early cord clamping and cutting, and controlled cord traction of the umbilical cord. 'Active management' is superior to 'expectant management' in terms of blood loss, PPH and other serious complications of the third stage of labour. Active management was, however, associated with an increased risk of side-effects such as nausea and vomiting, and hypertension, if ergometrine is used in the oxytocic. The authors concluded that 'active' management should be the routine management of choice for women expecting to deliver a baby by vaginal delivery in a maternity hospital. Of note is that the implications were less clear for other settings, including domiciliary practice (in developing and industrialised countries).

Reflective exercise

What would you say (and how would you say it) to a red-haired woman who is convinced that as a redhead she is much more likely to have a postpartum haemorrhage?

Clinical point

Retained placental fragments are a common cause of primary PPH and the most frequent cause of late haemorrhage. Retention of fragments is usually caused by partial separation of the placenta during massage of the uterine fundus prior to spontaneous placental separation. Following birth, the placenta and membranes should always be checked for completeness. Always look on the maternal side of the placenta for missing placental fragments or cotyledons. On the fetal side, blood vessels that traverse the edge of the placenta and then outwards into the membranes are suggestive of a succenturiate lobe.

altered haemodynamic state of pregnancy and immediately post birth can mask the signs of hypovolaemia even in the presence of large blood loss. Indeed, a woman may lose 1500 mL, almost a third of her total blood volume, before overt signs of shock become apparent. All women should be informed about the signs and symptoms of PPH and have strategies in place to detect primary and secondary PPH and to seek timely and appropriate assistance.

Management

The cornerstones of management of resuscitation following a PPH are:

- restoration of the blood volume and oxygen-carrying capacity
- stopping the haemorrhage.

Each maternity setting should have a clear local plan of action to deal with PPH, and all grades of staff should participate in obstetric haemorrhage 'drills' (CEMCH 2002). The first priorities are to identify the cause, seek help, and control the haemorrhage. Given that the vast majority of PPHs are caused by atonia, the midwife's first action is to check the tone and position of the uterus and, if necessary, massage it or 'rub up the fundus' to promote uterine contractions and control of bleeding. Uterotonic agents are administered as required (see Box 36.11). In most cases these measures will expel any blood clots, and the uterus then contracts and the

bleeding is controlled. If this is not the case, the midwife calls for help and commences resuscitation. Blood samples are taken for group and cross-match and two large-bore 14 G cannulae are sited. Crystalloid solutions (Hartmann's/normal saline) are infused at a rate of three times the measured blood loss. When estimating the required amount to infuse, it is important to remember that clinicians tend to underestimate blood loss at birth. Initial resuscitation with crystalloid and colloid infusions followed by blood transfusion is aimed at restoring systolic blood pressure and oxygen-carrying capacity. A urinary catheter is inserted into the bladder to ensure that a full bladder does not impede uterine contractions. A urine output of a minimum of 30 mL an hour indicates a functioning renal system and is a useful guide to the required amount of fluid to be infused. Some clinicians have suggested that if the baby is put to the breast this can stimulate the release of endogenous oxytocic; there is no evidence to support the efficacy of this intervention. If the uterus fails to contract, bimanual compression (Fig 36.14) is an effective method to initiate uterine contractions and stop PPH.

If on inspection there is no evidence of retained placental fragments or missing cotyledons, it may be necessary for a medical practitioner to perform a uterine exploration, preferably in an operating theatre and with adequate maternal analgesia. However, if the uterus is empty and well-contracted and there is no evidence of retained placental fragments, the most experienced clinician examines the genital tract and repairs cervical, vaginal and perineal lacerations. Uterine inversion and rupture are increasingly common causes of PPH. The former should always be suspected if the uterus is not palpable after the birth. This complication is dealt with later in the chapter. The diagnosis of uterine rupture is often only made when a well-contracted uterus does not stop bleeding. If bleeding persists despite the implementation of primary emergency measures, the woman's condition must be stabilised and then she is transferred to an operating theatre as soon as possible. Intractable haemorrhage requires a multidisciplinary team approach that focuses on the identification of cause, replacement of blood/clotting factors and surgery if all other measures fail. Manual removal of placenta (Fig 36.15) is associated with an increase in PPH and infection. Other life-saving surgery such as hysterectomy may be required.

Following a PPH the woman may develop disseminated intravascular coagulation (DIC) a potentially catastrophic complication. The laboratory diagnosis of acute DIC is based on prolongation of the prothrombin time, activated partial thromboplastin time, and thrombin time, due to consumption of clotting factors and inhibition of their function. A condition of thrombocytopenia may also exist, caused by the consumption of platelets. Increased titres of fibrin degradation products can be measured due to resultant fibrinolysis. This topic is considered in more detail later in this chapter.

Special case: women who decline blood products

Some women faced with an objective, informed and clear explanation of the need to use blood products in the advent of massive obstetric haemorrhage will consent to their use as a life-saving measure. Others do not consent to blood transfusions because of religious or cultural beliefs. The UK Confidential Enquiry into Maternal Deaths report of 2002 provides guidance for maternity care providers faced with this ethical dilemma. Management begins at booking, with open discussion and identifying and remedying anaemia or other risk factors. Ultrasound can be used to locate the placental site. A senior obstetrician and anaesthetist are informed when labour is established. Caesarean section is only performed when there is a medical indication for this intervention. The third stage of labour is actively managed and the woman's wellbeing is closely monitored after birth. In the event of haemorrhage, the focus should be on pharmacological interventions such as the administration of vitamin K and early surgical intervention, as well as further discussion with the woman and her family if there is a medical indication for blood transfusion. Nevertheless, the woman's wishes must

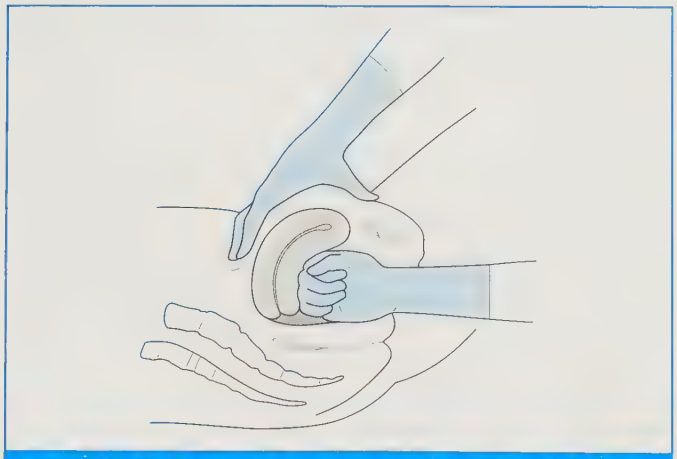

Figure 36.14 Bimanual compression (based on ALSO®)

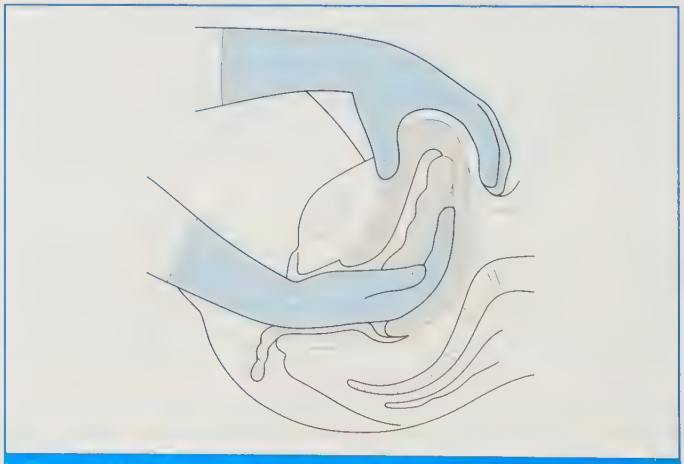

Figure 36.15 Manual removal of placenta (based on Henderson & MacDonald 2004)

BOX 36.11 Uterotonic drugs

Action, effect, dosage and route of uterotonic drugs

Syntocinon® (synthetic oxytocin) is the recommended drug to prevent PPH. It works rapidly, with minimal side-effects. Syntocinon® has an immediate onset and causes rhythmic uterine contractions for about an hour. It can be administered as an injection after birth of the anterior shoulder with no increase in the incidence of retained placenta or hypertension. The recommended prophylactic dose is 10 IU/mL intramuscularly or by **slow** intravenous (IV) injection of a bolus dose. Side-effects include mild, transient hypertension, water intoxication and hypertonic uterine action.

- **Syntocinon®** 40 IU/mL in 1000 mL Hartmann's (250 mL/hr) can be used as an infusion to maintain uterine contraction and can be left running for several hours after birth to ensure bleeding is controlled. The administration of 40 IU/mL has no demonstrable cardiovascular effect. However, even a small amount of Syntocinon® given as a bolus dose via IV push may elicit a pattern of hypotension and tachycardia
- **Syntometrine®** contains 5 units of Syntocinon® and 0.5 mg of ergometrine. Onset is 2–5 minutes and duration about 3 hours. Syntometrine® causes sustained tetanic uterine contraction. It is usually administered intramuscularly and is more effective than Syntocinon® in action. However, its routine use has declined in recent years due to its adverse effects, which include vomiting, dizziness, acute abdominal pain, headache, vasoconstriction, hypertension, chest pain and seizures. It should not be administered to a woman with a diastolic BP > 90 mmHg.
- **Ergometrine maleate** is available in a 500 µ/mL preparation that can be administered as an intramuscular or IV injection. Onset is 7 minutes and duration 3 hours. It too causes sustained uterine contractions. It is not recommended as a first-line drug for prophylaxis but can be used for severe PPH. It is contraindicated in hypertensive women with diastolic BP > 90 mmHg.
- **Prostaglandin $PGF_2\alpha$** (Dinaprost® 5 mg/mL) is used to control refractory cases of PPH The dose is 0.5 mg (1 mL) of a 5 mg/mL solution. This is diluted with 9 mL normal saline and injected intramuscularly or transabdominally directly into the myometrium on each side of the fundus. The dose can be repeated up to a maximum of 3 mg. This is a life-saving measure and should always be carried out in the presence of an anaesthetist with resuscitation equipment available. All the prostaglandin drugs are contraindicated in women with active cardiovascular, renal, liver disease or asthma. Side-effects include nausea, vomiting, wheezing, pyrexia, uterine rupture and cardiac arrest.
- **Misoprostol** (Cytec®) is not approved for use in pregnancy but can be given rectally (800–1000 mg) if oxytocin has failed to work and PGF_2 is not available (NSW Health Department 2002). Side-effects include diarrhoea, fever and abdominal pain.
- **Carboprost** (Haemabate®, 14-methyl prostaglandin F_2) is a synthetic prostaglandin currently awaiting approval for use in Australia. It can be given IM (250 µg), and works within 5 minutes, lasting up to an hour. It can be repeated every 15 minutes to a total of 2 mg. Side-effects include hypertension, pulmonary oedema, nausea and dyspnoea due to vasoconstriction.

always be respected and family and staff supported in the event of her death.

Postnatal considerations

After any PPH the woman is observed closely for 24 to 48 hours. Blood pressure, pulse and vaginal loss are accurately documented and fundal tone and height checked regularly. A urinary indwelling catheter is usually left in situ to promote adequate drainage of the bladder and to further aid uterine contractions as well as providing a means to accurately measure and document urinary output. Women who have experienced an obstetric haemorrhage are predisposed to renal tubular necrosis and may become anuric.

Following a PPH the woman is at increased risk of infection and lactation may be delayed. It is important to discuss the events with the woman and her support people so that they can understand what has occurred and ask questions. Any subsequent pregnancies will require specialist care and counselling to prevent/manage recurrence. In developing countries, women who survive PPH are more likely to suffer from long-term anaemia and other complications. Because their health is already compromised, such women often need blood transfusions but are susceptible to the associated risks of transfusion reactions or infection with HIV or hepatitis. Other possible morbidities include delayed healing and initiation of lactation, iron deficiency anaemia and exposure to blood products, haemorrhagic shock, coagulopathy, renal necrosis, and surgical intervention, which may result in hysterectomy and resultant sterilisation to control blood loss. Such procedures are costly and painful and may be emotionally devastating to the woman and her family. In addition, these procedures carry the risk of infection, reactions to anaesthesia and other complications.

Summary: postpartum haemorrhage

Catastrophic haemorrhage is a significant, life-threatening problem for some women. Midwives can be proactive in the prevention and early detection of PPH. Antenatal discussion of possible risk factors and careful management of the third stage are important components of midwifery care. Midwives

BOX 36.12 PPH management

Protocol for management of PPH

Diagnosis of PPH

- Blood loss > 500 mL, or
- Clinically abnormal bleeding with increase in pulse rate by 20 bpm or drop in systolic pressure by 20 mmHg
- If vital signs are worse than expected for observed blood loss, look for internal bleeding or uterine inversion.
- Monitor vital signs every five minutes as these may change rapidly.
- Consider calling emergency transport team.

General measures

- Call for help—notify senior obstetrician, anaesthetist and team leader. (Do not leave the woman alone.)
- Measure all blood loss (weigh pads, sheets etc).
- Massage uterine fundus, give slow injection of 10 IU/mL Syntocinon IV or intramuscularly.
- Take baseline vital assessments immediately and then every 5 minutes until the woman's condition is stable (document these).
- Continuous assessment of vaginal blood loss.
- Obtain IV access 14–16 G (x 2 if necessary)—collect blood for haemoglobin, coagulation studies, urgent cross-match.
- Commence normal saline infusion (Haemaccel if hypotensive) if blood loss >1000 mL.
- Administer oxygen 6–8 L/min by Hudson mask.
- Insert indwelling urinary catheter, hourly urine measurement, aiming to keep urine output > 30 mL/hr.
- Explain what is happening and reassure the woman and her support people.
- Call for assistance from emergency transport team if necessary.

Clinical point

Signs of disseminated intravascular coagulation
Bleeding from non-genital sites in the body, such as venous puncture sites, may suggest the development of disseminated intravascular coagulation (DIC).

should also be competent in managing active and physiological third stage, employing interventions as required. Before the midwife–woman relationship ends, it is important that the woman is able to identify abnormal changes that may occur at home and understands the importance of notifying her lead carer if they develop. Arrangements for follow-up care and tests such as haemoglobin tests should be made before discharge from hospital.

Neonatal resuscitation

The vast majority of newborn infants start to breathe without assistance and often cry almost immediately after birth. By one minute, most newly born infants are breathing spontaneously. These babies require little intervention immediately post birth. Caregivers should therefore practise from a philosophy of minimal invasiveness, coupled with maximal awareness and readiness. However, if the newly born infant fails to establish adequate, sustained respiration after birth, the infant is said to have neonatal asphyxia—an important cause of neonatal death if it is not managed quickly and correctly.

Effective resuscitation of the newly born infant requires: adequate training and preparation of staff involved in the care of women in labour; a knowledge of maternal, fetal and intrapartal risk factors that may influence the infant's ability to make the transition from fetus to neonate; and adequate and functioning equipment. The need for neonatal resuscitation may often be predicted but in many instances it is unexpected. For this reason, irrespective of the place of birth it is crucial that appropriate equipment and skilled personnel are available to resuscitate the newly born baby if necessary. Resuscitation involves much more than having an ordered list of skills and a resuscitation team on hand; it also requires excellent assessment skills and an in-depth knowledge of the physiological events triggering the transition from fetus to newly born infant.

Definition and purpose

The purpose of neonatal resuscitation is to establish or restore oxygenation, ventilation and circulation to depressed infants. Resuscitation is a series of actions taken to establish normal breathing, heart rate, colour, tone and activity in a newly born infant with depressed vital signs (i.e. low Apgar score). All babies who do not breathe well after birth (i.e. have neonatal asphyxia) or have a one-minute Apgar score below 7 need immediate resuscitation. Any newly born infant who has apnoea or who has depressed vital signs any time after birth also requires resuscitation. Guidelines have been established by various organisations such as the International Liaison Committee on Resuscitation (ILCOR). Australia and New Zealand are members of ILCOR. This section on neonatal resuscitation is based on two resources: ILCOR's Advisory Statement on Resuscitation of the Newly Born Infant (Kattwinkel et al 1999) and the Australian National Guidelines for the Resuscitation of the Newborn Infant (Draft 2, February 2004).

Unique physiology of the newly born

The transition from fetal to extrauterine life is characterised by a number of critical events, and these affect resuscitative interventions. After birth, for the lungs to operate as a functional respiratory unit providing adequate gas exchange, the airways must be cleared of fetal lung fluid; an increase in pulmonary blood flow must also occur. If the newborn infant's lungs do not rapidly become the site for gas exchange, cyanosis and hypoxia develop rapidly. The first breath must overcome the viscosity of the lung fluid and intra-alveolar tension. The initial breaths also generate high transpulmonary

pressure, which helps to push the lung fluid across the alveolar epithelium and into the lymphatic circulation. Once this happens:

- The lungs change from fluid-filled to air-filled.
- Pulmonary blood flow increases dramatically and intracardiac and extracardiac shunts (foramen ovale and ductus arteriosus) initially reverse direction and subsequently close.
- Physical expansion of the lungs, with establishment of functional residual capacity and increase in alveolar oxygen tension, both mediate the critical decrease in pulmonary vascular resistance and result in an increase in pulmonary blood flow.

Developmental considerations at various gestational ages or additional pathology also influence resuscitative efforts. For instance, surfactant deficiency in the preterm lung alters compliance and resistance. Thus, in a preterm baby, for initial lung expansion to occur, higher pressures (peak inspiratory and/or expiratory) than those usually used during resuscitation of the term baby or in infancy may be required. Some experts state early prophylactic administration of surfactant is associated with better outcomes in extremely premature infants.

If the fetus passes meconium into the amniotic fluid, this irritating substance may be aspirated into the tracheobronchial tree in utero or during the first few breaths after birth, leading to airway obstruction and possibly meconium aspiration syndrome (MAS). Complications of MAS are particularly likely in infants who are small for their gestational age, or those born after term or with significant fetal compromise, perhaps after a long labour.

Response to asphyxia

The fetus or newly born infant who has been subjected to asphyxia begins a 'diving' reflex (so-called because of certain similarities to the physiology of diving seals) in an attempt to maintain perfusion and oxygen delivery to vital organs. The asphyxiated infant passes through a series of events that have been well described from experimental evidence in animal models.

Primary apnoea

After a few shallow breaths, the asphyxiated infant stops breathing. This phase is called primary apnoea and may last for as long as 10 minutes. Most infants with primary apnoea respond to stimulation alone. During this phase, heart rate and pH are maintained.

Secondary apnoea

Following this period, the infant begins to gasp. The period between the last gasp and cardiac arrest is known as secondary apnoea. In the phase of secondary or terminal apnoea, the newborn has a mixed acidosis, and active intervention is required to stimulate respiration. It is not possible to clinically distinguish primary from secondary apnoea, and for this reason it is important to assume that the apnoeic infant is in secondary apnoea. If there is no response to simple interventions, active resuscitation is commenced immediately.

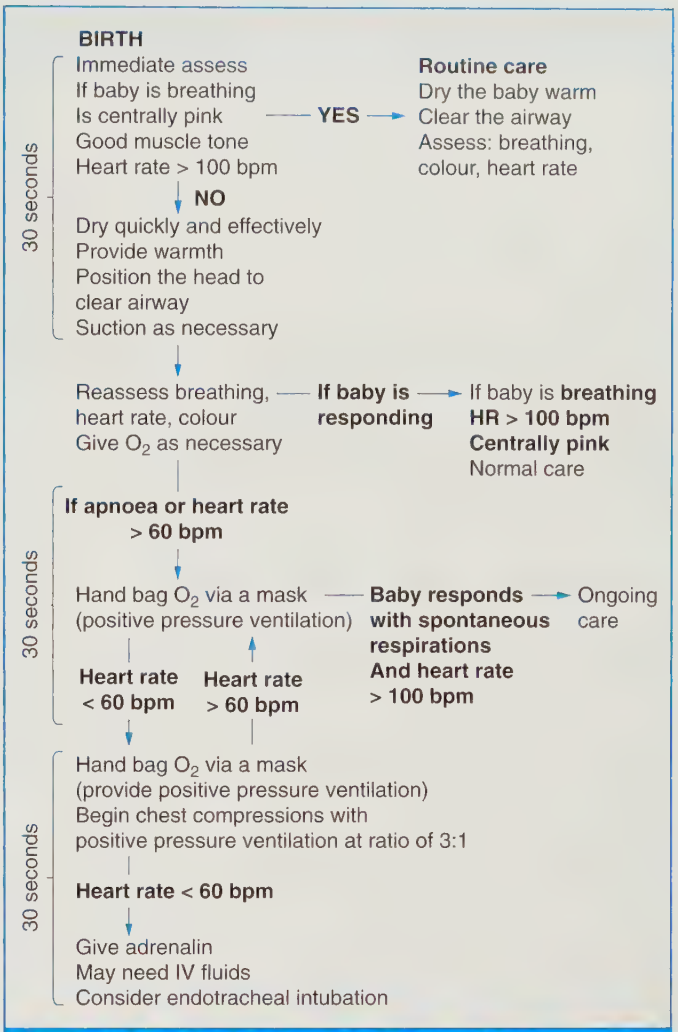

Figure 36.16 Algorithm for resuscitation of the term neonate at birth (based on Niermeyer et al 2000)

Clinical point

Definition of newborn, neonate and infant

In Australia and New Zealand, a fetus is viable if it weighs more than 400 g at birth or has a gestation of more than 20 weeks. However, a baby born at less than 23 weeks gestation is unlikely to survive. '*Newborn*' refers to an infant in the first minutes to hours following birth. In contrast, the *neonatal* period is defined as the first 28 days of life. *Infancy* includes the neonatal period and extends through the first 12 months of life. In this section the term 'newly born' is used to prevent confusion with the other terms.

Incidence and risk factors

Approximately 5% of all newly born infants require some stimulation to breathe (Saugstad 1998), and about 1:100 infants born in hospital require assisted ventilation (Palme-Kilander 1992). Even though prenatal care is able to identify many potential fetal difficulties ante partum, poor cardiorespiratory adaptation at birth (low Apgar scores) cannot be predicted. Perinatal asphyxia and extreme prematurity (babies weighing less than 1000 g) are the two complications of pregnancy that most frequently require complex resuscitation. However, only 60% of asphyxiated newborns can be predicted ante partum and are often not identified until the time of birth. Also, approximately 80% of low birthweight infants (< 2500 g) require resuscitation and stabilisation immediately after birth. Effective, prompt resuscitation and management of asphyxia in the first few minutes of life may influence the long-term outcome for these infants.

Anticipation of resuscitation need

Anticipation and preparation are the key features of effective neonatal resuscitation. Anticipating those infants who may need resuscitation at birth begins in pregnancy, with careful screening of the maternal social, medical and obstetric health record. Each birth setting should establish criteria (see Table 36.8) that would indicate the need to:

- increase surveillance
- summon extra or expert help
- transfer to a centre that has the staff, equipment and resources readily available for immediate resuscitation.

Arranging for transfer should be initiated in a timely way, because maternal transfer is less risky than neonatal transfer. Support and consultation should always be available from Level III centres. Once labour begins, the mother's history and records often provide clues to the possibility that the newly born infant will require resuscitation. Therefore, it is important to ensure that:

- the maternal history is checked meticulously
- all events are documented in a systematic and orderly way
- personnel communicate effectively
- all equipment is present and functioning
- the environment is suitable for birth.

The following clinical situations often lead to the birth of an infant with birth asphyxia and a low Apgar score at one minute:

- signs of fetal compromise in labour
- depressed vital signs
- prematurity
- difficult or traumatic delivery
- meconium aspiration
- general anaesthesia or recent maternal analgesia (narcotics within the past four hours).

Personnel

At least two trained people are required for adequate resuscitation involving ventilation and cardiac compressions.

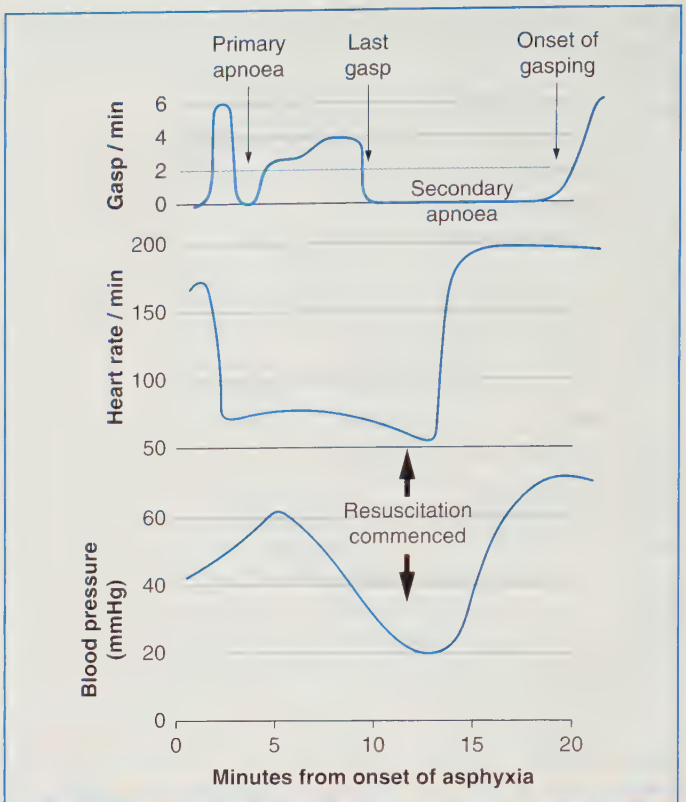

Figure 36.17 Physiological effect of acute asphyxia and the response to resuscitation (based on Levene et al 2000)

Therefore, it is important to always call for help. The most senior person available coordinates the resuscitation. Each person should have a dedicated job; for example, with three people, one is solely responsible for airway, one solely responsible for chest compressions and the third person coordinates the resuscitation and administers medication as necessary. If possible another person is responsible for recording events, including time of administration of drugs and the baby's response to resuscitation.

Equipment

Because it is not always possible to predict when resuscitation is required, emergency preparedness requires that a complete inventory of functioning resuscitation equipment and drugs be readily available for every birth. It is important that the care provider checks the resuscitation equipment at least daily and after each usage. When use is anticipated then the equipment is again rechecked.

- At every birth setting:
  - radiant warmer or other heat source
  - clock, timer
  - light source
  - warm towels, blankets, clothes
  - resuscitation bag and masks (Laerdal™ or Neopuff™)
  - oxygen source and tubing
  - suction device and catheters

TABLE 36.8 Risk factors associated with the need for resuscitation in the newly born infant

Maternal	Fetal	Intrapartal
Premature/prolonged rupture of the membranes	Multiple gestation	Fetal compromise
Bleeding in second or third trimester	Preterm gestation (especially < 35 wks)	Abnormal presentation
Severe hypertension (PE and chronic)	Post-dates gestation (≥ 42 wks)	Prolapsed cord
Substance abuse	Size–date discrepancy	Prolonged rupture of the membranes
Pharmacology therapy (lithium, magnesium sulphate, adrenergic blocking agents)	Intrauterine growth restriction	Prolonged labour (or prolonged second stage of labour)
Maternal diabetes mellitus	Rh isoimmunisation/ hydrops fetalis	Precipitous labour, hypertonic uterine action
Chronic illness (anaemia, cyanotic congenital heart disease)	Polyhydramnios and oligohydramnios	Antepartum haemorrhage (abruptio placenta, placenta praevia)
Maternal infection	Reduced fetal movement before the onset of labour	Thick meconium staining of the amniotic fluid
Heavy sedation	Congenital anomalies	Non-reassuring FHR patterns
Previous fetal or neonatal death	Intrauterine infection	Narcotic administration to mother within four hours of birth
No antenatal care		Operative delivery (caesarean, forceps, ventouse)

(Source: Kattwinkel et al 1999)

- oropharyngeal airways
- stethoscope
- syringes and needles
- polyethylene (or other equipment to keep the baby warm)

- Equipment in hospitals:
  - endotracheal tubes and introducers (sizes 2, 2.5, 3, 3.5 and 4 mmID)
  - laryngoscope and blades, batteries and bulbs
  - intravenous cannulae at various sites
  - umbilical vein catheterisation tray
  - pulse oximeter
- Drugs:
  - adrenaline 1:10,000 concentration (0.1 mg/mL)
  - volume expanders: normal saline, 4–5% albumin–saline, Hartmann's solution
  - naloxone hydrochloride: 400 µg/mL solution
  - sodium bicarbonate: 0.5 meq/mL solution (4.2% concentration)
  - dextrose: 5% and 10% solutions
  - sterile water for injection.

Communication

Effective communication is vital to smooth resuscitation. Preparation for an anticipated 'high-risk' birth and when arranging transfer requires effective communication between all members of the healthcare team. Communication among caregivers should include discussion of maternal condition, fetal condition and maternal therapies, including details of maternal social, medical and obstetric conditions and treatments that will affect the resuscitation and management of the newly born—for example, gestation, results of antenatal tests, ultrasonography and labour status, or the administration of maternal analgesia, tocolytics and corticosteroids, all of which influence respiratory function. A description of the results of FHR monitoring may give information about fetal wellbeing. Whenever time permits, the team responsible for the resuscitation should introduce themselves to the woman and her family before the birth. If possible they should outline their plan of care and carefully respond to the family's questions and concerns. This is especially important in cases of potentially lethal fetal anomalies or extreme prematurity, when the family's values and beliefs may affect their wishes for resuscitation of their baby.

Environment

Prevention of heat loss is important for the newly born and reduces the mortality of low birthweight infants. Cold stress increases oxygen consumption and impedes effective resuscitation. Whenever possible the infant should be born into a warm, draft-free area. An excellent strategy to reduce heat loss is to place the newly born skin-to-skin on the mother's chest or abdomen to use her body as a heat source. It is essential to prevent further heat loss during resuscitation. Rapid drying of the skin, removing wet linens, placing the infant under a radiant warmer and wrapping the newly born in pre-warmed blankets are also ways to reduce heat loss.

Techniques of resuscitation

The techniques of ACLS described here are the same as those recommended by ILCOR (Kattwinkel et al 1999) and the Australian National Guidelines for the Resuscitation of the Newborn Infant (Draft 2, February 2004). Being properly prepared is the first step in successfully resuscitating the newly born.

Assessment

All newly born infants should be assessed immediately following birth for signs that indicate inadequate oxygenation, ventilation or circulation and thus the need to initiate resuscitative efforts. The steps of evaluation and intervention are often simultaneous processes. Evaluation begins immediately after birth and continues throughout the resuscitation process until the infant's vital signs have normalised. The complex of signs (initial cry, respirations, heart rate, colour, response to stimulation) should be evaluated simultaneously. It is crucial not to wait for the one-minute Apgar score to identify the newly born infant in need of resuscitation.

Initial steps

Infants who are blue, apnoeic, flaccid and cyanosed with a heart rate < 100 bpm (primary apnoea), and those who are white, apnoeic, flaccid and pallid with a heart rate < 100 bpm (secondary apnoea), can be recognised at or soon after birth and resuscitation should begin without delay. In addition, active resuscitation should be commenced for infants with persisting bradycardia, central cyanosis, poor respiratory effort, significant respiratory distress and/or low Apgar scores (< 6 at one minute). The clock is turned on and the umbilical cord is clamped and cut, and the baby is taken to a pre-warmed radiant source. The infant is dried with pre-warmed towels and all wet linen is removed. The infant's airway is opened, with positioning and clearing of secretions. The infant is placed on her or his back with the head in the 'neutral' or 'sniffing' position (see Fig 36.18). If respiratory efforts are present but not producing effective tidal ventilation, often the airway is obstructed; immediate efforts to reposition the head or clear the airway are warranted. There is, however, no evidence to support routine suctioning of the upper airway or stomach of newly born infants. If necessary, secretions should be cleared with a suction device (bulb syringe, suction catheter).

Clinical point

Signs that indicate an immediate need for intervention include:

- *absent or weak response to tactile stimulation*—drying the infant with a towel, rubbing the back, flicking the soles of the feet
- *respiratory effort absent or gasping*—the newly born infant should establish regular respirations in order to maintain HR > 100 bpm
- *heart rate < 100 bpm*—determined from direct palpation of cord, apex beat or with stethoscope. Peripheral pulses are often difficult to feel. If no pulsation is felt on palpation of the cord, auscultate the chest.
- *colour*—central cyanosis (blue trunk and oral mucosa). The well newly born infant should be able to maintain a central pink colour in room air.

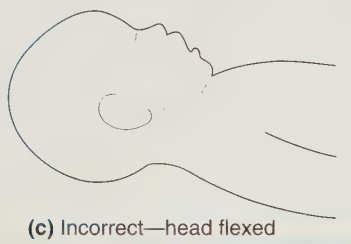
Oxygenation and ventilation

In all cases, the first priority is to ensure adequate inflation of the lungs, followed by close attention to the desired concentration of inspired oxygen, if required. The traditional management of central cyanosis is administration of 100% oxygen either by passive delivery via an oxygen mask or by positive pressure delivered by a resuscitation device. If the newly born infant's heart rate is > 100 bpm and the infant is breathing but is still cyanotic, 100% oxygen can easily be delivered at 5 L/min using oxygen tubing in the cupped hand over the baby's face (see Fig 36.19). Should supplemental oxygen be required for a prolonged period, then heated humidified oxygen is administered via head-box with the FiO_2 adjusted to result in a pulse oximetry saturation of 92–96% in the term infant and 88–92% in the preterm baby.

Although there is some clinical evidence to support resuscitation with lower oxygen concentrations or room air (21% oxygen), there is as yet insufficient evidence to support this as a routine practice (Ramji et al 1993, 2003; Saugstad et al 2003).

Drying and stimulation with or without suctioning is often enough to stimulate spontaneous respiration, and most infants do not require further intervention. If there is no response to stimulation, it may be assumed that the newly born is in secondary apnoea and positive pressure ventilation should be initiated. ILCOR guidelines recommend that the newly born infant's condition (respiratory rate, heart rate, colour, muscle tone, response to stimulation) be re-evaluated every 30 seconds until vital signs are stable.

Assisted ventilation



Assisted ventilation is initiated if the infant remains apnoeic after stimulation, or the heart rate remains < 100 bpm or is dropping. The rate for assisted ventilation is 40–60 breaths per minute. Effectiveness of ventilation is judged by watching the movement of the chest and upper abdomen with each inflation. Effective ventilation produces an increase in heart rate followed by the baby flushing pink. Few infants require immediate intubation. The majority can be managed with a 240 mL self-inflating bag and mask (e.g. Laerdal or a 'T piece' device such as Neopuff™) ventilation. Both require skill and continuous practice so that care providers can deliver a consistent peak inspiratory pressure (PIP). The PIP is usually limited by a pressure-release valve, which is set to activate at about 40 cmH_2O and can be overridden should higher PIP be required. As an added precaution, a pressure manometer limiting the positive pressure to 30–35 cmH_2O is attached to all Resuscitaires®. To provide adequate distending pressure, the infant must be positioned properly and the airway cleared of secretions; the mask must be the correct size and form a tight seal on the face. It should be remembered that during the baby's first breaths, the lungs are converting from a fetal, non-aerated status to the newly born state. Thus the first three to five 'rescue breaths' require

(a) Correct sniffing position

(b) Incorrect—hyperextended head

(c) Incorrect—head flexed

Figure 36.18 Sniffing position

Clinical point

Aggressive pharyngeal suction can cause laryngeal spasm, vagal bradycardia and delay the onset of spontaneous respiration. In the absence of meconium or blood, suction with a catheter should be limited to a depth of 5 cm for the lips for 5 seconds. Negative pressure of the suction apparatus should not exceed 100 mmHg (13.2 kPa). There is evidence that tracheal suctioning of the vigorous infant with meconium-stained fluid does not improve outcomes and may cause additional complications (Wiswell & Bent 1993).

higher inflation pressures and longer inflation times than subsequent breaths, particularly in infants who have not yet made any respiratory effort. For the first breaths, 30–40 cmH_2O is usually enough. For subsequent breaths, 15–20 cmH_2O is adequate. If appropriately skilled personnel are available, tracheal intubation may be considered if ventilation via face mask is ineffective or prolonged.

Cardiac compression

Chest compressions are started if, after 30 seconds of adequate, assisted ventilation with 100% oxygen, the heart rate is:

- absent
- < 60 bpm
- 60–80 bpm and falling.

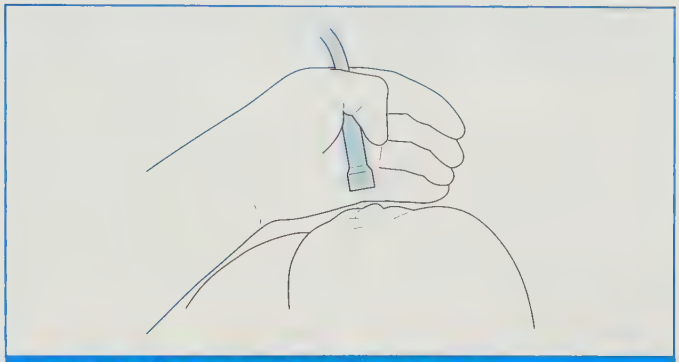


Figure 36.19 Cupping the catheter to deliver oxygen

Clinical point

Effective ventilation is the key to successful neonatal resuscitation.

Chest compressions may diminish the effectiveness of ventilation.

Procedure

The sternum is compressed one finger breadth below a line drawn between the nipples. No pressure should be applied to the xiphoid process or the chest margins, and it is important not to restrict chest re-expansion. Compressions should move the lower third of the anteroposterior diameter of the chest (1–2 cm) to generate a palpable pulse. Compressions and inflations are synchronised at a 3:1 ratio of compressions to inflations at a rate of 90 compressions and 30 inflations to achieve approximately 120 'events' per minute: count one-and-two-and-three-and-breath.

Specific techniques

Acceptable techniques are:

- two thumbs on the sternum, superimposed or adjacent to one another according to the size of the newly born infant, with fingers of both hands encircling the chest to support the back
- two fingers placed on the sternum at right angles to the chest (Fig 36.20).

Research suggests that the two-thumb technique may offer some advantage over the two-finger technique in generating higher blood pressure and better coronary perfusion pressure without introducing additional complications. Nevertheless, single operators find the 'two-finger technique' preferable.

Endotracheal intubation

Infants may require endotracheal intubation when:

- bag-and-mask ventilation and intermittent positive pressure ventilation (IPPV) is ineffective
- tracheal suction is required (in the presence of thick meconium)

- prolonged IPPV is necessary
- diaphragmatic hernia is suspected.

Endotracheal intubation is not a midwifery skill, and so only very brief details are included in this section. In summary, an appropriately sized blade and endotracheal tube (ETT) (depending on the size of the infant) are chosen. On insertion of the ETT, the tube is advanced until the vocal cord guide mark near the distal tip of the tube is visualised. This guide mark is positioned at a variable distance from the distal tip (depending on the ETT size) and is designed to result in the placement of the tube tip between the vocal cords and the carina at the bifurcation of the right and left main-stem bronchi. The ETT is secured with the appropriate centimetre marking at the upper lip. The depth of insertion should be recorded and maintained. Care providers should be aware that variation in head position alters the depth of insertion and may predispose to unintentional extubation or endobronchial intubation.

Medications in resuscitation

Drugs are rarely needed in resuscitation of the newly born infant and so they are dealt with only briefly here.

Possible routes of delivery

- umbilical venous catheter
- ETT—for either adrenaline or naloxone
- peripheral IV line—difficult to cannulate in the collapsed infant.

Umbilical arterial catheter should not be used for vasoactive substances and is not rapidly accessible.

Adrenaline

Adrenaline is recommended if the heart rate remains < 60 bpm for more than 30 seconds despite one minute of effective ventilation and compressions. The only exception to this rule may be newly born infants born without a detectable pulse or heart rate.

- *Dosage*: 0.1–0.3 mL/kg 1 in 10,000, repeated at 3–5 minute intervals
- *Volume* (preload) 10–15 mL/kg in normal saline and then repeated 2–3 times.

Sodium bicarbonate

Sodium bicarbonate has been recommended to reverse the effects of metabolic acidosis related to hypoxia and asphyxia. Currently there is insufficient evidence for routine use. Argument for correction of acidosis includes theoretical concerns about hypoxia and elevated pulmonary vascular bed pressure and poor cardiac contractility with acidosis. Argument against correction includes concerns regarding hyperosmolarity and carbon dioxide generation with intracellular acidosis from alkali infusion.

Dosage: 2 mL/kg of 4.2% sodium bicarbonate into the umbilical vein to correct acidosis and stimulate the cardiorespiratory system. It should only be given once adequate ventilation has been achieved. It is important to obtain early blood gases after resuscitation.

Dextrose: glucose has not been shown in animal models or adult humans to change the outcomes of CPR. No trial of glucose for resuscitation exists in neonates. Neonates requiring CPR should have an early blood sugar estimate after resuscitation and correction of hypoglycaemia if BSL < 3.0 mmol/L.

Volume replacement in resuscitation: volume replacement is not routine in neonatal resuscitation. Volume expanders (whole blood—difficult to obtain immediately after birth, 5% albumin, normal saline or Hartmann's solution) should be considered when there is suspected blood loss and/or the newly born infant appears to be in shock (pale, poor perfusion, weak pulse) and has not responded to other resuscitative measures. The initial dose is 10 mL/kg by slow IV push.

Post-resuscitation issues

After resuscitation with ACLS, ongoing supportive care, monitoring and appropriate diagnostic care must be provided. All newly born infants who require resuscitation must be

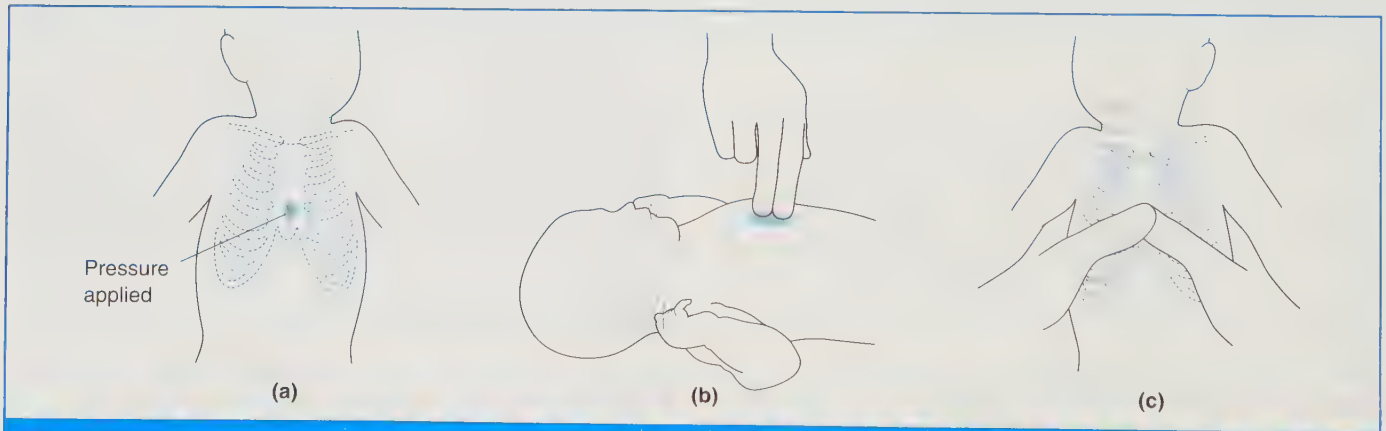

Figure 36.20 Cardiac compression **(a)** Position for applying pressure **(b)** Using two fingers **(c)** Using two thumbs with the hands encircling the chest (based on Henderson & MacDonald 2004)

carefully observed for at least four hours. Temperature, pulse rate, colour and activity, and urinary output should be recorded. Hypoglycaemia may occur rapidly in critically ill or preterm infants. It is important to check blood glucose levels as soon as possible. These babies are often cold-stressed and so they must be kept warm, preferably in an isolette. A newly born infant who has required resuscitation, perhaps with ongoing respiratory compromise, may have experienced an insult to the gastrointestinal tract. It is important to provide fluids and energy; consideration should be given to parenteral versus oral hydration and nutrition for several days.

Preparation for transport

Medical transport of critically ill newly born infants requires skilled personnel and specialised equipment. Ideally, neonatal transport teams form a single component associated with a larger system of perinatal care composed of a tertiary care neonatal intensive care unit (NICU), and a neonatal outreach program. Preparation of the infant for transfer to a Level III nursery for subsequent care requires several considerations. First, it is important to complete all the routine care required for such ill infants. These basics may be neglected in the rush to prepare the newly born infant for transport. It is important to secure all lines, tubes, catheters and leads for transport. Monitoring en route to hospital is made more difficult if leads and lines are dislodged or do not function. Rapid and complete documentation of the resuscitation and subsequent therapies also is required for the receiving NICU.

Continuing care of the family

Irrespective of the outcome, witnessing the resuscitation of their baby is a distressing event for the family. While the resuscitation team is concentrating their efforts on the newly born infant and can often see that their efforts are achieving success, the parents cannot see what is happening. It is important that caregivers keep the family informed about what is going on and that the parents have contact with their baby as soon as possible. Most parents are unfamiliar with the complexities of care required for an extremely ill infant. It is often necessary to provide the information in small segments at frequent intervals to help the parents begin to comprehend the issues. The family needs clear and consistent explanations of the various supportive procedures that will likely be necessary after the infant's birth. Family members should also be provided with an overview of the potential complications of their infant's condition, including the possible need for prolonged intensive care. It is important to address the parents' needs and to be frank and honest in answering their questions.

Clinical point

Naloxone

Naloxone is used to reverse respiratory depression in the newly born infant who is considered to be depressed by opiates given to the mother in labour (within four hours of birth), who require active resuscitation and/or continue to have inadequate spontaneous respiratory effort. It reverses narcotic-induced respiratory depression, analgesia, sedation, hypotension and pupillary constriction within 1–2 minutes. However, support with artificial ventilation remains the mainstay of treatment. The intramuscular administration of maloxone should not be used for other forms of vigorous stimulation.

Route, dose and frequency

Dose is 100 µg/kg solution for term or near-term infants. It can be given intramuscularly, intravenously or endotracheally. Naloxone acts more rapidly if it is injected into the umbilical vein, so all midwives should practise this technique. The dose can be repeated in 3–5 minutes if there is no improvement.

Contraindications

Infants of narcotic-dependent mothers (heroin, methadone) may experience abrupt withdrawal syndrome (increased heart rate and blood pressure, vomiting, seizures and tremors).

Neonatal side-effects

Excessive doses may result in irritability, increased crying and possible prolongation of partial thromboplastin time (PTT); tachycardia may occur. Some narcotics have a longer half-life in the newly born infant than naloxone, which may lead to respiratory depression in the postpartum unit. Therefore, any infant who has received naloxone should be closely monitored for the recurrence of respiratory depression for 12 hours. Naloxone acts more rapidly if it is injected into the umbilical vein, so all midwives should practise this technique.

Midwifery considerations

- Monitor respirations: rate and depth for improved respiratory effort.
- Assess for return of respiratory depression for 12 hours—when Naloxone's effects wear off and effects of longer-acting narcotics reappear.
- Monitor bleeding studies.
- Naloxone is incompatible with alkaline solutions such as sodium bicarbonate.
- Store at room temperatures and protect from light.
- Naloxone is compatible with heparin.

Stopping resuscitation

It is difficult to accurately define a time beyond which active support worsens brain injury. However, it is reasonable to discontinue resuscitation after 10–15 minutes of appropriate resuscitative efforts for the infant with cardiorespiratory arrest who has not responded with spontaneous circulation (measurable heart rate). Both survival and quality of life deteriorate precipitously at this point in term infants. Before resuscitation is stopped, a second opinion should be sought if possible.

Reflective exercise

Parents are often excluded from the room while their baby is being resuscitated or stabilised. Often, however, they are in an adjacent room and so they have some idea of what is going on and can often recall who said what to whom. Ask yourself:

- Is removing the parents to another room for the benefit of the parents, or for the comfort and benefit of the staff?
- If this was your baby, where would you want to be?
- How would you feel about a staff member who tried to prevent you from seeing your baby?
- Is it more frightening to see what is actually going on or to imagine what is going on?

Ethical issues

The birth of extremely immature babies and those with severe congenital anomalies raises questions among parents and care providers about the initiation of active resuscitation of the newly born infant. In such cases, initiation of resuscitation does not mandate continued support. Kattwinkel and colleagures (1999) point out that non-initiation of support and later withdrawal are usually considered to be ethically equivalent; however, the latter approach allows time to gather more complete clinical data and to provide counselling for the family. The authors (1999) comment that possible exceptions include infants with anencephaly or those who are extremely immature and for whom there is no possibility of survival.

Documentation

It is crucial for effective, quality care, and for medico-legal concerns, that all care providers attending a resuscitation of a newborn take responsibility for ensuring that assessments and the actions taken in the resuscitation are fully documented. Apgar scores quantify and summarise the response of a newly born infant to the extrauterine environment; they also provide an indication of the success of the resuscitation. Apgar scores should be recorded at one and five minutes, and sequentially after every five minutes until vital signs have normalised. However, Apgar scores should not be used to dictate appropriate resuscitative efforts (Kattwinkel et al 1999). A comprehensive, accurate narrative must also include a description of the events leading up to the birth of the infant, resuscitative efforts, and their timing and outcomes.

Review questions

1. Develop a plan of care for families at risk of complications in the postpartum period.
2. Identify the major causes of PPH, and for each one describe the appropriate strategies to prevent or manage it should it occur.
3. Do you think all parents should be taught the skills of neonatal resuscitation in pregnancy? If so, how would you go about doing this?
4. Describe the identification and assessment of a woman who has developed an amniotic fluid embolism.
5. What evidence-based strategies (if any) should be put in place for women at term with a macrosomic fetus?
6. Discuss the implications of trauma from accidents or battering for the pregnant woman and her fetus.
7. With colleagues and a torso and doll, practise using the HELPERR mnemonic during a 'mock' shoulder dystocia.
8. Practice neonatal resuscitation with colleagues during a 'fire drill'.
9. Name five interventions you would initiate for a woman who appears to have a cord prolapse.
10. Make a directory of the support networks available near you, for women who have had a traumatic pregnancy and birth.

CHAPTER 37

Complications in the postnatal period

Jenny Gamble and Debra Creedy

Key terms

anxiety disorders, counselling, emotional support, endometritis, fatigue, pelvic floor dysfunction, postnatal depression, postpartum pain, post-traumatic stress disorder, psychological trauma, retained products of conception, secondary postpartum haemorrhage, sexual problems, thromboembolism, urinary incontinence

Chapter overview

This chapter describes and discusses physical and psychological morbidity following childbirth. The postnatal period has conventionally been defined as extending to six weeks following birth. After this time, women are presumed to have physically recovered from the birth and to be able to resume their roles. However, it is becoming clear that many women experience ongoing health problems related to the pregnancy and birth during the first year post partum. The considerable variety, duration and severity of morbidity is now being documented. In the past, health problems were narrowly defined as medical conditions requiring medical treatment, such as haemorrhage, thromboembolism and infection. More recently, researchers have broadened the scope of their work to incorporate women's perspectives on their health, which encompasses both physical and emotional dimensions, and other types of problems that are commonly experienced. This chapter commences with a review of physical complications and morbidity following childbirth. The second section relates to common emotional complications such as postnatal depression and anxiety disorders.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe the range of physical health problems women may experience following childbirth
2. To discuss the factors associated with postpartum physical morbidity
3. To explain the assessment and treatment of secondary postpartum haemorrhage and infection
4. To discuss the various emotional responses to childbirth, and the factors that place women at risk for emotional distress
5. To apply the best available evidence to the care of postpartum women.

Postpartum physical morbidity

This section begins with a description of the extent of postpartum physical health problems and factors associated with poor postpartum physical health. Women's responses to their health concerns are outlined. Following this, specific postpartum health problems are described, along with associated factors, and research evidence on available treatment. Physical complications to be addressed include infection, vaginal bleeding, secondary postpartum haemorrhage, pelvic floor dysfunction, pain, thromboembolism and fatigue.

The extent of postpartum physical health problems warrants close attention. In a large questionnaire-based survey in the United Kingdom, 76% of women reported at least one health problem at eight weeks post partum (Bick & MacArthur 1995). An Australian study showed that 94% of surveyed mothers in Victoria reported ongoing health concerns up to six months post partum (Brown & Lumley 1998). In an Australian Capital Territory (ACT) study, 94% of new mothers reported health problems at eight weeks post partum. By 18–24 weeks post partum, this had declined only slightly to 81% (Thompson et al 2002). Recently, a study involving Queensland women found that although women's general health had largely been restored a year after birth, one-fifth of women continued to experience specific health concerns (Bogossian 2003). All studies (summarised in Table 37.1) highlight the extent of postpartum morbidity, with the percentage of postpartum women reporting health problems varying according to the types of problems measured, timing, and method of data collection.

Associated factors

There are several known factors consistently associated with poorer maternal health outcomes, such as obesity, poverty and smoking. Research has also predominantly examined factors associated with specific morbidities such as urinary incontinence. However, two recent studies (summarised below) investigated the association between general health status and type of birth. Women experiencing an operative birth generally have poorer postpartum health than women experiencing a spontaneous vaginal birth (Bogossian 2003; Lydon-Rochelle et al 2001).

A study by Lydon-Rochelle et al (2001) of 971 women in the United States found that primiparous women experiencing a caesarean section or operative vaginal birth reported significantly lower postpartum general health than women with spontaneous vaginal births. At seven weeks post partum, women experiencing a spontaneous birth reported better health status in terms of physical functioning, mental health, general health perception, bodily pain, social functioning and daily activity. These women also reported better physical, social, sexual, bowel and urinary functioning. Significant differences between groups were maintained even when the analysis was adjusted for maternal age, education, health insurance status, income, living situation, race/ethnicity and newborn length of stay (Lydon-Rochelle et al 2001).

TABLE 37.1 Selective summary of reported maternal morbidity

Study	Sample size (*n*)	Postnatal period (months)	Tiredness (%)	Perineal problems (%)	Backache (%)	Haemorrhoids (%)	Bowel problems (%)	Sexual problems (%)	Headache (%)	Vaginal bleeding (%)	Urinary incontinence (%)
Bick & MacArthur (1995)	1278	6–7 months	40	NM	46	NM	NM	NM	20	NM	22
Glazener et al (1995)	438	12–18 months	54	10	20	15	7	NM	15	13	14
Brown & Lumley (1998)	1336	6–7 months	69	21	43	25	NM	26	NM	NM	11
Thompson et al (2000)	1193	6 months	49	4	45	13	17	20	17	2	14
Bogossian (2003)	135	12 months	58	23	42	24	13	23	20		46

NM: not measured.
(Source: adapted from Bogossian 2003, pp 18, 169)

In an Australian study by Thompson et al (2002), women who had caesarean sections reported more exhaustion, lack of sleep and bowel problems, and were more likely to be readmitted to hospital within eight weeks of birth than women who had spontaneous vaginal births. In particular, women who had forceps or vacuum extraction reported more perineal pain and sexual problems than women who had had a spontaneous vaginal birth, after adjusting for parity, perineal trauma and length of labour.

Seeking healthcare for postpartum problems

Although many women experience a considerable burden of morbidity in the year following birth, they often do not seek any professional assistance for their health concerns (Bick & MacArthur 1995; Glazener 1997). In a study by Brown and Lumley (1998), one in seven women reporting a health problem had not talked to a health professional about their own health. Of women reporting health problems, 49% would have liked more help or advice. Similarly, Bogossian (2003) found that 47% of women did not seek any advice for prevalent health concerns. When women did seek advice, they most commonly consulted a GP (35%) or a medical specialist (12%). Only 3% of women sought advice from a nurse, midwife or other therapist.

Women may seem reluctant to seek professional help for ongoing postpartum health problems for several reasons. Some women may believe that their health concerns are minor, self-limiting or an expected consequence of having a baby. They may feel embarrassed or inadequate about their ability to get 'back to normal' as quickly as anticipated (Percival & McCourt 2000). Women may perceive that health professionals are unable to help or that there are limited options available to treat common postpartum problems such as extreme tiredness or musculoskeletal pain. Prescribing medication is a common response to women's postpartum health problems, and some women may find this unacceptable because they are breastfeeding or for other reasons (Bogossian 2003). When women do have contact with health professionals for routine care or for specific concerns, the focus by health professionals seems to be the wellbeing of the baby, not that of the mother. Women may perceive that health professionals lack interest in their wellbeing (Glazener 1997).

Postpartum infection

Postpartum infection can be a precursor to other postpartum problems such as secondary postpartum haemorrhage and pelvic pain. This section describes endometritis; however, infections of caesarean section and perineal wounds or urinary tract infections can hamper postpartum recovery and become a significant burden in women's lives.

Endometritis

Endometritis is inflammation of the lining of the uterus, usually caused by infection and causing pain. Caesarean section is the single most important risk factor for postpartum maternal infection (Smaill & Hofmeyr 2002). Preterm labour (often associated with genital tract infection) is strongly associated with the development of postpartum sepsis (Kankuri et al 2003). Any procedure or event that introduces infection into the uterus or adversely affects women's ability to ward off infection predisposes them to endometritis. These include pre-labour rupture of membranes, blood loss, anaemia, operative vaginal birth, manual removal of placenta, repeated vaginal examinations, and internal electronic fetal monitoring. Although endometritis is frequently linked with uterine infection, it is not always the case. Sometimes the cause is unknown (Alexander et al 2002).

Women with endometritis may be febrile, with possibly only a low-grade temperature, and report abdominal/pelvic pain. On palpation, the uterus may be tender and sub-involuted. The lochial loss might be an unusual colour and frequently has an offensive smell. Bowel and bladder function may be disturbed and other possible infection or inflammation sites such as mastitis, or urinary tract or wound infections, need to be excluded. Treatment is with antibiotics. A risk of endometritis is septic shock.

Case study

On day 10 post partum, following a normal birth of a 3570 g boy, Julie phones you, her midwife, and says, 'Last night, to my surprise, my husband took out the rubbish and washed out the bin. When my sister visited me this morning, she said, "You smell like road kill". I guess I need you to visit me.' You visit Julie at 12:30 pm. She is walking around and chatting but says she is feeling 'off-colour'. Her lochial loss has an offensive smell.

1. What does normal lochial loss smell like?
2. What additional assessment data would you seek? (Be specific.)
3. If you suspected endometritis, what would you do next?
4. How will you respond to Julie's comment about smelling like 'road kill'?

Postnatal vaginal bleeding

Many women experience problems with postpartum vaginal loss that does not follow the expected course of lochial loss. Results from a UK survey showed that 20% of women had problems with postnatal loss occurring between 28 days and three months post partum. Only half of these women consulted a GP (Marchant et al 2002). A follow-up of GP data indicated that the common presenting symptoms were excessive bleeding (29/48; 66%) and prolonged bleeding (26/48; 54%). The most common form of treatment was antibiotics alone (15/48; 31%), however, 12 women (25%) were neither treated nor referred. Referral ($n = 19$) was for hospital admission, outpatient appointment, or direct referral for ultrasound scans.

Question

Is there a difference in the incidence of prolonged or excessive postpartum lochial loss between women who experienced physiological third stage labour and those who had actively managed third stage of labour?

Similarly, in an Australian study, 20% of women reported excessive or prolonged bleeding at eight weeks post partum, and although this problem resolved to a large extent by 24 weeks post partum, 2% of women continued to identify prolonged or excessive bleeding as a problem (Thompson et al 2002).

Secondary postpartum haemorrhage

Secondary postpartum haemorrhage (PPH) can be a life-threatening emergency, although in developed countries it is predominantly a problem of morbidity (Neill et al 2002). It has traditionally been defined as excessive bleeding from the genital tract that occurs after the first 24 hours following birth until the sixth postpartum week. However, many women bleed for longer than this period. Consequently, Marchant et al (2002) define it as any abnormal or excessive bleeding from the birth canal between 24 hours and 12 weeks post partum. This definition includes no reference to volume of blood loss or the woman's condition and, because normal lochial loss is poorly described, it is not very helpful in determining the incidence of secondary haemorrhage.

The incidence of secondary PPH determined by hospital admission is 1–2% (Alexander et al 2002; Hoveyda & Mackenzie 2001). In light of the findings from the study on postpartum vaginal loss described above (Marchant et al 2002), which showed that 'abnormal' bleeding is managed primarily in the community, calculating the incidence of secondary PPH from hospital admissions data results in under-reporting of the problem.

A history of primary PPH and manual removal of placenta are the only significant risk factors found to be associated with secondary PPH (Hoveyda & Mackenzie 2001). Other factors that may predispose women to secondary PPH include smoking, multiple pregnancy, threatened miscarriage, antepartum haemorrhage, hospital admission in the third trimester, precipitate labour of less than two hours, prolonged third stage, incomplete products of conception passed at birth, primary PPH, not breastfeeding and a history of previous secondary haemorrhage.

Assessment

Most women seek treatment for secondary PPH during the second week after the birth (Hoveyda & Mackenzie 2001). Because secondary haemorrhage and endometritis are not mutually exclusive conditions, some or all of the symptoms of endometritis may also be present for women who experience a secondary PPH. In addition, there must be abnormal bleeding. The blood loss varies in consistency and amount. Some women may have a highly offensive scant loss, while other women gush red blood or pass clots, some of which can be very large. Careful history-taking and clinical assessment of the woman is important, particularly in relation to the amount and duration of bleeding, signs of infection, and her current cardiovascular state.

Treatment

Women requiring admission to hospital for secondary PPH are treated with drug therapy and/or surgery. From UK figures, 1% of women undergo surgical uterine evacuation of retained products of conception and a further 1% of women are admitted to hospital and managed with drugs but not surgery (Alexander et al 2002). A study of 132 women with secondary PPH presenting to a hospital identified that 84% required hospital admission, 63% experienced surgical evacuation of the uterus, 17% received a blood transfusion, three women suffered uterine perforation, and a hysterectomy was performed on one woman (Hoveyda & Mackenzie 2001).

The rationale for these treatments appears to be that the uterus has failed to contract sufficiently to prevent bleeding from the placental site and that the underlying cause is retained products of conception and/or intrauterine infection (Alexander et al 2002). Previously undiagnosed genital tract tears may also be a cause of secondary PPH, especially in the presence of infection. Drug therapy consists of oxytocics and/or antibiotics to control the bleeding and treat the possible infection. Hormones such as prostaglandins may also be given to help control bleeding. Some women will require a blood transfusion. Surgery might involve evacuation of the products of conception, repair of cervical tear or uterine rupture and, rarely, hysterectomy (Alexander et al 2002).

In recent years, there has been an attempt to determine which women require surgical intervention to evacuate the uterus, because many women undergo this procedure with no resulting evidence of retained products of conception. The surgery itself has risks such as increasing haemorrhage by removing the placental site's clot, introducing infection, and uterine rupture. It was hoped that pelvic and/or abdominal ultrasound would assist in guiding treatment decisions about whether to intervene surgically. In a UK study, preoperative ultrasound examination did not provide better discrimination over clinical assessment about the likelihood of retained products of conception being removed during curettage (Hoveyda & Mackenzie 2001). It seems that retained products of conception can be over-diagnosed clinically and on ultrasound, as large clots produce a subinvoluted uterus and show echogenic material similar to retained products of conception.

A study conducted in Israel supports this finding. Histopathologic reports confirmed the diagnosis of retained products of conception in only 17 (48.5%) of the 35 postpartum women who underwent evacuation of the uterus for suspected retained products of conception. Since the false-positive rate for sonographic diagnosis of retained products of conception

Reflective exercise

1. Is there a role for alternative therapies such as reflexology, acupuncture and naturopathy in preventing secondary PPH?
2. What is the impact of secondary PPH on women's wellbeing?
3. How would women prefer to have this problem managed?
4. Are women informed of the benefits, risks and unknowns of various treatment options? (Explain how you would ensure that the woman had all the information she needed to make a decision about treatment options for secondary PPH.)
5. What are the implications of this complication for breastfeeding?

BOX 37.1 Summary: secondary PPH

- Secondary PPH is a significant cause of morbidity.
- Life-threatening secondary PPH in developed countries is rare.
- Secondary PPH is frequently associated with intrauterine infection.
- Treatment includes IV fluids, antibiotics, uterotonic medication, and surgical evacuation of the uterus.
- Prostaglandins or other drugs to control bleeding and/or hysterectomy and/or blood transfusion may be needed in extreme cases.
- Surgical evacuation of the uterus in cases of suspected retained products of conception carries risks and is possibly performed more often than warranted.

in postpartum women is high, the authors suggest a more conservative approach to the treatment of this condition (Sadan et al 2004). Similarly, Neill et al (2002) found that histology often failed to confirm retained placental tissue in women undergoing curettage for suspected retained products of conception.

Pelvic floor dysfunction

Pelvic floor dysfunction relates to urinary and faecal incontinence, perineal pain and dyspareunia. Previously a hidden burden associated with childbearing, pelvic floor dysfunction has recently received considerable media attention in Australia as part of a debate over the relative risks and benefits of different types of birth. While raising community awareness of the potential burden of pelvic floor dysfunction among childbearing women, the information provided was biased towards the protective effects of caesarean section in an attempt to justify the high caesarean section rates in Australia.

Urinary incontinence

The incidence of postpartum urinary incontinence is high. The most common type of incontinence suffered by postpartum women is stress incontinence, but urge incontinence is also common and many women experience a combination of different types of incontinence. Variable rates of urinary incontinence are reported in the literature as a result of different data collection methods, definitions of incontinence and the postpartum period in which incontinence was assessed.

A large population-based cohort study of women from the ACT (n = 1193) found that 19% of women reported incontinence at eight weeks post partum and 11% reported incontinence at 24 weeks post partum (Thompson et al 2002). Similarly, Burgio et al (2003) found that 11% of women reported some degree of incontinence at six weeks post partum. Other researchers have found higher rates of incontinence. Mason and colleagues (1999) reported that 31% of women had stress incontinence at eight weeks post partum. A New Zealand study on the prevalence, type, onset and frequency of urinary incontinence with over 1500 women reported that at three months post partum 34% of women experienced urinary incontinence, with 21% indicating that it occurred less than once per week (Wilson et al 1996).

Although problems with urinary incontinence often diminish in the weeks and months following birth, this is not always the case (Bogossian 2003; Burgio et al 2003). Importantly, urinary incontinence symptoms may worsen over the years (Continence Foundation of Australia 2003). A study by Grodstein et al (2003) reported that 34.1% of women (age range 50–75) had leaked urine at least once per month during the previous 12 months.

Factors associated with urinary incontinence

Childbearing per se has long been implicated in urinary incontinence. Parity is related to incontinence (e.g. Grodstein et al 2003; Thompson et al 2002) and the higher the parity the more likely the woman is to suffer from symptoms of incontinence (Mason et al 1999).

While parity has been found to be associated with urinary incontinence in a number of studies, the complete picture is far from clear. A longitudinal study involving 150 nuns (mean age 68 years, SD = 11.7) found that half had urinary incontinence and more than half of these women used sanitary pads for protection (Buchsbaum et al 2002). Stress incontinence was more common than urge incontinence. The authors concluded that the prevalence of incontinence in nulliparous, menopausal nuns was similar to rates reported in parous, postmenopausal women. While nuns differ from other women in a number of significant ways (due to their lifestyle), this study suggests that the effect of parity on urinary incontinence may contribute to differential morbidity in the premenopausal years.

Other variables associated with pregnancy and childbearing also affect pelvic floor function. It seems that some or all of the following factors may have a role to play in postpartum pelvic floor function:

- becoming pregnant
- antenatal pelvic floor exercises (Wilson et al 1996) and antenatal incontinence
- antenatal perineal massage (Heit et al 2001)
- gestation of pregnancy at birth
- age of mother at first birth (Grodstein et al 2003)
- commencing labour
- the nature of the labour (e.g. duration) (Brown & Lumley 1998)
- events and procedures during labour (e.g. type of birth, perineal trauma, type of pushing)
- birthweight of infant (Brown & Lumley 1998)
- length of breastfeeding (Burgio et al 2003).

There is conflicting evidence about a number of these variables (e.g. type of birth, infant birthweight), and the relative contribution of these factors to urinary incontinence requires further investigation. Other factors, not specific to pregnancy and childbirth, have been found to be associated with postpartum urinary incontinence. These include maternal obesity, smoking, pre-existing incontinence, race and lifestyle (Baessler & Schuessler 2003; Burgio et al 2003; Grodstein et al 2003; Hvidman et al 2003). The remainder of this section will examine the evidence relating to type of birth.

It seems that type of birth (elective caesarean section, emergency caesarean section, forceps, vacuum, spontaneous vaginal birth) is associated with differing rates of urinary incontinence. In the short-term, women having a caesarean section may have a lower incidence of incontinence (but not other urinary problems). Thompson et al (2002) found that compared with women having spontaneous vaginal birth, women having a caesarean section were significantly less likely to report urinary incontinence at eight weeks post partum, but this difference was not statistically significant at 16 and 24 weeks post partum. At 24 weeks post partum, women delivered by caesarean section were more likely to report other urinary problems, such as passing urine frequently or being unable to pass urine, than women having a spontaneous vaginal birth. Similar results were found in a population survey in South Australia, which reported that caesarean section may not be associated with significant reduction in long-term pelvic floor morbidity compared with spontaneous birth (MacLennan et al 2000).

A recent Israeli study, which excluded women with pre-existing stress incontinence, showed the prevalence of stress incontinence one year after the first birth to be 10.3% for women experiencing a spontaneous birth, 12% for women experiencing a caesarean for prolonged labour, and 3.4% for women experiencing a caesarean before the onset of labour (elective caesarean) (Groutz et al 2004). These rates support earlier findings of a New Zealand study (Wilson et al 1996). Similarly, an investigation of incontinence at six months post partum found that 9% of women who had a caesarean section reported incontinence, in contrast with 25% of other women (Hvidman et al 2003).

In their review, Baessler and Schuessler (2003) concluded that elective caesarean section might prevent trauma to the anal sphincter but not necessarily the urethral sphincter. The development or presentation of defects in the endopelvic fascia leading to cystocele, rectocele, enterocele or loss of paravaginal support has not been investigated. Furthermore, prospective research is required on the impact of vaginal delivery and intrapartum management on the endopelvic fascia.

Critical thinking exercise

1. How have certain birthing practices affected pelvic floor function? (You may wish to consider the effects of Valsalva 'coached' pushing, birthing positions, and use of traction for controlled cord traction delivery of the placenta.)
2. How might teaching pelvic floor control in pregnancy, not just strengthening exercises (i.e. ability to relax pelvic floor for birth, not just lifting pelvic floor for strengthening), affect postpartum pelvic floor function and other birth outcomes?
3. What is the impact of delayed versus active pushing for women without an epidural?

Inconclusive results are also evident on the effects of operative vaginal birth. The results of some studies have shown that women experiencing an operative vaginal birth are at higher risk of urinary incontinence than women following a spontaneous vaginal birth (Arya et al 2001; Brown & Lumley 1998). However, other studies have not demonstrated this association (Bogossian 2003; Hvidman et al 2003; Thompson et al 2002; Wilson et al 1996).

Urinary incontinence has a complex aetiology due in part to conflicting evidence. There are a large number of associated factors, lack of standardisation in categorising incontinence, and variable measures of duration and severity of symptoms. Rather than examine individual factors associated with the development of incontinence, predictive models of risk are required to promote prevention, early detection and effective treatment.

Postpartum pain

Compared with the intensity of the pain of labour, there has been little acknowledgement of postpartum pain except in the acute postoperative phase following caesarean section or perineal repair. After-birth pain and sore breasts/nipples also fit into the immediate aftermath of birth. Sources of ongoing postpartum pain include damage to the perineum, surgical wound pain following caesarean section, frequent headaches, shoulder, neck and back ache, and haemorrhoids.

The experience of ongoing pain is more common than realised. In a large Victorian survey, 43.5% of participants reported problems with backache 6–7 months post partum (Brown & Lumley 1998). The same study determined that 24.6% of women experienced problems with haemorrhoids 6–7 months post partum. Similar results were identified in a Queensland study, with 24% of women reporting pain from haemorrhoids one year after childbirth (Bogossian 2003).

Perineal pain and dyspareunia

Pain from perineal damage and associated dyspareunia can significantly affect the quality of life for postpartum women. A UK survey of 5404 women experiencing a spontaneous vaginal birth found that 7% of respondents reported perineal pain at three months post partum. Higher levels of pain were statistically associated with mid/upper vaginal lacerations and those women who had third- and fourth-degree perineal tears (Albers et al 1999). Brown and Lumley (1998) found that 21% of women reported problems with perineal pain 6–7 months post partum. Similarly, Bogossian (2003) found that 48% of women reported perineal pain at eight weeks, and 23% at one year post partum. Compared with women having a spontaneous vaginal birth, women who had a forceps or vacuum extraction consistently reported higher levels of postpartum perineal pain (Albers et al 1999; Thompson et al 2002).

Sexual problems and dyspareunia are commonly associated with perineal damage and operative vaginal birth. Brown and Lumley (1998) found that 26.3% of women reported sexual problems 6–7 months post partum. In a large UK study with over one thousand women, 53% of participants reported problems with intercourse at 8–12 weeks. These problems continued, with 49% of women still reporting difficulties in the subsequent year (Glazener 1997). Problems with intercourse were associated with perineal pain for 22% of women. Other concerns affecting sexual activity were tiredness, lack of interest, concerns about soreness or difficulty, worry about another pregnancy, or bleeding.

As with incontinence, prevention of perineal pain is aimed at maintaining perineal integrity during birth. Good general health in pregnancy, antenatal pelvic floor exercises, antenatal perineal massage, intrapartum midwifery care that maximises the chance of an intact perineum, early competent repair of the perineum if damaged, and postpartum pelvic floor exercises, should be part of routine practice. Women with persistent perineal pain or dyspareunia require further assessment and should be referred to a speciality service.

Thromboembolism

Pulmonary thromboembolism (PTE) is a leading cause of maternal death in Australia and New Zealand. PTE arises from deep vein thrombosis (DVT), which is frequently not recognised before PTE occurs. There were six maternal deaths from PTE in the 1997–1999 triennial report on maternal deaths in Australia (Slaytor et al 2004). Two of the six women who died from PTE were delivered by caesarean section; one woman had a spontaneous vaginal birth and the remaining three women died during pregnancy. Based on preliminary hospital discharge data, there is one case of PTE in every 1500 pregnancies and a case fatality rate of 1% (Slaytor et al 2004).

The major risk factors for venous thromboembolism include older age (35 years or older), caesarean section (particularly as an emergency in labour), operative vaginal birth, body mass index (BMI) greater than 29, heritable or acquired thrombophilia, a history of DVT or PTE, gross varicose veins, pre-eclampsia, immobility or a significant current medical problem (Greer 2002). Prophylaxis should be given when risk factors exist (Obstetric Medicine Group of Australasia (OMGA) 2001; Royal College of Obstetricians and Gynaecologists (RCOG) 2004). Postpartum women who have had a caesarean section should be assessed carefully for venous thrombosis.

Emerging issues

Fatigue

Sleep disruption during pregnancy and post partum is nearly universal and is often perceived as normal. However, when it leads to extreme tiredness, fatigue or exhaustion, it is a problem in itself. Sleep disruption may also contribute to other postpartum morbidities such as infection. Feeding and taking care of the newborn account for most sleep disturbances in the postpartum period and are greatest in the first postpartum months, especially for first-time mothers (Gay et al 2004; Moline et al 2003; Thompson et al 2002).

In one study, 60% of women reported problems of exhaustion/extreme tiredness at eight weeks post partum. At 24 weeks post partum this rate had dropped to 49% (Thompson et al 2002). Brown and Lumley (1998) measured problems with tiredness rather than exhaustion/extreme tiredness and found that 69% of women reported problems with tiredness 6–7 months post partum.

Postpartum fatigue is related to low levels of ferritin and haemoglobin (Lee & Zaffke 1999). Women who experienced a caesarean section are more likely to report exhaustion/extreme tiredness than women experiencing a spontaneous vaginal birth at eight weeks post partum (Thompson et al 2002), possibly because of the increase in postpartum pain or greater blood loss at the time of birth. Fatigue may also contribute to emotional distress. Reports of fatigue as early as seven days post partum have been found to be predictive of depression at day 28 post partum (Bozoky & Corwin 2002).

Emotional complications

Childbirth can be associated with a range of short- and long-term emotional consequences. Postnatal depression (PND) is the most prevalent psychological disorder associated with childbirth, but anxiety disorders are becoming increasingly prevalent. This section describes women's experiences of PND and postnatal anxiety disorders. This section also reviews research evidence on treatment of PND and outlines a midwifery model of emotional care.

Childbirth is a complex life event characterised by rapid biological, social and emotional transition. Many women experience significant somatic (physical) and cognitive–affective (thinking–feeling) changes following childbirth, but may not be clinically depressed. Changes in mood may be part of normal postpartum adjustment. The mildest and most common form of postpartum mood change is the baby

blues, which occurs in the first few days post partum and lasts from 24 to 48 hours. Symptoms include weepiness, irritability, insomnia and anxiousness. Prevalence is thought to be around 80%, and so common as to be regarded as a normal reaction resulting from hormonal changes immediately following childbirth. For some women, however, the blues may represent the onset of clinical depression.

The most severe disturbance of mood is puerperal psychosis, which is extremely incapacitating, but relatively rare, occurring in one to two of every 1000 childbearing women (Buist 1996). It is characterised by severe depression with delusions (false ideas not based in reality). The severe disconnection from reality means that women with puerperal psychosis require hospitalisation.

Between the baby blues and puerperal psychosis is PND, affecting around 12% to 19% of childbearing women, and usually occurring within four to six weeks of childbirth (O'Hara 1997; Maternity Centre Association 2004). PND has a similar symptom pattern to that of depression, which can occur at any stage in life. There are differences, however, in the number, type and severity of depressive symptoms reported by postpartum women. In particular, PND is characterised by irritability, anger, low energy levels, loss of interest and feelings of guilt (Buist 1996).

PND often persists for many months but usually remits at around four to six months (O'Hara 1997); however, around 15% to 25% of cases continue for 12 months. A smaller proportion will continue for years, with inadequate treatment probably contributing to chronicity. Women with a first episode of depression following childbirth are less likely to experience depression at other times in their life but are more likely to experience PND with subsequent children. In contrast, women with a previous history of depression are more vulnerable to both childbearing and non-childbearing depressive episodes (Pope 2000).

Risk factors for postnatal depression

There has been considerable research on the factors that place women at risk of developing PND. Predictive risk factors for PND include a previous history of depression, psychological stress during pregnancy, young childbearing age (under 18 years), lack of social support (particularly partner support), stressful life events, and low socio-economic status (Pope 2000). This picture may be further complicated, however, if women experience difficult marital and parenting adjustments in the early postnatal period. Webster and colleagues (2003) completed a Brisbane-based study that identified that women in a violent relationship are at increased risk for PND.

There are significant associations between maternal depression and marital relationship, the partner's level of depression, and the infant's cognitive, emotional and social development. Depression associated with childbearing is particularly important, as the first year of childrearing brings additional responsibilities, personal disruptions and consequences in regards to relationships, loss of income and lifestyle changes.

Reflective exercise

1. How would you describe normal emotional reactions to early motherhood?
2. When would you become concerned about the emotional wellbeing of a new mother?
3. How comfortable would you be talking with a mother about her emotional response to childbirth?

BOX 37.2 Emotional complications

- Baby blues is common, involves mild weeping and anxiety, and occurs between two and 10 days post partum.
- Depression has its onset around two weeks post partum. Enduring symptoms relate to anxiety, sleep and appetite disturbance at 4–6 weeks. Can last for up to 12 months.
- Common presenting symptoms include dysphoria, tearfulness, irritability, sleep disturbances and fatigue.

Anxiety disorders and post-traumatic stress following childbirth

In addition to depressed mood, some women may experience symptoms of anxiety disorders. It has been proposed by some researchers that stress experienced around the time of birth can result in post-traumatic stress disorder (PTSD) (Wijma et al 1997). PTSD is a complex set of anxiety-related symptoms that result from and persist after exposure to extreme stress. According to the *Diagnostic and Statistical Manual of Mental Disorders* (4th edn) (DSM-IV-TR) (American Psychiatric Association 2000), there are explicit criteria that must be fulfilled for a specific time period in determining PTSD (as outlined in Box 37.3). First, the person must have experienced or witnessed an event that involves actual or threatened death or serious injury, or damage to self or others. Furthermore, the person's response should involve intense fear, helplessness or horror. The main symptoms of acute PTSD include persistent re-experiencing of the traumatic event, avoidance of stimuli associated with the event, and emotional numbing, as well as symptoms of increased physiological arousal. Symptoms must last for at least one month and cause impairment in daily life. A diagnosis of PTSD is made when at least one re-experiencing, three avoidance and two arousal symptoms are reported.

An Australian study found that one in three women (33%, $n = 186$) identified a stressful birthing event and reported the presence of at least three trauma symptoms. Twenty-eight women (5.6%) met DSM-IV criteria for acute PTSD (Creedy et al 2000). The findings from this study identified that obstetric intervention and a perception of poor care were

BOX 37.3 PTSD

Diagnostic criteria for post-traumatic stress disorder

A The person has been exposed to a traumatic event in which both of the following were present:
  1 the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or threat to the physical integrity of self or others
  2 the person's response involved intense fear, helplessness, or horror

B The traumatic event is persistently re-experienced in one (or more) of the following ways:
  1 recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions
  2 recurrent distressing dreams of the event
  3 acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on wakening or when intoxicated
  4 intense psychological distress at exposure to internal or external cues that symbolise or resemble an aspect of the traumatic event
  5 physiological reactivity on exposure to internal or external cues that symbolise or resemble an aspect of the traumatic event

C Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three or more of the following:
  1 efforts to avoid thoughts, feelings or conversations associated with the trauma
  2 efforts to avoid activities, places, or people that arouse recollections of the trauma
  3 inability to recall an important aspect of the trauma
  4 markedly diminished interest or participation in significant activities
  5 feeling of detachment or estrangement from others
  6 restricted range of affect (e.g. unable to have loving feelings)
  7 sense of a foreshortened future (e.g. does not expect to have a career, marriage, children, or a normal lifespan)

D Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
  1 difficulty falling or staying asleep
  2 irritability or outbursts of anger
  3 difficulty concentrating
  4 hypervigilance
  5 exaggerated startle response

E Duration of the disturbance is more than one month.

F The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

(Source: American Psychiatric Association 2000, p 468)

associated with the development of PTSD. Given the lifetime prevalence of PTSD for women in the general population of around 4% due to events such as assault, rape and natural disasters, Ayers and Pickering (2001) investigated whether PTSD following childbirth could be a continuation of the disorder in pregnancy. They screened and excluded women suffering from PTSD during pregnancy but still found that 3% of women suffered from PTSD following childbirth and that 1.5% continued to report significant symptoms six months later.

Anxiety disorders such as PTSD and mood disorders such as PND are commonly evoked by stressful events. Many of the anxiety-based symptoms reported by traumatised women, such as avoidance, sleep difficulties, trouble concentrating and preoccupation with the birth, may also be interpreted as symptoms of depression, and need to be delineated. Negative emotional states such as guilt, shame and anger are common in acute anxiety disorders and also associated with depression. After birth a woman may experience guilt or anger about the things she did or did not do. Women may also express feelings that they had let themselves down by not coping with the pain or by requiring more analgesia than anticipated. It is therefore particularly important to examine the symptoms of anxiety in order to understand possible ensuing depression and provide appropriate care and intervention. The case study of Maggie (on p 812) outlines the development of trauma responses in one young woman.

Consequences of postnatal emotional disorders

The consequences of postpartum emotional disorders can be debilitating at a time when a woman has to manage the extra demands of caring for her baby. Depressive symptoms may include impaired concentration and memory deficits, whereas anxious mothers may report unrealistic concern and worry about the baby. The effects of maternal anxiety on mothering are outlined in the case study of Gabrielle (on p 812).

The children of women who suffer from depression can have long-term disturbances to their emotional, behavioural and cognitive development (Righetti-Veltema et al 2003). For example, two-month-old infants of depressed mothers received less appropriate and responsive care, and more negative and rejecting care than babies of non-depressed mothers (Murray & Cooper 2003). Depression may also result in marital problems which, if unresolved, may lead to separation and divorce (Boyce & Stubbs 1994). Importantly, PND can progress to become a chronic condition that is disabling and difficult to treat successfully (Grace et al 2003).

Treatment of PND: review of the evidence

The following section reviews existing research evidence on treatment approaches to postpartum emotional disorders.

Psychological approaches to treatment

Counselling that involves emotional support and education by trained health professionals is a common and effective

Case study

Maggie, a primigravida, was induced using prostaglandin gel at 40 weeks gestation. She subsequently had a Syntocinon infusion, artificial rupture of membranes, epidural analgesia, continuous electronic monitoring and seven vaginal examinations. After a 14-hour labour the baby was delivered by vacuum extraction. Maggie said she needed 'loads of stitches'. Her baby needed resuscitation, had 'massive bruising on his head' and was admitted to the special care nursery. The baby was in a humidicrib for three days, developed jaundice and experienced feeding difficulties. A month later, Maggie still had difficulty sleeping. She experienced flashbacks, remembering 'every gruesome detail, all the fear and other emotions'. She reported being nervous and constantly on guard, especially about the baby, and described fearing that her baby would die or that she would die and her baby would be left motherless. She was anxious about the baby's health and insisted that visitors wash their hands before touching the baby, and sprayed the room with disinfectant when they left. She became so anxious following a news report of two cases of meningitis in another part of the city that she stayed with her mother out of town. Maggie described uncharacteristic angry outbursts and feeling detached or estranged from others for up to three months following the birth.

Case study

At six weeks post partum, Gabrielle reported 'difficulty caring for him [the baby]', and was 'slow to realise things like when he is crying for attention or when my older child is hitting the baby'. By three months she summed this up by saying, 'I am less responsive to him; I have a bonding problem'. She was experiencing symptoms of PTSD such as intense recollections of birth events, difficulty sleeping unrelated to the baby's needs, difficulty concentrating, feeling detached from others, and irritability.

approach to minimise the effects of depression. Women consistently respond positively to opportunities to talk about the birth with a supportive health professional. One study on women's postpartum needs found that 90% of nulliparous women and 79% of multiparous women wanted opportunities to express their feelings about the birth with a midwife (Cooke & Stacey 2003). Although many women want to discuss their feelings about the birth with a midwife, it seems that few women are offered this opportunity. Cooke and Stacey (2003) found that only 42% of primiparous and 20% of multiparous women were offered an opportunity to discuss the birth. Similarly, recent Australian studies reported that only 13.5% of postpartum women were offered an opportunity to express how they felt about the birth to health professionals prior to discharge (Creedy et al 2000; Gamble 2003).

Well-controlled research trials report that PND responds well to treatment in the short term, almost doubling the spontaneous recovery rate (O'Hara et al 2000). In a landmark British study, women in the intervention group received eight weekly, one-hour counselling visits in their own homes by nurses who had received very brief training on non-directive counselling, and who had been told that the women were depressed (Holden et al 1989). The women in the control group received standard care from the same group of health visitors, who had not been told that these women were also depressed. At the end of the intervention, 69% of women were no longer depressed compared with 38% of women in the control group.

The long-term effects of psychological approaches are less clear. In one longitudinal study, nulliparous women were randomly allocated to one of four conditions: routine care, non-directive counselling, cognitive-behavioural therapy and psychodynamic therapy (Cooper et al 2003). Women received a one-hour home visit each week for 10 weeks. Although all therapeutic approaches were initially effective in reducing depressive symptoms (as measured by the Edinburgh Postnatal Depression Scale), by nine months post partum there were no apparent benefits between any treatment group and the control group. Similarly, a 12-month Australian study did not find statistically significant differences between mothers in a counselling intervention and those in control groups (Morse et al 2004).

Given the geographic distances faced by many health services in Australia and New Zealand, other methods of support need to be investigated. Telephone interventions have been used to deliver a range of community health services including the provision of health information, anticipatory guidance and crisis intervention. Increasingly, studies are investigating the effectiveness of telephone intervention as a means of postpartum follow-up. One Canadian study found that women from disadvantaged backgrounds who received a 'telephone visit' by a midwife were more likely to utilise parent–baby support groups than women who received mailed information or a reminder call by a ward clerk (Edwards & Sims-Jones 1997).

Debriefing

Debriefing describes a structured intervention intended to act as primary prevention to mitigate, or at least inhibit, acute stress reactions. There is insufficient evidence at present to draw conclusions about the effectiveness of debriefing following childbirth, primarily because it is unclear whether a standardised debriefing intervention was used in many of the studies (Lavender & Walkinshaw 1998; Priest et al 2003; Small et al 2000). The extent of training or therapeutic skills of the person providing the counselling is not often explained in the literature (Gamble & Creedy 2004). The idea that one simply

'allows the woman to talk' belies the depth of skill involved in facilitating such disclosure. The woman may have very good reasons not to talk; mistrust, lack of rapport, previous experience of being patronised, silenced or disregarded by health professionals may all adversely hinder the therapeutic process. Midwives providing counselling may be effective if the model of care provides time to develop a meaningful relationship with women throughout the pregnancy, birth and recovery, and training to understand and develop these 'listening' skills.

Although there is consensus in the literature about the importance of providing counselling for postpartum women, this does not seem to have been translated into practice. Many studies have been critical of the poor postpartum emotional care provided, and yet women consistently report that the intervention facilitated their postpartum adjustment/recovery (Lavender & Walkinshaw 1998; Priest et al 2003; Small et al 2000). Consumer groups such as Trauma and Birth Support (TABS), based in New Zealand, and Birth Experience Stress and Trauma support group (BEST), in Australia, continue to advocate for women to be provided with opportunities to talk with a supportive person about their birth experience (www.tabs.org.nz/; Yee, BEST Coordinator, personal communication, July 2003).

Response

Little is known about the specific skills of midwives in counselling postpartum women, and it may be that midwives are unsure about exactly what to do in providing counselling in the aftermath of a negative or distressing birth experience (Alexander 1998; Hunter 2001). Several published papers advocate postpartum counselling, but descriptions of how to engage with women in this way are general and non-specific (Gamble & Creedy 2004). Midwives may also be concerned that providing counselling about the birth is ineffective or potentially harmful. Hammett (1997) argued, however, that such concerns may be a reflection of midwives' anxieties in providing debriefing rather than substantiated misadventures.

Pharmacological approaches

There is a paucity of evidence for the treatment of PND using antidepressant medication. In a small, double-blind, randomised controlled trial (RCT) of antidepressant treatment (using nortriptyline or sertaline for eight weeks), depressive symptoms and most measures of functional status of women improved; however, improvement in one dimension did not imply improvement in the other (Logsdon et al 2003). Although participants were assessed after eight weeks of antidepressant treatment, clinical guidelines recommend continuation of antidepressants for six to nine months after remission of symptoms (Wisner et al 2002). Given that most psychotropic drugs are excreted into breast milk, many women suffering from PND prefer not to take them (Whitton et al 1996). Furthermore, there is little available evidence on adverse effects of psychotropic drugs on the infant, and long-term effects are not known (Austin & Mitchell 1998).

Reflective exercise

What are some of the possible reasons that midwives may not provide women with opportunities to discuss their birth experiences?

Combined pharmacological and psychological approaches

There is limited research on different combinations of pharmacological and psychological therapies for PND. Appleby and colleagues (1997) conducted a double-blind RCT of fluoxetine and a psychoeducational program. CREST (Childcare advice, Reassurance, Enjoyment, Support from others, Targets) is an intervention program based on cognitive behavioural counselling and designed for health workers who are not specialists in mental health. Women were randomised to receive either fluoxetine or a placebo, plus either one session or six sessions of counselling for three months. There was significant improvement in all four groups but improvement was greater in women receiving six group sessions as opposed to one, and women receiving fluoxetine showed greater improvement than those receiving a placebo. It is important to note that of the 188 eligible women, 101 refused to participate because they did not wish to take medication, and a further nine women dropped out of the study due to adverse drug effects.

Social support

Social support has long been recognised as playing an important role in the prevention and treatment of depression. Misri and colleagues (2000), in a small Canadian study, offered women a support group of women alone ($n = 13$) or a group with partners ($n = 16$) in comparison with women and their partners in a control group. The intervention groups consisted of seven sessions and partners attended four sessions. In comparison to women who received standard care, women attending either support group had decreased symptoms of depression. Both women and their partners in the intervention groups perceived their relationship more positively, and ratings of general health improved, while those of the control group deteriorated.

An eight-week support program by Morgan et al (1997) offered women ($n = 34$) the opportunity to explore the myths of motherhood, receive information on PND, and challenge negative beliefs through the use of cognitive-behavioural exercises. Partners attended one session and opportunities were provided for women to explain their difficulties, for partners to add their perceptions, couples to discuss issues together, and for group discussion. There was a significant improvement in women's scores for depression, general health and couple satisfaction.

Hormonal approaches to treatment

Currently there is limited evidence of a link between hormones and PND. Lawrie and colleagues (2000) conducted a Cochrane

Review of the role of progesterone and oestrogen in the treatment and prevention of PND. They included only one RCT double-blind study, by Gregoire et al (1996) with women who had severe and chronic PND. The women received either treatment with oestradiol skin patches or placebo patches. Ten out of 35 women dropped out of the study. Although a positive effect was reported, no consideration was given to the influence of the women's menstrual cycle and whether any of the women suffered from premenstrual syndrome. Furthermore, 47% of women in the treatment group and 37% of women in the control group were already taking antidepressant medication, and this was not considered in the analysis.

Critical reflection on the evidence

Despite the relatively high prevalence and negative impact of PND on the mother, her infant, and her social and marital relationship, the quantity and quality of research on the treatment of PND is surprisingly limited. Indeed, a comprehensive review by Boath and Henshaw (2001) identified only 30 studies. While there are good theoretical justifications for many of these treatment approaches, the methodological limitations of these studies means that the efficacy of these approaches have not been clearly established, and there is very little good evidence available on which to make policy and practice recommendations.

Despite the intuitive appeal of a link between a hormonal trigger and PND, there is no evidence to support this. The limitations of the only RCT that has been carried out (Gregoire et al 1996) mean that many questions remain unanswered. There has been no study that has reported the use of only oestrogen on mood. Inevitably, women in such studies have received some form of antidepressant medication or counselling in addition to hormonal treatment.

Antidepressant medication is the most common form of treatment for depression in primary care and there is extensive evidence to support its use in the general population (Clinical Evidence 2000). There are no RCTs of antidepressants alone in the treatment of PND, and clinicians must rely on general recommendations for depression occurring at other times. In the absence of any evidence specifically for women with PND, the ethics of continuing to prescribe antidepressants to postnatal women, particularly in light of the range of unpleasant side-effects such as sedation, weight gain and dry mouth, needs to be considered. These drugs are known to pass through breast milk, and the long-term effects on infants are unknown.

The evidence suggests that cognitive and interpersonal therapy are as effective as antidepressants in treating depression. There is no evidence of a difference between these treatments in terms of long-term benefits, and combining drug and psychological treatments may be more effective in severe, but not mild to moderate depression (Clinical Evidence 2000). Further research is required on whether antidepressants should be prescribed only when counselling interventions have proved ineffective. Clinical trials on the treatment of depression suggest that continuing antidepressant drug treatment for four to six months after recovery reduces the risk of relapse, but we do not know whether this continuation treatment is the same for women with PND.

Implications for practice

Unlike New Zealand, childbirth practices in Australia remain predominantly hospital-centered and highly medicalised. The adverse psychological consequences for birthing women demand changes to maternity care. In particular, there needs to be a continued review to reduce the use of invasive obstetric procedures during labour and birth. It is also necessary to inform women of the incidence of obstetric interventions and associated risks so they can participate more effectively in decision-making.

There is evidence that depression and anxiety disorders are often overlooked in routine clinical practice. If trauma symptoms are not recognised in women with depression then it is likely that counselling approaches will not be provided. Psychological trauma that is not acknowledged and dealt with will manifest in a variety of destructive and negative ways. Women who have not processed the trauma associated with childbirth may experience depression, helplessness, self-destructive behaviours, marital difficulties, anger and hostility.

There is a strong association between women's perception of the helpfulness of the midwife and emotional wellbeing. Having the care of a midwife who is kind, respectful, informative and 'on-side' may be emotionally protective. The relationship may also be enhanced if the woman and midwife come to know and trust each other, as occurs in woman-centred midwifery (where the woman has the same midwife throughout the pregnancy).

The incidence and severity of postpartum emotional distress is of grave concern. Traumatised women may experience emotional numbing and dissociation as a result of the delivery that hinders their ability to engage with the baby and others. Alternatively, women may experience intense emotions that result in feelings of uncontrollable anxiety and an inability to make sense of what has happened. Accordingly, staff should provide opportunities to discuss the birth and try to bring structure to the experiences of the woman in an adaptive, reality-oriented manner. The discussion should involve reviewing the chronology of events, providing an explanation for interventions and procedures, and acknowledging feelings. It may also be necessary for staff to acknowledge issues of poor management and poor affective care. Robinson (1999) claims that women's fears in relation to childbirth are iatrogenic in

Reflective exercise

Given the number of questions surrounding the use of antidepressants and the fact that many women prefer not to take antidepressants, or may refuse medication if it requires stopping breastfeeding, should research concentrate on psychological interventions?

origin and result in women feeling unsafe and powerless. Health professionals need to reflect on their own practices and the service provided to women, and aim to engender more choice and control. As the woman begins to understand the sequence of events during labour and birth, and makes sense of her feelings, she may be able to recapture a sense of fundamental safety and control.

Effective follow-up in the community following discharge is important, as emotional distress is debilitating and may have long-term consequences for the mother, the child and the family. Women at risk of developing acute and/or chronic depression and anxiety can be readily identified prior to discharge from hospital and it is therefore feasible to organise for targeted follow-up of these women. Appropriate referral mechanisms to mental health services should be instituted so that women experiencing emotional distress, which cannot be effectively addressed by a midwife or child health nurse, can receive appropriate care (e.g. psychiatric liaison linked to maternity services).

Meaningful consultation with consumers is still in its infancy (Chambers 2000). Interventions for PND are more likely to be appropriate and effective if they are based on needs identified together with women. Logically, the people who should be involved and consulted are those for whom the interventions are destined. None of the studies reviewed included service users. Women with postnatal depression, together with their partners, should be involved in designing studies and interventions.

Summary: emotional support

Midwives need to acknowledge the unique nature of childbirth for each woman and attend to the emotional aspects of care in order to promote wellbeing.

Review questions

1. What are some of the factors associated with poorer postpartum health?
2. List some of the barriers women face in accessing professional assistance for healthcare.
3. Describe the symptoms and treatment of endometritis.
4. What assessment data would you need to determine whether a woman was experiencing a secondary postpartum haemorrhage?
5. Describe the initial treatment for a woman admitted to hospital via ambulance reporting that she is 12 days postpartum and bleeding heavily.
6. What are the factors that place women at risk for postpartum emotional distress?
7. How would you respond to a woman who seems to have the 'baby blues'?
8. Identify the symptoms of depression.
9. Briefly describe the effect of social support in relation to postnatal depression.
10. Describe best practice in maternity care to specifically prevent emotional distress for postpartum women.

CHAPTER 38

Complications of the newborn

Linda Jones and Annette Wright

Key terms

apnoea, birth asphyxia, cephalhaematoma, chromosomal abnormalities, cleft palate, coagulopathies, congenital abnormalities, congenital dislocation of the hip, cystic fibrosis, cytomegalovirus, exomphalos, galactosaemia, gastroschisis, Group B haemolytic streptococcus, hepatitis, hypoglycaemia, imperforate anus, listeriosis, meconium aspiration syndrome, neonatal jaundice, neural tube defects, oesophageal fistula, phenylketonuria, physiological jaundice, pneumothorax, preterm neonate, rubella, SIDS, sticky eyes, subarachnoid haemorrhage, subdural haemorrhage, talipes, thermal instability, transient tachypnoea of the newborn, undescended testes, vitamin K

Chapter overview

This chapter outlines the common complications of the newborn; it includes preterm birth, jaundice, infections and bleeding in the neonate. In addition, this chapter discusses congenital, cardiorespiratory, metabolic and endocrine disorders that could affect the neonate, and sudden infant death syndrome. It is not within the scope of this chapter to discuss all the neonatal disorders in detail—a brief outline of conditions is given. It is important to remember that, when caring for neonates, midwives must always be prepared for the unexpected in this fragile population.

Learning outcomes

Learning outcomes for this chapter are:

1. To outline the common causes of preterm births and the characteristics of the neonate
2. To describe the problems faced by preterm neonates and give an overview of management
3. To explain the normal physiology of bilirubin metabolism and identify common causes of hyperbilirubinaemia
4. To describe the assessment and management of jaundice
5. To explain the neonatal immune system and its role in preventing infection in the neonate
6. To discuss common neonatal infections
7. To identify the common causes of bleeding in the neonate
8. To explain the aetiology and risk factors for congenital abnormalities, and identify some common congenital abnormalities
9. To describe the most common types of cardiac lesions and their prognosis
10. To discuss some common neonatal respiratory disorders and the various respiratory support measures for a neonate
11. To describe the features of the common metabolic and endocrine disorders
12. To identify the risk factors for sudden infant death syndrome (SIDS), and discuss how to provide clear and accurate information to parents and families on reducing the risk of SIDS.

Preterm neonate

The role of the midwife regarding preterm neonates is in prevention and in assisting parents in identifying the potential risk factors. In the event of a preterm birth, the midwife plays a crucial role in supporting the parents. This section outlines the causes and characteristics of a preterm neonate. The emphasis of this section is on neonatal care, highlighting some of the major problems encountered in the preterm neonate.

Definition and causes

Preterm birth is defined as the birth of a newborn before 37 weeks gestation, occurring either spontaneously or after being induced for maternal or fetal health problems. This group of neonates provide the majority of work in neonatal units. The incidence of preterm birth varies from one part of the country to another and depending on the ethnic group. In 2000, the rate of neonates born at less than 32 weeks gestation was 2.23% of live births in Australia, and 3.43% of live births in New Zealand. Overall survival for preterm neonates at more than 28 weeks gestation is 92%, a figure that has remained constant since 1998 (ANZNN 2002).

The gestational age at which a preterm neonate is considered viable has been falling in recent years. Current technology and care offer considerable hope for neonates born at 24 to 25 weeks gestation. Neonates as young as 22 to 23 weeks gestation can now be saved by the intensive care facilities currently available. Obviously, the earlier the gestational age at birth, the greater the risk of neurological deficits in those neonates who survive. Current evidence indicates that 90% of neonates born at 26 to 28 weeks gestation will develop into normal, healthy children (Johnston et al 2003).

The cause of spontaneous preterm births is unknown in 40% of cases; however, there are certain predisposing antenatal factors, including:

- poor socio-economic status
- pre-eclampsia
- infection
- smoking, substance abuse or alcoholism in pregnancy
- antepartum haemorrhage
- overdistension of the uterus—multiple pregnancies, polyhydramnios
- fetal development abnormalities
- maternal age < 20 years or > 35 years
- serious maternal diseases—acute or chronic, such as pyelonephritis, chronic nephritis or essential hypertension
- cervical incompetence
- poor obstetric history
- short maternal stature
- primiparity (Henderson & Macdonald 2004; Johnston et al 2003).

Characteristics

Preterm neonatal characteristics will depend on the gestational age at birth. Generally speaking, preterm neonates have a head circumference that exceeds that of the chest. In turn, the chest tends to be relatively small and narrow, with no breast tissue. The face of the preterm neonate is triangular, with a pointed chin, and the fontanelles and sutures are widely spaced due to poor ossification. Ears in the preterm are easily folded, lacking firmed cartilage. Also, the length of the trunk in proportion to the limbs is greater in the preterm than in the term neonate. The skin in the preterm is pinkish red with prominent surface veins due to the absence of subcutaneous fat. Fine hair, or lanugo, on the face and trunk is more plentiful in the preterm, as is the protective creamy white substance known as vernix. The limbs are thin, with decreased muscle tone, and the nails are soft. With neonates of less than 34 weeks gestation, the creases in the feet are almost absent. In the preterm female, the labia minora are prominent and gaping, and the male usually has incompletely descended testes. In addition, the suck-and-swallow reflex is uncoordinated in preterm neonates.

Assessment

Many scoring systems have been developed over the years in order to estimate the gestational age of the neonate. These scoring systems require a complete and careful examination of the neonate. The scoring system examines characteristics such as appearance, and reflexes that give an indication of whether the neonate is small or preterm. The two most commonly used scoring systems are the Dubowitz and, more recently, the Ballard, an adaptation of the former.

Labour and birth care

In most cases it should be possible to diagnose the onset of preterm labour early enough to ensure that the birth occurs in a maternity unit containing the necessary neonatal services and thus avoid the greater hazard of transfer after birth. During a preterm labour, the midwife should avoid giving narcotics to the woman, in order to prevent respiratory depression in the neonate at birth. All resuscitation equipment must be checked and ready before the birth. It is important that an experienced neonatologist and midwife be present at the birth of the preterm to ensure immediate and expert resuscitation. Cold stress at birth must be prevented, as this increases neonatal oxygen requirements. The neonate, therefore, must be dried quickly and thoroughly with warm towels and placed under a radiant heater immediately after birth.

Specific preterm problems

The preterm neonate is unable to adequately perform many physiological functions, due to immaturity. The aim of neonatal care is, therefore, to compensate and support these deficiencies until support is no longer needed. The main problems are:

- *birth asphyxia*—can occur if there is any disruption to the oxygen supply prior to or during birth, due to reduced energy reserves of the preterm neonate
- *thermal instability*—preterm neonates have little or no

brown fat stores to maintain their core temperature. In addition, preterm neonates have a larger surface area relative to their size, with thin skin, which facilitates rapid heat loss. Those born at less than 30 weeks gestation also have porous skin, allowing evaporation of fluids. The aim of care, therefore, is to maintain body temperature within the thermoneutral range, thus reducing energy and oxygen requirements.

- *diminished primitive survival reflexes*—these include the suck, swallow and gag reflex
- *jaundice*—physiological jaundice in preterm neonates is exacerbated due to an immature liver, resulting in delayed conjugation of bilirubin. This will be discussed in more detail later in the chapter.
- *respiratory diseases*—this is the most common problem experienced by preterm neonates, and is exacerbated by younger gestation. Preterm neonates have weak muscles and immature respiratory control. It is not uncommon for the preterm neonate to breathe well initially, later developing expiratory grunt, apnoeic episodes and cyanosis, requiring respiratory support. Respiratory conditions experienced by preterm neonates are discussed later in this chapter; they include apnoea, hyaline membrane disease, transient tachypnoea of the newborn, pneumothorax, pneumonia and bronchopulmonary dysplasia.
- *metabolic disturbances*—these include hypoglycaemia, hypocalcaemia, hypomagnesaemia, hyponatraemia and hypokalaemia
- *patent ductus arteriosus*—the ductus arteriosus fails to close in very preterm neonates due to immaturity and as a consequence of the chemical imbalance that results from hypoxia and ventilation perfusion mismatching. Closure of the ductus is usually achieved by a course of indomethacin, with surgical ligation sometimes being necessary.
- *neurological problems*—these include intracranial haemorrhage, the risk factors for which include poor skull ossification, fragile blood vessels and episodes of hypotension, hypertension or hypoxia
- *susceptibility to infection*—this is increased due to low maternal IgG levels, less efficient skin barrier, fewer immune cells, and being subjected to more invasive procedures and multiple caregivers
- *gastrointestinal intolerance and necrotising enterocolitis (NEC)*—NEC is an inflammatory disease of the bowel usually associated with septicaemia
- *ophthalmic problems*—these include retinopathy of prematurity, with the major risk factor being excessive oxygen exposure or fluctuating quantities; myopia; and strabismus
- *surgical lesions*—including the possibility of undescended testes, inguinal and umbilical herniae
- *haematological problems*—this includes haemorrhagic disease of prematurity due to accentuation of the normal neonatal deficiency of vitamin K-dependent clotting factors; and iron deficiency anaemia resulting from frequent blood sampling, often requiring a transfusion of packed red blood cells
- *renal immaturity*—inability to concentrate urine and excrete an acid load, resulting in late metabolic acidosis (Henderson & Macdonald 2004; Levene et al 2000).

Clinical point

There is a growing body of evidence regarding management of painful procedures in neonates with use of breastfeeding (Carbajal et al 2003) and sucrose (Gibbins et al 2002; Gradin et al 2002) to help reduce the pain experienced by the neonate during these procedures.

Nutrition

Fetal sucking is seen as early as 13 weeks gestation (Hafstrom & Kjellmer 2000). Suck-swallow coordination, however, is not efficient until nearer term. Preterm neonates of less than 34 weeks gestation are, therefore, usually fed via an orogastric or nasogastric tube (Levene et al 2000). Breast, cup or bottle feeds may be tried, depending on the gestational age and the responses of the preterm. Feeding is usually necessary every one, two or three hours, as preterm neonates have small gastric capacity and to prevent respiratory compromise from a full stomach. Whenever possible, breast milk is the feed of choice, as it is tailor made to the neonate's requirements (Blackburn 2003). A very preterm, ventilated or sick neonate may require parenteral fluids, as milk in the stomach increases the respiratory effort (Henderson & Macdonald 2004).

Neonatal intensive care environment

The neonatal intensive care environment is busy, bright, noisy and harsh for the preterm neonate. In recent times, developmental care programs have been initiated in many neonatal units in an attempt to minimise many of these insults on the preterm neonate. This includes such measures as clustering of nursing activities or minimal handling, positioning, creating a night pattern in the day, and minimising noise (Johnson 2003), and the involvement of parents in the care of their neonate as much as possible (Israel 2003), including the use of massage (Yellott 2001). The aim of developmental care is to decrease respiratory effort, achieve acceptable growth patterns, decrease length of hospital stay and improve neurological outcomes. All these objectives appear to have been achieved (Symington & Pinelli 2003).

Neonatal jaundice

Jaundice can potentially affect a large number of term as well as preterm infants and its management therefore is an important part of the day-to-day role of the midwife. This section examines only the main causes of jaundice in the neonate as well as the assessment and management of these.

Physiology of bilirubin metabolism

When red blood cells age, or are immature or malformed, they are removed from the circulation and broken down in the reticuloendothelial system (liver, spleen and macrophages). Haemoglobin is broken down to form:

- *haem*, which is converted to unconjugated bilirubin
- *globin*, which is broken down into amino acids, and then used by the body to make proteins
- *iron*, which in turn is either stored by the body or recycled to make new red blood cells.

Two forms of bilirubin are found in the body.

- *Unconjugated bilirubin* cannot be excreted easily from the body via urine or bile, as it is fat-soluble. The fat-soluble unconjugated bilirubin is deposited in the connective tissue of the skin, with excess levels giving rise to the characteristic skin yellowing. Unconjugated bilirubin is transported to the liver, linked to albumin for processing. Being fat-soluble means that unconjugated bilirubin has the potential to cross the blood–brain barrier and enter the brain cells to cause kernicterus (discussed in detail later in this section).
- *Conjugated bilirubin* has been processed by the liver to become water-soluble, and can then be easily excreted from the body, through faeces mainly, and urine. Some conjugated bilirubin is hydrolysed back to unconjugated bilirubin in the colon. This unconjugated bilirubin is then absorbed across the intestinal mucosa into the capillaries.

Physiological jaundice

Physiological jaundice is a normal state that occurs in 50% of term neonates as a consequence of the transition from intrauterine to extrauterine life (Fraser & Cooper 2003) and 80% of preterm neonates (Levene et al 2000). Hypoxia is the stimulus for red blood cell (RBC) production. Hypoxia leads to release of erythropoietin, which stimulates RBC production. At birth, the neonate is exposed to air breathing, with a higher oxygen level, and therefore the stimulus to release erythropoietin is reduced. Neonatal RBCs have a shorter lifespan than adult RBCs, and preterm neonates even shorter. During the first three to four months following birth, destruction of RBCs exceeds production. This increased destruction leads to increased bilirubin load on the immature liver. Characteristically, physiological jaundice never appears before 24 hours of age, peaks on day 3, and usually resolves by one week, with serum bilirubin levels not exceeding 200–215 μmol/L. The neonate with physiological jaundice is usually well, though not as alert as normal. Physiological jaundice may be exacerbated by:

- increased bilirubin production—polycythaemia, bruising
- decreased albumin-binding capacity—acidotic neonate, competition from some drugs (e.g. gentamycin)
- decreased bilirubin excretion—delayed feeding or poor feeding, resulting in delayed intestinal transit and delayed stooling
- sepsis in the neonate.

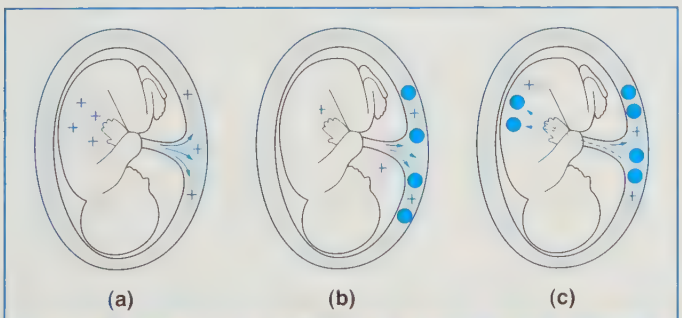

Figure 38.1 Antibody formation. **(a)** Transfer of Rhesus antigen (+) to the maternal circulation. **(b)** Antibody formation (●) in the Rhesus-negative mother. **(c)** Transfer of Rhesus antibody to the fetus (based on Henderson & Macdonald 2004)

Unconjugated hyperbilirubinaemia

Increased red cell breakdown, or haemolytic disease of the newborn, describes the immune-mediated red cell breakdown that occurs in Rhesus disease and ABO incompatability. The maternal immune system can become sensitised to fetal RBC. Usually this sensitisation process occurs in a previous pregnancy, during which fetal blood cells entered the maternal circulation; or it can occur following a blood transfusion and ABO incompatability.

Rhesus disease can occur when an Rh-negative woman is pregnant with an Rh-positive fetus. During pregnancy or birth, small amounts of fetal Rh-positive blood may cross the placenta and enter the maternal circulation. This triggers a reaction by the women's immune system to produce anti-D antibodies, resulting in sensitisation. Then, in a subsequent pregnancy, the antibodies cross the placenta and destroy fetal RBCs.

At-risk women and neonates can be identified by assessing maternal and cord blood after birth in order to identify the blood group and perform a Coombs' test on the neonate. The Coombs' test identifies the level of maternal antibodies in the neonate's blood. A Kleihauer test is also undertaken to identify the number of fetal cells in the maternal blood.

The overall aim of care with Rh-negative women is to prevent Rh isoimmunisation from occurring, by administering anti-D immunoglobulin to women at risk. This prevention process has changed considerably in recent years, following the results of a Cochrane Review (Crowther & Keirse 1999). The current regimen recommended by CSL (2002) is that all primigravida Rh-negative women should receive Rh D immunoglobulin injections at 28 and 34 weeks gestation and within 72 hours following the birth of an Rh-positive neonate. In addition, Rh D immunoglobulin should be given to Rh-negative women following any sensitising events, such as miscarriage, termination of pregnancy, ectopic pregnancy, amniocentesis or chorion villus sampling, external cephalic version, abdominal trauma, antepartum haemorrhage or fetal death in utero.

Other causes of unconjugated hyperbilirubinaemia include:

- glucose-6-phosphate dehydrogenase (G6PD) deficiency—x-linked (male-affected); increased incidence in people of Mediterranean and Asian descent; strong correlation between maternal infection, taking a variety of drugs, and eating fava beans; possible trigger is G6PD deficiency (Henderson & Macdonald 2004)
- hereditary spherocytosis
- septicaemia and TORCH infection
- twin-to-twin transfusion
- dehydration
- delayed passage of meconium
- hypothyroidism
- galactosaemia
- infant of a diabetic mother (Merenstein & Gardner 2002)
- breast milk jaundice.

Kernicterus is a complication that may result from excessive levels of serum unconjugated hyperbilirubinaemia in the neonate. The term 'kernicterus' describes the yellow staining of the basal ganglia noted on postmortem. This condition presents in the affected neonate as a progressive development over 24 hours of lethargy, rigidity, opisthotonos, high-pitched cry, fever and convulsions. Fifty per cent of affected neonates will die, with survivors developing some level of brain damage, resulting in cerebral palsy, deafness, developmental delay and paralysis of upward gaze (Henderson & Macdonald 2004; Levene et al 2000). The development of kernicterus is influenced by the rate at which the unconjugated bilirubin level rises, as well as the level it reaches.

Assessment of jaundice

Jaundice is defined as levels of serum bilirubin of 85–100 μmol/L. The most common method of determining the level of jaundice is to use Kramer's rule (Kramer 1969). This technique involves assessing the skin of the neonate to determine how much of the body is jaundiced. The more zones of the neonate's skin that are affected, the greater the level of jaundice (Fig 38.2).

The Kramer's rule assessment may be undertaken in conjunction with transcutaneous measuring devices. Transcutaneous measuring devices have been shown to correlate well with serum bilirubin measurements (Rubaltelli et al 2001), which is the next level of total bilirubin measurement. Further investigations to establish the cause of the jaundice should be undertaken in the following circumstances:

- neonate who is visibly jaundiced in the first 24 hours
- jaundiced neonate whose mother has Rhesus antibodes
- preterm neonate whose serum bilirubin exceeds 200 μmol/L
- neonate who has clinical signs of obstructive jaundice
- prolonged hyperbilirubinaemia of greater than one week in term and two weeks in preterm neonates.

A thorough investigation of the jaundiced neonate would also take into consideration the pregnancy history, and the gestational and neonatal age. In addition, it is important to note the racial origins of the parents (see G6PD deficiency above) and the use of medications. The assessment would also include a physical examination of the neonate and laboratory investigations.

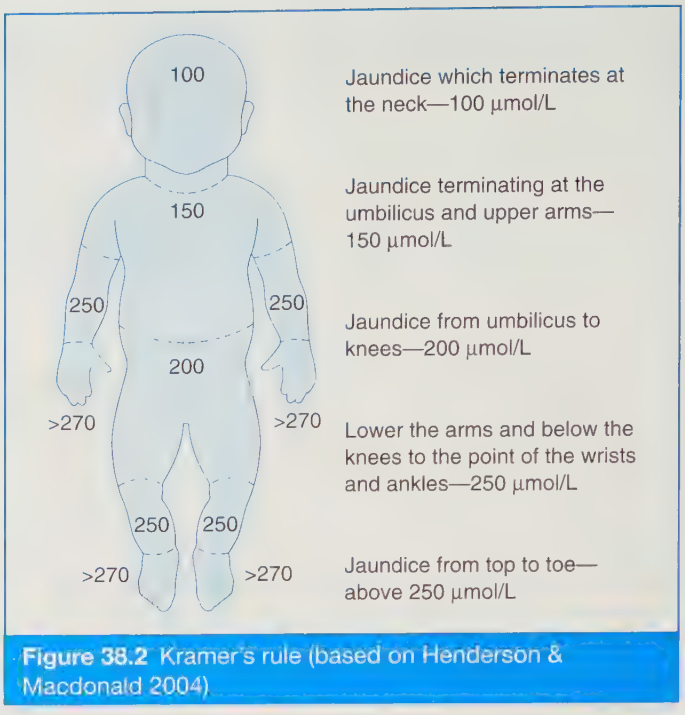

Figure 38.2 Kramer's rule (based on Henderson & Macdonald 2004)

Management

Effective, frequent and early breastfeeding assists the neonate by providing hydration, supplying glucose to the liver, encouraging normal bowel colonisation and increasing bowel motility. Supplying glucose to the liver assists in the production of enzymes needed for conjugation. Increasing the bowel motility in turn decreases the time that bilirubin stays in the gut and thereby decreases enterohepatic reabsorption. General supportive measures in the treatment of jaundice may include the correction of dehydration and the administration of antibiotics if septicaemia or TORCH infections are noted to be the cause.

Phototherapy

Phototherapy is the use of blue light to enhance bilirubin excretion by photochemically converting unconjugated bilirubin into water-soluble bilirubin, which can be excreted through the kidneys. Phototherapy may be intermittent or continuous, and aims to prevent unconjugated bilirubin from reaching neurotoxic levels in the blood. Phototherapy is delivered through the use of either conventional overhead units or a fibreoptic pad (biliblanket) or a bilibed placed around the neonate. In all instances, the entire skin surface of the neonate must be exposed to the light. There are a number of considerations of care in the use of overhead phototherapy units:

- temperature control of the environment

- loose stools due to decreased intestinal transit time, resulting in increased fluid loss
- risk of dehydration
- eye protection—risk of retinal damage from high-intensity light
- disruption of maternal–neonatal interaction
- maternal anxiety.

The use of phototherapy makes it impossible to assess the level of jaundice by examining the skin alone, and therefore serum bilirubin measurement should occur, usually twice daily. If phototherapy fails to reduce the serum bilirubin levels sufficiently, an exchange transfusion may be performed in order to prevent kernicterus. An exchange transfusion involves removing the blood of the neonate, which contains maternal antibodies and bilirubin, and replacing it with fresh, Rhesus-negative blood.

Neonatal infections

The potential impact of a neonatal infection cannot be overstated, as it can very quickly affect the neonate and be fatal. The midwife's role is in prevention, early detection and prompt management of neonatal infections, and in providing support for the parents. This section gives an overview of neonatal defences, followed by a discussion of the main prenatal, perinatal and postnatal infections.

Neonatal defences

Neonates are prone to a higher incidence of infection, due to their immunodeficiency compared with older children. Maternal immunoglobulin (IgG) is able to cross the placenta from 32 weeks gestation, and this confers limited passive immunity to the neonate against specific viral infections. Neonates born before 32 weeks, therefore, are more susceptible to infection. Breast milk, particularly colostrum, is rich in IgA and interferon, enhancing resistance to enteric infections in the neonate through passive immunity. In addition, breast milk may actively stimulate the immune system of the neonate (Oddy 2001) as well as providing passive immunity through IgD, lactoferrin, *Lactobacillus bifidus* and lysozyme, an anti-infective agent (Henderson & Macdonald 2004). Neonates have limited passive and active immunity—prevention, early detection and prompt treatment of neonatal infection are crucial.

Prevention of infections

In utero

The first line of defence that midwives can direct to women is the use of vaccinations known to prevent conditions that can affect the fetus, such as hepatitis B and rubella. The next level of prevention is the sensitive screening and identification of risk factors for infections in women, such as sexually transmitted infections and HIV. The final line of defence is through health education of women to decrease the risk of infection by avoiding: high-risk foods (e.g. soft cheeses); high-risk lifestyle/behaviour (e.g. not using condoms, needle sharing); countries or areas with high prevalence of some infections; and contact with people who have infectious diseases. When an infection does occur, timely and appropriate management of the women is crucial.

Handwashing

The most important means of preventing infection in the neonate is careful and frequent handwashing with soap. The impact of handwashing alone should not be underestimated. Carers should wash their hands with soap before and after handling each baby, particularly after nappy changes, to reduce the incidence of cross-infection. Use of alcohol-based hand-rub solutions has been shown to also be effective in preventing infection and to increase compliance in busy units (Fraser & Cooper 2003; Girou et al 2002). Recent work has examined the increased risk of infection with carers who wear rings, watches, false nails and nail polish.

Equipment

Equipment should be provided for each neonate. Any shared equipment should be thoroughly cleaned between uses. Feeding equipment should be effectively sterilised before use and milk should be appropriately prepared and stored.

Environment

Strategies to significantly reduce cross-infection risks in neonatal units include adequate spacing of cots and rooming-in with the mother. Neonates or mothers with a known contagious disease should be isolated. Likewise, visitors who have infections should be discouraged from entering the unit.

Invasive procedures

Keeping invasive procedures to a minimum can further reduce the risk of infection in the neonate. When invasive procedures are undertaken, strict aseptic techniques and gloves should be used. Strict attention given to wound care following the invasive procedure will also help reduce the risk. Undertaking the procedure with great care will help prevent the necessity for a repeated attempt.

Prenatal infections

Certain protozoa and viruses are small enough to cross the placenta and cause teratogenic effects and infection. The acronym TORCH (toxoplasmosis, other, rubella, cytomegalovirus and hepatitis) lists some of these.

Toxoplasmosis

Toxoplasmosis is caused by a protozoan found in uncooked meat, and in cat and dog faeces. Risk factors include eating uncooked meat, having a pet cat or dog, poor hand hygiene, contact with soil, travel outside Western countries, and frequent consumption of raw vegetables outside the home (Cook et al 2000). Congenital infection with toxoplasmosis is rare in Australia (Levene et al 2000). Preventative advice to

Clinical point

The evidence suggests that there is a strong association between the practice of placing toys in the micro-environment of neonates in intensive care, and neonatal infections (Hanrahan & Lofgren 2004).

women by the midwife is essential, including advice on hygiene and safe preparation of food.

Adults with toxoplasmosis are usually asymptomatic or experience flu-like symptoms. Anti-toxoplasmosis IgM antibodies would be detected in the blood of infected women. Transmitting the infection to the fetus between 10 and 24 weeks gestation can result in intrauterine death and subsequent miscarriage. Infections in the third trimester are more likely to be transmitted to the fetus. The infected neonate may present with low birthweight, hepatosplenomegaly, jaundice, anaemia, blindness, intercranial calcifications, cerebral ventricular dilation and deafness.

Other infections

Syphilis

Syphilis rates are increasing worldwide, with antenatal screening of all women recommended to detect, treat and prevent congenital syphilis (WHO 1991). Fetal infections occur in the second trimester of pregnancy (never before 16 weeks gestation) and can result in miscarriage, stillbirth, preterm birth or congenital syphilis. Infected neonates may present with hepatosplenomegaly, skin lesions, maculopapular rashes, eye infection, persistent snuffles, jaundice and widespread metaphysical bony lesions.

Varicella zoster

Varicella zoster is a highly contagious virus that is responsible for chickenpox infection. If contracted during the first trimester of pregnancy, congenital varicella syndrome occurs in 2–5% of neonates, resulting in possible neurological damage and skeletal abnormalities. Maternal infection between seven days prior and 28 days after the birth is more serious, with up to 25% of neonates developing the infection, with possible complications of renal disorders and pneumonia (Henderson & Macdonald 2004; Levene et al 2000).

Listeriosis

Listeriosis is caused by a Gram-positive bacterium found in certain foods. It causes non-specific, flu-like symptoms in the woman if contracted. Intrauterine infection results in spontaneous miscarriage or stillbirth in 20% of cases, and preterm labour and amnionitis may occur in the remainder. Neonatal infections result in severe pneumonia, general sepsis and meningitis, accounting for a 50% mortality rate. Those neonates who survive have significant handicaps (Henderson & Macdonald 2004).

Rubella

Rubella vaccination programs for infants and women of childbearing age are readily available. All women are screened antenatally for rubella antibodies. Infections in the first trimester of pregnancy have the most effect, with the fetus developing viraemia. The earlier the gestation (< 8 weeks), the more likely it is that the fetus will be affected (Levene et al 2000). Viraemia inhibits cell division and causes defects of the developing organs, specifically the eyes, ears, and cardiovascular and nervous systems. Spontaneous miscarriage may occur. Women in this situation require a great deal of information and support, and some may request a termination. Infected neonates are highly infectious, excreting rubella virus in the urine for up to 12 months. Isolation of these neonates is therefore crucial. Preventative advice from the midwife is essential, emphasising the importance of the women avoiding contact with rubella during pregnancy. After 20 weeks gestation, congenital infection of rubella does not occur.

Cytomegalovirus

Cytomegalovirus is a common perinatal infection, occurring in 0.4–2.3% of all births (Witters et al 2000), the rate of in-utero transmission increasing with gestational age. The risk of transmission during birth or breastfeeding is minimal. Infection in the woman results in flu-like symptoms and possible severe abnormalities in the fetus, including eye and ear defects, hepatitis, thrombocytopenia and meningoencephalitis. Neonatal mortality of 20–30% results from disseminated intravascular coagulation, sepsis or liver problems, with survivors having severe neurological deficits. Isolation of these neonates is crucial as they remain infectious for many months, secreting the virus in the urine.

Hepatitis

Hepatitis infections in the neonate may occur from in-utero transfer or during birth. The currently identified hepatitis viruses are A, B, C, D, E and G. In-utero transfer of A and E are rare but can result in fetal abnormalities. Pregnant women who are chronically infected with hepatitis B may have a neonate who is positive for the hepatitis B e antigen. This neonate will in turn have an 80–90% risk of being chronically infected with hepatitis B (Shiraki 2000). The midwife's role is in antenatal education, screening and ensuring that the neonate receives a hepatitis B vaccination within 12 hours of birth. Currently, all women receive information on hepatitis B vaccinations, including the follow-up injections at six weeks and three months of age. All women are then offered the vaccination following birth.

Hepatitis C is common among intravenous drug users and in-utero transfer rates are approximately 5%, and higher if also HIV-positive (10%), resulting in liver cirrhosis, carcinoma, failure and death. The midwife's role is in antenatal education and screening of all women. During labour and birth, transmission can be minimised by avoiding invasive procedures such as artificial rupture of membranes.

Perinatal infections

It is often difficult to decide at birth whether a neonate is infected or not. Important points to consider are:

- evidence of maternal sepsis
- membranes ruptured for longer than 18 hours
- length of labour greater than 12 hours
- number of vaginal examinations undertaken
- instrumental birth
- presence of fetal distress or birth asphyxia.

All these factors increase the risk of a neonatal infection. Signs of neonatal infection include lethargy, vomiting, diarrhoea, jaundice, mild respiratory difficulty, pyrexia, hypothermia, hypotonia, irritability, poor feeding, weak cry, abdominal distension, failure to thrive, rashes, purpura, respiratory distress, shock and renal failure.

Group B haemolytic Streptococcus

Group B haemolytic Streptococcus (GBS) is one of the most common causes of early-onset perinatal infection in industrialised countries, affecting 1–4:1000 births and fatal in 20% of cases. Approximately 12–15% of Australian women are asymptomatic vaginal carriers of GBS (NSW Health Department 2002). Vertical transmission at birth is the process by which neonates acquire the infection, occurring in approximately 10% (Levene et al 2000). The neonate then suffers from either early or late onset of disease. Early onset typically presents with symptoms of septicaemia, respiratory distress and septic shock, which will rapidly detoriate to be fatal if untreated. Late onset presents as meningitis after five to seven days.

Postnatal infections

Mild eye infection

Mild eye infections (sticky eyes) are common in neonates and can be treated with routine eye care, colostrum and antibiotics, if required for aggressive infections. Eye care involves the use of cool, boiled water or sterile saline and cotton wool swabs, cleaning the eye from inner to outer aspect once, and discarding the swab. Hand washing before and after eye care is also important.

Clinical point

The incidence of early-onset Group B streptococcal disease in the neonate was found to be reduced from 3.5 to 0.6 per 1000 live births following universal screening and intrapartum antibiotics for all maternal carriers (Jeffery & Moses 1998). This is supported by later work (Gilbert 2004; Oddie & Embleton 2002), which emphasised the importance of the use of prophylaxic antibiotics with women who have identified risk factors, such as prolonged rupture of membranes, rupture of membranes before the onset of labour and intrapartum fever. A conclusion reached from another study indicated that routine screening for GBS during pregnancy prevents more cases of early-onset disease in the neonate than the risk-based approach (Schrag et al 2002).

Skin infections

Skin infections are mostly caused by *S. aureus*, resulting in septic spots or pustules, located either as solitary lesions or clustered in the umbilical or buttock regions. Treatment involves regular cleaning and antibiotics if more extensive.

Umbilical infections

Umbilical infections are rare, and with good standards of hygiene can be prevented. Signs of infection include inflammation, a moist, offensive-smelling cord, and delay in separation. The most common organism responsible is *S. aureus*. Antibiotics are required as there is a risk of transportation through the umbilical vein to the liver, causing hepatitis and septicaemia. Prevention with good care and monitoring is best.

Urinary tract infections

Urinary tract infections can be caused by *E. coli* or may result from a congenital abnormality obstructing the flow of urine. Signs of infection include non-specific symptoms such as feeding difficulties, failure to thrive, occasionally pyrexia and jaundice. Management involves undertaking a urine culture and administering appropriate antibiotics.

Neonatal bleeding

This section discusses the main causes of neonatal bleeding, including those due to trauma, coagulopathies and other causes.

Bleeding due to trauma

Cephalhaematoma

Cephalhaematoma is bleeding that occurs between the periosteum and the skull bone as a result of friction, usually between the skull and the pelvis. A cephalhaematoma may also occur during a forceps or vacuum birth. The bleeding results in a separation of the periosteum from the underlying bone and subsequent bleeding. This bleeding is therefore confined to the area of the skull bone contained by the periosteum layer (see Fig 38.3).

A cephalhaematoma:

- appears 12–72 hours after birth
- tends to enlarge after birth
- usually affects the parietal bone
- is circumscribed, firm and does not pit on pressure
- may be bilateral
- may contribute to jaundice
- can persist for weeks, slowly subsiding.

Subdural haemorrhage

Subdural haemorrhage occurs due to excessive compression or abnormal stretching of the fetal head. This results in

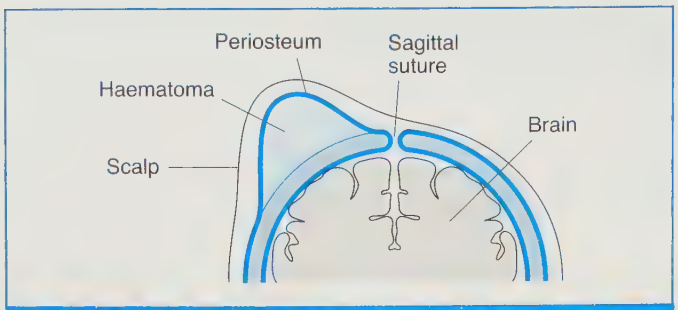

Figure 38.3 Cephalhaematoma (based on Henderson & Macdonald 2004)

tearing of the dura, and rupture of the venous sinuses. Predisposing factors for a subdural haemorrhage include situations in which the moulding is rapid, abnormal or excessive, such as from precipitate labour or rapid birth, malpositions, malpresentations, cephalo-pelvic disproportion or undue pressure from forceps application. Tearing of the tentorium (tentorial tear) results from these events, followed by cerebral haemorrhage. The neonate presents with signs of cerebral irritation and raised intracranial pressure, such as tense, expanded fontanelle, asphyxia, abnormal eye movements, vomiting, non-responsiveness and convulsions. Its incidence has decreased somewhat owing to a reduced use of high and mid-cavity forceps, prolonged labours and a simultaneous increase in caesarean births.

Bleeding due to disruptions in blood flow

Subarachnoid haemorrhage

A primary subarachnoid haemorrhage is bleeding directly into the subarachnoid space. This occurs in response to hypoxia or trauma in preterm or term neonates and is a common, benign condition. A secondary subarachnoid haemorrhage, however, is caused by leakage of blood from an intraventricular haemorrhage into the subarachnoid space. The neonate with subarachnoid haemorrhage is usually asymptomatic, but may present with convulsions and apnoea, and is neurologically normal.

Bleeding due to coagulopathies

Vitamin K deficiency bleeding

Vitamin K deficiency bleeding was previously termed 'haemorrhagic disease of the newborn' and occurs in 0.4–1.7% of neonates in the first week of life (Merenstein et al 1993). This bleeding is due to an accentuated deficiency of normal neonatal vitamin K dependent clotting factors. Vitamin K is poorly transferred across the placenta, resulting in low fetal levels that are quickly depleted after birth. Synthesis of vitamin K occurs in the bowel flora, which is restricted until colonisation occurs, as the neonate's bowel is sterile. Colonisation does not occur until feeding has been established, making neonates susceptible to vitamin K deficiency bleeding. The amount of vitamin K in breast milk is low, though colostrum and hind milk contain the highest amounts (Enkin et al 2000). Milk from cows has a higher, though still low, level of vitamin K. Formula milk is fortified with vitamin K, offering some protection.

Vitamin K deficiency bleeding is classified according to its onset:

- Early-onset occurs within the first 24 hours. It is rare, seen in neonates of women prescribed certain medications, including vitamin K antagonist anticoagulants (warfarin) and some anticonvulsants (phenobarbital or phenytoin). Women should be asked antenatally if they are taking these medications and alternatives prescribed if possible. Otherwise, women require vitamin K supplementation towards the end of pregnancy. Administering neonatal vitamin K will not prevent it.
- Classic occurs one to seven days after birth. It is preventable by the administration of the recommended schedule of vitamin K at birth (Puckett & Offringa 2002).
- Late-onset occurs 8–12 months after birth. This type of bleeding presents as intraventricular or pulmonary haemorrhage in mostly exclusively breastfed neonates. The morbidity rate is reported to be as high as 33% (Bor et al 2000).

The recommendation is that all neonates at birth receive prophylactic vitamin K, although the optimal route, dosage and frequency of administration are still subject to great debate (Autret-Leca & Jonville-Bera 2001). Such is the debate that some question whether vitamin K is needed. This may be because of the evidence indicating that neonates who do not breastfeed effectively, frequently and early are at increased risk of bleeding (Hey 2003). The areas of contention are the efficacy of prophylaxis for the different categories (described above), the most efficient administration for at-risk neonates, and the possible link between intramuscular administration and a potential increased risk of childhood leukaemia (Roman et al 2002). Subsequent studies have disputed this link (Hull 1992; Merenstein et al 1993; Puckett and Offringa 2002). It is the role of the midwife to discuss this issue with parents, giving them all the information and gaining their consent.

The alternatives available to parents are: no prophylactic administration of vitamin K at birth; oral vitamin K at birth, repeated at 3–5 days and again at 4–6 weeks for breastfed neonates; or a single intramuscular dose of vitamin K at birth. Oral administration has compliance issues and has not yet undergone randomised controlled trials to assess its efficicacy (Puckett & Offringa 2002). It is recommended that all high-risk neonates receive intramuscular vitamin K at birth. This group includes preterm, hypoxic neonates and those who have had a difficult or instrumental birth. Neonates who are artificially fed do not require prophylactic vitamin K (Hey 2003).

Bleeding due to other causes

Vaginal

Vaginal discharge consisting of bloodstained mucus in the first days after birth in the female neonate is termed pseudo-

menstruation. It is due to the withdrawal of maternal oestrogen and is normal, and self-limiting. Midwives need to reassure women that this is a possibility and that it is normal.

Haematemesis

Haematemeis occurs when the neonate has swallowed maternal blood, either during birth or from cracked nipples while breastfeeding. This needs investigating to ensure that the underlying cause is not something more sinister, such as oesophageal, gastric or duodenal ulceration. Cracked nipples need to be appropriately managed by checking positioning and attachment. The woman needs reassuring that this is self-limiting and no cause for alarm.

Congenital conditions

Parents expect to have a normal, healthy neonate, which predominantly is the case. There is no guarantee, however, that this will happen. When a neonate is found at birth to have an abnormality, it can be devasting for the parents. The role of the midwife in such circumstances is to assist in early detection and then to provide support and sensitivity for the parents. This section outlines some of the potential causes of congenital abnormalities, and the main conditions.

Causes

A congenital abnormality, by definition, is a defect present at birth; it can be either a malformation or a deformation. The incidence is believed to be around 2–3% of neonates, with more malformations than deformations. A malformation is a defect in the development of an organ or tissue in the fetus, whereas a deformation is damage that occurs to normal structure as a result of external factors. The specific cause of up to 80% of abnormalities is unknown, with the remainder occurring because of the following factors (Henderson & Macdonald 2004):

- genetic—a fault occurs either during the formation of the gametes or following fertilisation, resulting in an excess or deficit of chromosomal material
- teratogenic—refers to agents that increase the incidence of congenital abnormalities. These include: prescribed medications (such as anticonvulsants, anticoagulants, thalidomide); substance abuse (such as heroin, nicotine, alcohol, cocaine); environmental factors (such as radiation, pesticides); infective agents (such as rubella, cytomegalovirus); sustained hyperthermia (saunas during pregnancy are discouraged, as is exercise that is likely to raise maternal temperature); and maternal disease (such as poorly controlled diabetes mellitus).
- iatrogenic—includes such things as congenital constriction band syndrome, occurring when early amniotic rupture results in a constriction band forming and occluding some part of the fetal body.

The role of the midwife is in giving preconceptual advice to would-be parents about maximising their health prior to conception. Unfortunately, most of the damage may have been done by the time the woman sees the midwife during her first antenatal visit. There is, therefore, a need to increase awareness regarding preconceptual health in the general community.

Early detection of abnormalities through antenatal screening is the next line of defence. Early detection results in some families making the decision to terminate the pregnancy, or allows families time to accept the news that their baby will be born with a particular problem. Great sensitivity and understanding are required at this time, to help support the family in making their decision.

Congenital conditions can affect any part of the fetus; the main conditions only are outlined here.

Central nervous system

Spina bifida

Spina bifida and anencephaly are the most common neural tube defects, affecting up to 1:1000 pregnancies (Henderson & Macdonald 2004). The recurrence rate in subsequent pregnancies is 1 in 25 (Fraser & Cooper 2003). Routine use of folic acid daily for one month preconceptually and during the first trimester has been shown to result in a dramatic drop in the incidence of these conditions (Hasenau 2002). Spina bifida results from a failure of the vertebral column to fuse, with a number of levels of involvement. This defect can occur anywhere between the head and the sacrum, most commonly affecting the lumbosacral region. There are a number of types. Spina bifida occulta involves a defect of the bone and is without symptoms. It is noticed by a tuft of hair or sinus at the base of the spine. Spina bifida meningocele is where there is no skin covering the spinal defect, allowing the protrusion of the meninges. This sac may contain cerebrospinal fluid but does not contain neural tissue. Spina bifida myelomeningocele does include the spinal cord and is therefore more serious. There may be leakage of cerebrospinal fluid, giving rise to the risk of meningitis.

Hydrocephalus

Hydrocephalus occurs when there is a blockage in the circulation or impaired absorption of the cerebrospinal fluid, resulting in an accumulation in the lateral ventricles and an increase in the size of the ventricle. This accumulation can eventually lead to compression of the brain tissue. Cerebrospinal fluid is produced in the lateral ventricles of the brain, and hence the effect. Diagnosis is usually by the midwife possibly feeling an enlarged head, or there may be CNS depression evident on cardiotocography (decreased variability and reactivity) or during an antenatal ultrasound.

Microcephalus

Microcephalus is defined by a head circumference of more than two standard deviations below normal for gestational age. This can result either from a brain that has not grown, or from prematurely ossified sutures constricting the growth of the brain.

Respiratory system

Diaphragmatic hernia

Diaphragmatic hernia is a defect in the formation of the diaphragm that allows herniation of the abdominal contents into the thoracic cavity. Lung development may be impaired due to compression or hypoplasia. The amount of compression that occurs depends on the gestational age at which herniation occurred and on the size of the defect, ranging from very small to complete agenesis of the diaphragm. Usually the left side is affected, though it may be unilateral or bilateral, and it is more common in males, with an overall incidence of 1:1000 to 10,000 births (Braby 2001). The true incidence is unknown, however, as the fetus or neonate often dies before being diagnosed. There is a high mortality and morbidity rate, with an approximate survival rate of 50% (Henderson & Macdonald 2004). This condition is often associated with other abnormalities, usually cardiac. The main aim of care is to avoid filling the gastrointestinal tract with air, as this may impede lung expansion. Immediate management involves free-flowing oxygen, insertion of a gastric tube and then endotracheal intubation and mechanical ventilation (Braby 2001; Juretschke 2001).

Choanal atresia

Choanal atresia involves the unilateral or bilateral narrowing of the nasal passage(s) by a membranous or bony septum, resulting in occlusion of the nasopharynx. Neonates will suffer from acute respiratory distress from birth, as they are predominantly nose breathers. These neonates find feeding impossible without cyanosis. Dyspnoea and cyanosis are improved by crying.

Alimentary system

Cleft lip and palate

Cleft lip and palate are one of the most common structural birth defects. Cleft lip may occur with or without a cleft palate, and can be unilateral or bilateral, involving the soft palate, hard palate or both. Incidence of cleft lip is 1:700 and cleft palate is 1:2000 births, being more common in Asian families (Henderson & Macdonald 2004). A thorough examination in good light is essential for accurate diagnosis.

Oesophageal atresia and tracheo-oesophageal fistula

Incomplete canalisation of the oesophagus in early fetal development results in oesophageal atresia, or a blind end. The condition affects 1:4000 neonates (Henderson & Maconald 2004). Tracheo-oesophageal fistulas are commonly associated with this condition, and involve one or two connections between the oesophagus and the trachea. The fetus is therefore unable to swallow amniotic fluid, and polyhydramnios results. After birth, the neonate has copious amounts of oral mucus. Aspiration in the presence of a fistula will cause cyanotic episodes. Patency of the oesophagus must be assured prior to commencing oral feeding.

Imperforate anus

Imperforate anus occurs in 1–3:5000 births and can be easily detected by visually examining the anus for patency (Henderson & Macdonald 2004). No object should be inserted into the anus in order to check for patency. A paediatric referral should be made if there is any doubt. There is a high association of imperforate anus with other abnormalities. A thorough examination of the neonate should therefore be undertaken.

Exomphalos and gastroschisis

Exomphalos and gastroschisis both occur late in first trimester, with an incidence of 1–2:10,000 neonates. The incidence has increased significantly over the past several decades (King & Askin 2003). Essentially these conditions are a herniation of the abdominal contents through either the base of the umbilical cord (exomphalos), or through a defect in the anterior abdominal wall (gastroschisis). With exomphalos there is a covering of fused peritoneum and amnion over the abdominal contents, which may rupture at birth. There is also a strong association with other abnormalities, more males being affected than females. In gastroschisis there is no protected covering of the abdominal contents, which may appear oedematous and have disrupted blood supply. The main aim of care is to avoid over-handling of abdominal contents, prevent infection, and reduce heat and fluid loss by covering with clear plastic. Proper diagnosis and treatment are crucial to achieve a satisfactory outcome.

Genitourinary

Undescended testes

By 36 weeks gestation, the testis would normally be present in the scrotum. Undescended testes may be unilateral or bilateral and occurs in 1–2% of male neonates. On examination at birth, if the testes are not felt in the scrotum, they may be felt in the inguinal pouch. This should be documented and checked again at six weeks. If the testes are not detected by four months, a paediatric referral is necessary (Henderson & Macdonald 2004).

Hypospadias

Hypospadias occurs when the urethral meatus opens on the under-surface of the penis. The meatus may be placed at any point along the penis, even the perineum. Circumcision should not be performed until repair has been undertaken. The further the meatus is from the tip of the penis, the more urgent the surgery.

Renal agenesis

Renal agensis is a fatal condition characterised by the failure of the development of the kidneys. Incidence is 1:1500, found during antenatal ultrasounds (Henderson & Macdonald 2004). There is a high association with other abnormalities.

Ambiguous genitalia

Great sensitivity and support for the parents are required in cases of ambiguous genitalia. Any doubt as to the sex of

the neonate should be further investigated by chromosome analysis before gender is defined. A physical examination may reveal any of the following: a small hypoplastic penis, chordee, bifid scrotum, undescended testis, enlarged clitoris, incompletely separated or poorly differentiated labia.

Limbs

Talipes

In talipes equinovarus, or club foot, the ankle is bent downwards (plantarflexed) and the front part of the foot is turned inwards (inverted) (see Fig 38.4). This is the most common type of talipes. In talipes calcaneovalgus, the foot is dorsiflexed and everted (see Fig 38.4). In talipes metatarsus varus, the forefoot is turned inwards. This deformity occurs due to contraction of certain muscles or tendons related to a restriction of movement in utero. It may also have a genetic origin if more severe.

Syndactyly and polydactyly

Syndactyly means webbing and polydactyly means extra digits (see Fig 38.5). Webbing is more commonly identified in the hands. This deformity may be hereditary or genetic. Extra digits may be fully formed, including bone, or simply extra tissue attached to a digit. The latter is usually ligated, causing necrosis, with the extra digit then falling off.

Congenital dislocation of the hip

Congenital dislocation of the hip is the abnormal development of one or both hips, with the head of femur being partially or wholly displaced from the acetabulum. It is more common in females, in the left hip, with breech presentation, fetal restriction in utero, and where there is a family history. The incidence is 1:1500 births. Early detection is important to prevent long-term problems. The hip may present as either dislocated, dislocatable or with subluxation of the joint. Treatment requires an abduction device and follow-up ultrasounds to assess progress (Wilkinson 2003).

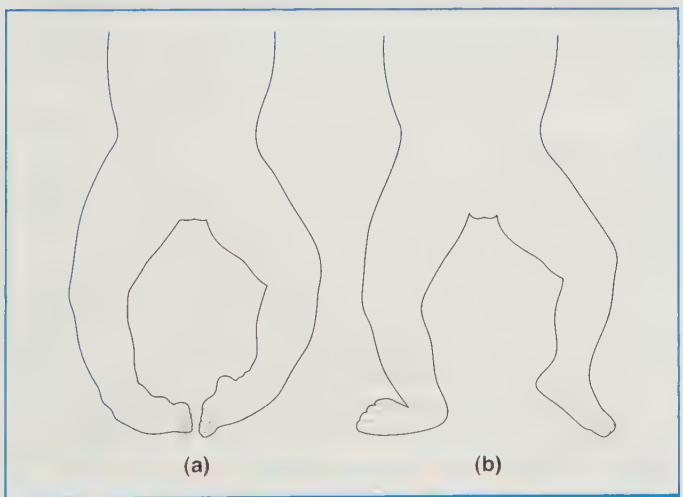

Figure 38.4 **(a)** Talipes equinovarus **(b)** Talipes calcaneovalgus (based on Henderson & Macdonald 2004)

Skin

Capillary haemangiomas

Capillary haemangiomas, or strawberry marks, are red, raised lesions that appear in the first few weeks of life, and are caused by dilated capillaries in the skin. These lesions can appear anywhere on the body. The lesions usually increase in size in the first few months and then regress, usually disappearing completely by five to six years of age.

Capillary malformations

Capillary malformations, or port wine stains, are purple-blue, flat, well-defined and dense lesions affecting the face. They occur in 1:3000 births. They occur more commonly in females and do not regress with time. Laser treatment has been fairly successful at removing the lesions (Sheehan-Dare 2001).

Pigmented naevi

Pigmented naevi are brown marks, or moles, on the skin that vary in size and may be flat or raised, or hairy. They are present at birth, can be anywhere on the body and do not usually require treatment, though they can become malignant (melanoma).

Chromosomal

Down syndrome

Down syndrome, or trisomy 21, occurs in 1:700 live births (Henderson & Macdonald 2004) and consists of a number of well-recognised characteristics, including:

- varying degrees of intellectual disability
- widely set and obliquely slanted eyes
- white flecks in the iris (Brushfield's spots)
- small head with a flattened occipital region
- increased fat pad on the neck
- small, droopy mouth
- protruding tongue
- broad, flat nose
- generalised hypotonia
- short, broad hands with an incurving little finger
- deep single palmar (simian) crease
- short, broad feet with a wide deviation of the great toe.

Not all these characteristics need be present and any of them can occur without implying a chromosomal

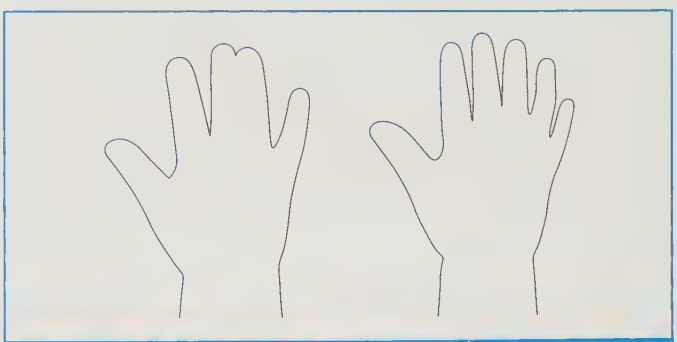

Figure 38.5 Syndactyly (left) and polydactyly (right) (based on Henderson & Macdonald 2004)

abnormality. Family resemblance alone may explain some neonates' appearance. Down syndrome neonates also have an increased incidence of cardiac abnormalities, leukaemia and hypothyroidism.

Potter syndrome

Potter syndrome is a condition characteristised by dysmorphic clinical features and renal agenesis. A consequence of the renal agenesis is oligohydramnios and severe hypoplastic lungs. Incidence is 1:4000 births, predominantly in males (Levene et al 2000). Other features include low-set ears, furrows under wide-set eyes, a beaked nose, two umbilical cord vessels and pulmonary hypoplasia resulting in severe respiratory failure. This condition is incompatible with life.

Turner syndrome

Turner syndrome, in which one of the X chromosomes is missing or abnormal, affects only females. The sex chromosomes are therefore defined as XO. These neonates are characterised by a short, webbed neck, widely spaced nipples, oedematous feet, short stature, low birthweight, underdeveloped ovaries and infertility. Many will be miscarried, with those surviving having a decreased life expectancy due to related heart defects.

Cardiorespiratory conditions

This section discusses some of the cardiorespiratory conditions the midwife may encounter in the neonate after birth. It is important that the midwife is able to recognise these conditions, as they can fatal. A brief overview of each condition is given. Various respiratory support mechanisms are also discussed at the end of this section.

Cardiac

Diagnosis

Routine antenatal ultrasound screening fails to diagnose 60–80% of cardiac abnormalities (Grandjean et al 1999). Approximately 50% of these abnormalities are missed at birth and more than 33% are missed at the six-week check (Ainsworth et al 1999). This highlights the fact that obvious clinical signs of cardiac abnormalities are not always present in the early neonatal period, often being picked up only when early signs of cardiac failure occur. The signs of cardiac failure include tachypnoea, tachycardia, hepatomegaly, dyspnoea, feeding difficulties and vomiting. A key to early diagnosis is the feeding pattern of the neonate. If the neonate is not feeding well, a full cardiac assessment should be undertaken.

Types of cardiac conditions

Acyanotic lesions

Acyanotic lesions are cardiac lesions where there is no cyanosis present in the neonate at birth:

- *Patent ductus arteriosus*—from 25 weeks gestation, specialised contractile tissue is formed. This enables spontaneous closure of the ductus arteriosus 15–24 hours after birth. The ductus is, however, not fully mature and functional until approximately three months. Preterm neonates therefore have a higher incidence of patent ductus. Any preterm neonate who sustains birth asphyxia or hypoxia after birth will commonly have a patent ductus arteriosus. This is the most common congenital heart abnormality and cause of congestive cardiac failure. The symptoms are tachypnoea, dyspnoea, lethargy, bounding pulses and audible systolic and diastolic murmurs occurring at around 3–10 days of age. Patent ductus results in reduced pulmonary resistance with reversed blood flow through the ductus from left to right. This results in oxygenated blood being shunted back into the pulmonary circulation. Management involves restricting fluid (though this is controversial), preventing hypoxia, administering indomethacin and ibuprofen, and, rarely, surgical ligation (Wyllie 2004).
- *Ventricular septal defect*—a hole in the ventricular septum permitting a left-to-right flow of blood. The size of the hole varies, as do the corresponding symptoms. This is often one component of an array of cardiac abnormalities.
- *Coarctation of the aorta*—a narrowing of the aorta at the entry point with the ductus arteriosus. If this narrowing is small, symptoms may not appear for several years. When severe, the neonate on day 2 to 10 suddenly becomes dyspnoeic and tachypnoeic with hepatomegaly, and signs of renal and cardiac failure. These neonates are given prostaglandins to maintain the ductus arteriosus. This condition is associated with other cardiac abnormalities in 50% of cases.
- *Aortic valve stenosis*—narrowing of the aortic valve, causing restricted blood flow through from the left ventricle to the aorta. It is commonly associated with coarctation of the aorta or other cardiac abnormalities. If mild to moderate, apart from a murmur, the neonate is usually asymptomatic. If severe, it may cause a sudden collapse, with a replacement valve being necessary.

Cyanotic lesions

Cyanotic lesions are cardiac lesions where there is cyanosis at birth.

- *Transposition of the great arteries*—the pulmonary artery exits the left ventricle and the aorta exits the right ventricle, creating two separate circulations. As the ductus arteriosus closes, severe cyanosis occurs, with dyspnoea and cardiac failure resulting. The ductus needs to be maintained urgently with prostaglandins, and surgery undertaken in the next few days to switch the circulation around to the normal positions.
- *Tetralogy of Fallot*—pulmonary stenosis, ventral septal defect, right ventricular hypertrophy and an overriding aorta across the ventricular septal defect. The neonate

presents as pink at birth, gradually becoming cyanosed when crying. As the pulmonary stenosis worsens at four to six months of age, the infant presents with cyanotic episodes in the morning, resulting in a loss of consciousness. Timing of the surgery depends on the severity of the symptoms.

- *Hypoplastic left heart syndrome*—underdevelopment of the left side of the heart, a hypoplastic ascending aorta and coronary arteries, and blood passing into the aorta through the patent ductus arteriosus. With closure of the ductus arteriosus, cyanosis and dyspnoea worsen. Unless a heart transplant is available, most neonates will die within the first week.

Respiratory

Asphyxia

Asphyxia results from impaired gas exchange leading to a depletion of oxygen (hypoxaemia) and accumulation of carbon dioxide (hypercapnia) and acidosis in the blood. Asphyxia may occur in utero, during labour or birth, or the neonatal period. The asphyxia will worsen unless respiratory function is established quickly. Immediate resuscitation is therefore necessary. Mild asphyxia may result in no neurological injury in the neonate, whereas severe asphyxia will result in significant neurological sequelae. The causes of birth asphyxia include:

- preterm birth
- obstruction of the trachea
- drugs that depress respirations
- congenital abnormalities
- cerebral damage
- infection
- haemorrhage
- pneumothorax.

Pharyngeal suctioning may cause a reflex apnoea.

The Apgar score performed at one minute after birth gives some indication of the level of birth asphyxia. A score of 7–10 indicates no asphyxia; 4–6 indicates mild to moderate birth asphyxia; and 3 or less indicates severe birth asphyxia with the need for immediate resuscitative measures.

Meconium aspiration syndrome

Fetal asphyxia results in the passage of meconium into the liquor, because hypoxia causes increased gut paralysis and relaxes the anal sphincter. This is normally unproblematic unless the neonate gasps or breathes in the amniotic fluid and, hence, meconium. The meconium becomes trapped in the airways, allowing air in but not out of the airways. This results in air accumulating behind the blockage. This in turn can cause the alveoli to rupture, resulting in a pneumothorax (discussed later in this chapter). Once the meconium touches the lung tissue, a pneumonitis develops, creating a fertile site for infection. In addition, the surfactant is broken down in the presence of meconium. This all culminates in a severe disease state, with gas exchange at the alveoli level inhibited, areas of hypoxic lung bypassed as blood is shunted away, and fetal circulation maintained due to increasing pulmonary resistance. These neonates need intensive care and ventilation to prevent further detoriation. Use of surfactant has been found to reduce the severity of respiratory distress in these babies (Merrell & Ballard 2003).

Clinical point

Mild brain hypothermia is proving promising in the management of neonates with asphyxia to prevent further neurological damage (Flavin 2001). Hypothermia reduces the infant's metabolic rate.

In approximately 10–15% of labours there is meconium-stained liquor, but only in approximately 1–5% of neonates will meconium aspiration syndrome occur (Henderson & Macdonald 2004). The majority of these neonates will suffer a mild respiratory distress, resolving over 24–48 hours. In the reminder of neonates, the respiratory distress initially may be mild, moderate or severe, with a gradual detoriation over 12–24 hours, the neonate becoming acutely ill.

Transient tachypnoea of the newborn

Transient tachypnoea of the newborn is thought to result from mild surfactant deficiency or failure to adequately absorb lung fluid following birth. Hence this condition is typically seen in neonates post caesarean birth, due to lack of chest compression. The neonate presents with a tachypnoea of up 120 breaths per minute, plus flaring of nostrils, sternal recession, expiratory grunting and cyanosis. These neonates may need oxygen and observation in an incubator. Symptoms usually resolve within 24 hours.

Respiratory distress syndrome

Respiratory distress syndrome occurs as a result of insufficient surfactant production. It is seen predominantly in preterm (less than 34 weeks) neonates, but is occasionally evident in infants of mothers with diabetes and infants with meconium aspiration syndrome. Surfactant reduces the surface tension in the alveoli, preventing complete collapse during expiration and facilitating lung expansion. A deficiency of surfactant means that more respiratory effort is required to inflate the lungs, and the neonate quickly becomes exhausted, the alveoli collapse and hypoxaemia results. This results in stimulation of prostaglandins from the wall of the ductus arteriosus, preventing its closure. Blood then continues to be shunted away from the lungs, further reducing the oxygenation. Hypoxaemia then further impedes the production of surfactant, and a vicious cycle ensues unless appropriate respiratory support is commenced immediately. The neonate will need to be ventilated for some time but should be gradually weaned off as soon as possible to prevent further lung damage. Long-term ventilation, particularly with the use of high pressure, may cause damage to the lungs, resulting in chronic lung disease or pneumothoraces. Respiratory distress syndrome occurs within four hours of birth.

Clinical point

Prevention of aspiration of the meconium previously involved routinely suctioning the oropharynx and nasopharynx before birth of the shoulders. Some work undertaken recently indicates that this in fact makes no difference to the incidence of meconium aspiration syndrome (Vain et al 2004).

Apnoeas

Apnoea is the cessation of respiratory effort for 20 seconds or more, and requires constant monitoring. It occurs commonly in preterm neonates, the incidence increasing with decreasing gestational age. Apnoeas are a consequence of the immature respiratory centre and immaturity of chemoreceptor response to hypoxia and acidosis. This tends to resolve as the neonate matures. Apnoea can also occur at the conclusion of increasing respiratory fatigue in term infants. In addition, apnoea can often be the first sign of sepsis, pneumonia, necrotising enterocolitis or meningitis in a neonate. There are three types of apnoea, depending on whether there is respiratory effort: central (no respiratory effort), obstructive (ineffective effort) and mixed (both). Factors affecting the respiratory centre include prematurity, hypoxia, maternal drug taking (narcotics, magnesium sulfate), metabolic (hypoglycaemia), sepsis, intercranial haemorrhage, necrotising enterocolitis, patent ductus, and temperature instability. Neonates with apnoea require cardiac/apnoea monitors and continual assessment of status, including the amount of stimulation required with an apnoea episode. Methylxanthines, such as theophylline, may be prescribed to help reduce the number of apnoeic episodes (Theobald et al 2000). These drugs work by stimulating the central respiratory control centre.

Chronic lung disease

In chronic lung disease, the preterm neonate continues to require supplemented oxygen supply at 36 weeks postconceptual age. Risk factors for chronic lung disease include:

- prematurity
- endotracheal intubation
- high-level ventilator peak inspiratory pressures
- oxygen toxicity
- low birthweight neonates with mild respiratory distress syndrome with patent ductus arteriosus and nosocomial infections.

It is clear that severe initial lung disease is not a prerequisite for developing chronic lung disease in the preterm neonate (Cole & Fiascone 2000). The aim of treatment of chronic lung disease is to reduce the requirements for supplementary oxygen and high ventilatory pressures in the neonate as soon as possible. Use of surfactant therapy and new ventilation techniques have helped to reduce the severity of the condition (Henderson & Macdonald 2004). The neonate with chronic lung disease will require low-flow oxygen therapy for several months, until the lung tissue has regenerated enough to support adequate oxygenation.

Pneumothorax

Pneumothorax occurs when the alveoli rupture, causing air to enter the pleural cavity. This may occur spontaneously at birth, due to the large pressures generated by the first breath, following meconium aspiration, or as a consequence of high ventilator pressures. The neonate's condition will suddenly deteriorate, with signs of respitatory distress indicating a possible pneumothorax. Mild cases will resolve spontaneously within a few days. It may be necessary to aspirate the air by inserting a needle into the pleural cavity. An underwater drain will need to be inserted for larger cases.

Respiratory support

For the parents of a neonate suffering from respiratory problems, a great deal of support, reassurance and explanation of what is happening to their baby, will be required. As much as possible, and at the earliest possible moment, women should be prepared for what might happen to their baby. If the woman is deemed at high risk antenatally of having a neonate who will need respiratory support, she should be prepared at that time, with visits to the nursery and explanation.

Oxygen therapy

Oxygen therapy needs to be administered carefully and monitored closely, to prevent hyperoxaemia and hypoxaemia in the neonate and the long-term disabilities that would result. The aim of care is to provide sufficient oxygen to maintain arterial oxygenation within normal limits, and avoid excessive or fluctuating concentrations of oxygen, which has been implicated in the cause of retinopathy of prematurity (Whitfill & Drack 2000). Previously termed 'retrolental fibroplasia', this condition causes various levels of retinal vascular changes, often resulting in blindness (Merenstein & Gardener 2002). The use of oxygen therapy therefore requires a skilful practitioner together with saturation monitors, transcutaneous monitors and arterial catheter readings. Regular eye examinations are undertaken on neonates of less than 32 weeks gestation until term to assess for early signs of retinal damage.

Intermittent positive-pressure ventilation

Intermittent positive-pressure ventilation (IPPV) involves the use of a ventilator that is preset for the pressures generated from a non-cuffed endotracheal tube. A non-cuffed endotracheal tube results in unavoidable and variable leak around the tube. The flow through the neonatal ventilator circuit is constant, with the pressure in the circuit being controlled at a valve in the gas return port. This means that the pressure required to open this valve varies with the ventilator settings, and in turn determines the pressure generated through the endotracheal tube. This is necessary as neonates with respiratory distress syndrome have small airways, which collapse at the end of each breath, taking considerable effort to reinflate.

Continuous positive airway pressure

Continuous positive airway pressure (CPAP) is administered through nasal prongs and prevents collapse of the alveoli on

expiration by maintaining a positive pressure in the airway while the neonate breathes spontaneously. This effectively keeps the airway open, reducing the respiratory oxygen required. It is important to leave a gastric tube in place at all times to prevent air accumulating in the stomach, causing distension and compromising respiratory effort. The use of CPAP in New Zealand and Australia has increased fourfold in the past decade. The technique is being used with increasing success as an alternative to intubation and ventilation of respiratory distress syndrome (De Paoli et al 2002).

Synchronous intermittent mandatory ventilation

Synchronous intermittent mandatory ventilation (SIMV) is helpful when weaning a neonate off a ventilator. During prolonged apnoea periods, for example, this system triggers ventilation, responding to pressure changes in the neonate's airway and causing the ventilator to produce an inspiration in time with the neonate's breathing pattern.

Nitric oxide

Nitric oxide is used as a vasodilator of the pulmonary circulation in neonates with persistent pulmonary hypertension associated with respiratory diseases. This technique improves arterial oxygenation, reducing the amount of ventilatory support required, and reducing mortality rates (Merenstein & Glicken 2002; Sadiq et al 2003).

Extracorporeal membrane oxygenation

Extracorporeal membrane oxygenation (ECMO) is used in severe cases of meconium aspiration syndrome, persistent pulmonary hypertension or respiratory distress syndrome that do not respond to other methods of ventilation. Basically, the right internal jugular vein is cannulated with blood which then circulates into an oxygenator and returns via the right common carotid artery. The benefits of ECMO have been well documented (Merenstein & Glicken 2002). There is great debate about the increase in risk of neurological damage from respiratory disorders with this technique, which has been shown to be minimised by inducing hypothermia (Ichiba et al 2003).

Exogenous surfactant

Surfactant deficiency has been shown to be the primary abnormality in respiratory distress syndrome, and hence the use of exogenous surfactant administered through an endotracheal tube (Levene et al 2000). The indications are that this results in an improved lung compliance and volume, improved gas exchange and a decrease in the need for high levels of oxygen and ventilatory support. Surfactant therapy also reduces the incidence of pneumothorax and increases survival rates (Merenstein & Glicken 2002).

Clinical point

Surfactant can be given prophylactically to all preterm neonates at birth, or as a rescue treatment to neonates following a diagnosis of respiratory distress syndrome. It has been shown, however, that not all preterm neonates need prophylactic surfactant, especially with increased rates of antenatal steroid use. A rapid bedside test, called a *click test*, has been developed to diagnose surfactant deficiency in the neonate. The click test is performed on a specimen of endotracheal aspirate taken immediately after intubation. Clicking occurs when air diffuses rapidly out of bubbles suspended in air-free water, and depends on the presence of surfactant. This test enables more appropriately targeted administration of surfactant with improved clinical outcomes and contained costs (Osborn et al 2000).

Metabolic and endocrine disorders

Screening

Screening consists of genetic counselling following gene mapping from collected blood samples of parents in situations of high-risk. Assessing the individual fetus for specific risk can be undertaken through amniocentesis or chorionic villus sampling. Parents need to be fully informed of the risks of each procedure and the options available to them. The role of the midwife is in supporting the parents through this decision-making process by providing the necessary information.

Inborn errors of metabolism

Phenylketonuria

Phenylketonuria (PKU) can be successfully screened for and is a treatable cause of brain injury, occurring in 1:10,000 births (Henderson & Macdonald 2004). This condition is due to a deficiency in the enzyme phenylalanine hydroxylase, which converts the amino acid found in most foods, phenylalanine, into tyrosine. On establishing milk feeds, the levels of phenylalanine, together with the by-product of its metabolism, phenylpyruvic acid, start to rise. Phenylpyruvic acid is toxic to the neonatal brain, causing irreversible neurological damage, manifesting at three months of age as persistent vomiting, eczema and a characteristic musty smell in the urine. Early detection through the newborn screening test, and placing the neonate on a phenylalanine-resticted diet, have led to excellent outcomes.

Galactosaemia

Galactosaemia is a disorder of carbohydrate metabolism occurring in 1:60,000 neonates (Henderson & Macdonald 2004). The cause is absence, or severe deficiency, of the enzyme galactose-1-phosphate uridyltransferase, important for converting galactose into glucose in the intestine. The result is an accumulation of galactose and galactose-1-phosphate in erythrocytes, causing liver cirrhosis, neurological damage and cataract formation. The neonate presents with failure to thrive, hypoglycaemia, vomiting, bleeding, persistent jaundice,

hypotonia, sepsis and signs of hepatosplenomegaly within the first week. Early detection through the newborn screening test and a galactose-free diet through use of soya milk, results in an improved prognosis.

Acquired errors of metabolism

Hypoglycaemia

The definition of hypoglycaemia is controversial, as is what constitutes a normal plasma glucose level in the neonate (Cornblath et al 2000; Cowett & Loughead 2002). It is well accepted that hypoglycaemia does cause damage to the newborn brain, but the severity and duration of hypoglycaemia required to cause this damage is unclear (Cowett & Loughead 2002). In addition, neonates with hypoglycaemia do not exhibit obvious signs of impairment (Cowett & Loughead 2002). The consensus appears to be that a glucose level of 2.6 mmol/L should be the lower limit (Henderson & Macdonald 2004). Levels lower than this should be treated in neonates who may be asymptomatic or show signs of lethargy, poor feeding, hypotonia and jitteriness. If hypoglycaemia is untreated, the neonate may suffer from convulsions, cyanosis and apnoea leading to possible neurological damage, coma and even death.

The causes of hypoglycaemia include the following:

- Preterm neonates lack energy stores, as the bulk of glycogen and fat stores are laid down in the last trimester.
- Small for gestational age neonates use up their energy reserves because of intrauterine malnutrition.
- Large for gestational age neonates rapidly use up their energy stores unless fed regularly.
- Neonates of diabetic mothers suffer from an overproduction of insulin, which quickly uses up glycogen stores.
- Inborn errors of metabolism
- Specific abnormalities such as pancreatic tumours or pituitary insufficiency
- Miscellaneous situations such as feeding difficulties, hypothermia, cerebral damage, infection and severe Rhesus isoimmunisation.

Mild cases of hypoglycaemia should be fed immediately, and regularly thereafter. A repeat blood glucose level should be undertaken one hour after feeding and, if still low, may warrant intravenous fluids with dextrose, and further investigation.

Exocrine disorders

Cystic fibrosis

Cystic fibrosis is the most common serious genetic disorder in Caucasian people, with an incidence of 1:2500–3500 neonates (Henderson & Macdonald 2004). It is an autosomal recessive disorder associated with chromosome 7, and as carriers are common (1:40), preconceptual or antenatal testing is available for parents. A newborn screening test indicates raised levels of immunoreactive trypsinogen, which is followed by a sweat test, measuring the salt content, before diagnosis is confirmed. Early diagnosis and treatment may greatly improve the prognosis.

Cystic fibrosis is a condition in which there is an abnormality of the exocrine mucus-secreting glands throughout the body, specifically the intestine, lungs and pancreas. The protein required to carry chloride ions across cell membranes is absent. This results in the formation of thick mucus with abnormal electrolyte concentrations, distending and dilating the affected area, leading to obstruction and fibrosis. Pulmonary disease is the primary cause of morbidity and mortality. Management includes chest physiotherapy, antibiotics, pancreatic enzyme supplementation, improved nutrition, use of DNase (a synthetic protein) to break down mucus and a heart–lung transplantation. Fertility tends to be reduced due to an alteration in the chemical constitution of the cervical mucus (Bolyard 2001). There is no cure for this condition, and management is aimed at preventing complications and maintaining optimal growth and development. Currently, the life expectancy is around 30 years (Chini 2002).

Endocrine disorders

Congenital adrenal hypoplasia

Congenital adrenal hypoplasia refers to a group of inherited disorders that result from a deficiency of the enzymes responsible for hormone production within the adrenal glands. This deficiency can result in, most commonly, an excess of androgenic hormones, or glucocorticoid, and mineralocorticoids less frequently. These disorders cause abnormalities in the formation of the genitalia, leading to ambiguous genitalia and symptoms of adrenal insufficiency (vomiting, diarrhoea, vascular collapse, hypoglycaemia, hyponatraemia or hyperkalaemia). Diagnosis is through the newborn screening test and chromosomal analysis may be necessary to ascertain the sex of the neonate.

Congenital hypothyroidism

Congenital hypothyroidism is detected through the newborn screening test and has an incidence of 1:3500 neonates. There are several possible causes, including abnormalities in gland formation, defects in hormone synthesis and secondary pituitary causes (rare). The affected neonate tends to be large, post mature and have a large posterior fontanelle, with coarse features and often an umbilical hernia. Untreated neonates develop impaired motor development, growth failure, a low IQ, impaired hearing and language problems. Neurological prognosis is poor unless treated early with thyroxine sodium.

Sudden infant death syndrome

(This section on SIDS was written by Sally Baddock.)

To make a diagnosis of sudden infant death syndrome (SIDS) requires exclusion of all other possibilities of a sudden death in an infant aged less than 12 months. In other words, where

death is unexplained following a postmortem examination, review of the clinical history and examination of the death scene are required. For the parents, this can be a very distressing process and requires an immense amount of support.

Incidence

The incidence of SIDS in Australia has fallen from 1.89 per 1000 live births in 1986 to 0.81 per 1000 live births in 1996, to 0.3 per 1000 live births in 2003. Despite this dramatic fall in incidence, SIDS remains the major cause of death in infants aged from one month to one year of age. The peak incidence is at four months of age, with the majority occurring under six months of age (80%). Winter remains a peak period, with the incidence being higher for Aboriginal infants, and boys in general (Mitchell 2000).

SIDS rates in industrialised countries have decreased more than 50% from their peak in the late 1980s but SIDS remains the leading single cause of post-neonatal death. In 2000 the rate in Australia was 0.6 deaths/1000 live births and in New Zealand, 1.1 deaths/1000 live births (NZHIS n.d.). New Zealand still has the highest rate in the industrialised world. Despite the decrease in national rates, Australian Aborigines and New Zealand Maori remain over-represented in the SIDS statistics. Effective strategies are needed to reduce risk factors in these groups.

Reducing the risk factors

No single cause of SIDS has been identified, and the cause of death is likely to be multifactorial. Mechanisms that have been explored include: asphyxiation due to rebreathing of expired air, hyperthermia (directly or leading to respiratory compromise), airways obstruction, impaired arousal, cardiovascular mechanisms and infection. One hypothesis is that SIDS may result from a vulnerable infant (e.g. of a smoking mother), during a vulnerable developmental period (three months of age), unable to respond to an environmental stress (e.g. accumulation of carbon dioxide due to inadvertent covering of the head by bedding) (Filiano & Kinney 1995).

Epidemiological studies have identified several infant and maternal risk factors that are largely unchangeable. These include lower socio-economic status, unmarried or young mother, lower level of education, non-attendance at antenatal classes, Indigenous ethnicity, increased parity, low birthweight, short gestation, male infant, and admission to a baby care unit (Mitchell et al 1991; Ponsonby et al 1992b). The presence of these factors should alert a midwife to an increased risk of SIDS.

There is also another group of factors that are potentially open to change This includes prone sleep position, smoking, bed sharing with a mother who smoked in pregnancy, solitary infant sleeping, not breastfeeding, infant head covering and over-wrapping (Mitchell et al 1991; Ponsonby et al 1992b; Scragg et al 1996). Midwives are in a key position to discuss these factors with families.

It was not until a successful prevention campaign in New Zealand that the potential for reducing the risk by modifying the risk factors was recognised in Australia. This campaign, in conjunction with Red Nose Day, commenced in 1991 in Australia. The risk factors targeted for change in Australia and New Zealand include:

- sleeping position
- position of bed covering
- smoking.

The infant sleeping position still accounts for many SIDS deaths. A large European study reported that 48% of SIDS cases were attributable to sleeping in the side or prone position (Carpenter et al 2004). The prone position often results from infants rolling from the side position. In the prone position babies sleep for longer (Kahn et al 1993) and are more difficult to rouse (Galland et al 1998), resulting in vulnerability to physiological stressors such as rebreathing or overheating. Autonomic nervous system function is reduced in the prone position (Galland et al 1998) and this may impair cardiovascular control. There has been concern that aspiration of vomit is more likely when infants sleep on their back, but evidence does not support this. One study showed that aspiration of vomit was more common in infants lying face down into bedding (Bajanowski et al 1996). Prone sleep may have contributed to overheating in cold climates, particularly if infants were over-wrapped and face down into bedding (Nelson et al 1989). With the reduction in prone sleep, SIDS

TABLE 38.1 Sudden unexpected death in infancy (SUDI) ethnicity by age group, 2002 and 2003

	4–52 weeks					1–4 years			
Ethnicity	2002	Per 1000 live births	2003	Per 1000 live births	Total	2002	2003	Total	Total
Māori	20	1.34	34	2.17	54	1	2	3	57
Pacific Island	3	0.52	2	0.33	5		1	1	6
Other	10	0.30	14	0.41	24	1	1	2	26
Total	33	0.61	50	0.89	83	2	4	6	89

Source: Child and Youth Mortality Review Committee 2005.

is no longer more common in colder climates. Identification of prone (front) sleeping as a risk factor for SIDS, and the subsequent education programs encouraging families to sleep babies on their back, have been credited with the decrease in SIDS (Ponsonby et al 2002).

All infants should be placed in a supine position for sleeping (Mitchell 2000). Healthy infants placed in a supine position for sleeping are not at an increased risk of choking, provided that swallowing and arousal mechanisms are intact and are therefore able to protect the airway (Page & Jeffery 1997).

Smoking is now the most important risk factor for SIDS, and has proved very resistant to change. Smoking is associated with over 80% of all SIDS cases (Blair et al 1999). Exposure to smoke in utero compromises the baby in many ways: placental blood flow is reduced, carbon monoxide is transported on haemoglobin at the expense of oxygen, and nicotine influences development of respiratory receptors in the brainstem and increases the risk of a small baby, of impaired lung development and impaired cardiorespiratory and thermal control. This may compromise responses to rebreathing or overheating situations. Exposure to smoking after birth, by mothers or other household members, poses a further risk. Components from cigarette smoke are shown to be re-emitted into the air from walls and furniture for hours to months after smoking (Daisey 1999). Babies are more likely to be hospitalised with a respiratory infection if the mother smokes in the same room compared with a separate room, and the effect is even greater for smoking while holding baby, and greater again while breastfeeding (Blizzard et al 2003).

It has been shown that infants of mothers who smoke are at a five-fold increased risk of SIDS. Where the fathers smoke around the infant there has been shown to be an independent additive risk. Bed sharing with a mother who smoked in pregnancy and after birth should be avoided. The recommendation is therefore to keep the infant in a smoke-free environment before and after birth (Mitchell 2000; SIDS and Kids Victoria 2004).

Another risk factor for SIDS is the covering of infants' head by bedding. The use of quilts has been shown to increase the risk, whereas firm tucking of the bedding around the infant had been shown to decrease the risk in New Zealand. Being found with head covered is a significant risk for SIDS. In a study of 30 cot-sleep infants it was demonstrated that only 23% at two months of age and 60% at five months could remove a duvet from their head when sleeping supine. When sleeping prone, only one five-month infant could clear the duvet from his face (Skadberg & Markestad 1997). Evidence supports both rebreathing and hyperthermia as potential mechanisms. Overwrapping and excess bedding is also associated with SIDS (Ponsonby et al 1992a), particularly in response to infant illness. The recommendation therefore is that infants be placed to the bottom of the infant bed or cot, and tucked in securely with the bedding. Quilts, pillows, soft toys and cot bumpers should not be used.

There is now strong evidence that sleeping baby in the same room as the parents is protective against SIDS. Infants sleeping prone in a separate room face a 17-fold increase in risk, but this reduces to a three-fold risk if sharing the room with parents. This suggests some protection from increased maternal interactions. Room sharing with siblings is not protective (Scragg et al 1996). Room sharing meets with resistance from many families, but it is calculated that 36% of SIDS could be prevented by infant–parent room sharing (Carpenter et al 2004).

Breastfeeding is targeted in many education campaigns. The evidence for a direct protective effect against SIDS is equivocal, but other health benefits to the infant are important. Protection from SIDS may be via reduced infections. Fleming and colleagues (1996) suggest that breastfeeding is simply associated with higher socio-economic level. Pacifier use has long been shown to be associated with a small decreased risk of SIDS (Carpenter et al 2004; Mitchell et al 1993) but it is also linked with decreased breastfeeding (Pollard et al 1999; Vogel et al 2001). Consequently, there is little support for pacifier use as a means of reducing SIDS.

While bed sharing is often a valued practice, it carries a high risk if the baby is exposed to smoking. The combination of bed sharing and maternal smoking has consistently been identified as a risk for SIDS and largely accounts for the high SIDS rates within Maori and Aboriginal communities. The risk to a two-week-old baby, bed sharing with a mother who smoked during pregnancy, is 27 times that of a baby without smoke exposure and sleeping in a cot. The risk decreases with age but is still 10-fold greater by six months (Carpenter et al 2004). Increased risk is also associated with factors that impair a parent's ability to respond to the baby (e.g. alcohol consumption). Unsafe sleeping places include bed sharing on a couch (50-fold increase in risk) (Blair et al 1999), and sleeping on waterbeds or surfaces other than firm mattresses.

The above factors have been the focus of 'reduce the risks' campaigns around the world. Since the decrease in prone sleep there has been a shift in the demographics of SIDS families to more deprived social groupings (Leach et al 1999). Midwives can play an important role in educating families to avoid known risk factors such as prone position, smoking, bed sharing if the baby has been exposed to smoking, head covering and over-wrapping. Circumstances often make change difficult for these families, but evidence suggests that choosing a messenger and medium appropriate to the family does have more effect (Abel et al 2001). Midwives may be well placed to deliver safe sleeping messages to families in a positive and trusting environment. More information is available from a number of websites, including the SIDS and kids website (see the online resources list at the end of this chapter).

Apnoea alarms

There are many issues regarding the use of apnoea alarms for monitoring normal, healthy neonates. First, apnoea monitors are impractical and undesirable, with a high rate of false alarms, which only serves to increase the parents' anxiety. In addition, parents may become too reliant on the apnoea monitors and ignore subtle signs of pending illness in the neonate. The evidence indicates that the use of apnoea

monitors at home does not decrease the incidence of SIDS, and they are therefore not recommended.

Neonatal abstinence syndrome

As drugs of addiction cross the placenta readily, the fetus of a drug-addicted mother becomes passively dependent on the drugs from conception. The main concern, then, is the withdrawal effects after the birth, when the neonate is deprived of the regular supply of drugs previously ingested by the mother. A wide variety of drugs may be consumed by the mother during pregnancy, with neonatal withdrawal symptoms being reported with alcohol, amphetamines, barbiturates, codeine, ethchlorvynol, heroin, pethidine, methadone, morphine and pentazocine. It should be remembered that a neonate will take longer to metabolise drugs than an adult, and that withdrawal may occur up to a week or more after birth.

Heroin and methadone are the drugs most commonly abused by women during pregnancy. The neonates of these women will exhibit withdrawal in 70% of cases, with symptoms appearing within 48 hours of birth (Levene et al 2000). It is important, therefore, to monitor all neonates of mothers who took opioids for prolonged periods of time during pregnancy. These neonates will exhibit extreme jitteriness, tachycardia, vomiting, diarrhoea and fever. Various assessment tools have been devised in order to fully assess these neonates for withdrawal or for neonatal abstinence syndrome. These neonates are often difficult to care for as they are usually irritable and difficult to feed. Added to this are the social issues that may occur as a consequence. The midwife plays a large role in supporting these families and monitoring the neonate.

Conclusion

This chapter has outlined the common complications of the newborn, which include preterm birth, neonatal jaundice, neonatal infections and neonatal bleeding. In addition, congenital conditions, cardiorespiratory conditions, metabolic and endocrine disorders and SIDS were discussed. It is important to emphasise that midwives must always be prepared for the unexpected when caring for this fragile population.

Review questions

1. While caring for a neonate who is 123 hours old, the midwife notices a yellow tint on the skin and sclera. What laboratory test should she consider ordering?
2. Describe the process of physiological jaundice.
3. A newborn is admitted to the nursery with transient tachypnoea of the newborn. In planning care for this neonate, what would be the goal?
4. While caring for a neonate receiving phototherapy, what assessment would warrant further investigation?
5. Describe the role of vaccination in preventing infection in the neonate.
6. Discuss the main causes of bleeding in the neonate.
7. Outline the process that midwives might follow for detecting an imperforate anus in a newborn infant.
8. Discuss four types of cardiac conditions that midwives might encounter in the neonate.
9. Discuss the risk factors associated with SIDS.
10. Briefly describe early signs and symptoms exhibited by neonates with a mother addicted to opioids.

CHAPTER 39

Grief and bereavement

Chris Stanbridge

Key terms

blighted ovum, complete miscarriage, early neonatal death, ectopic pregnancy, hydatidiform mole, incomplete miscarriage, inevitable miscarriage, infant death, late neonatal death, miscarriage, missed miscarriage, neonatal death, perinatal death, post neonatal death, recurrent miscarriage, spontaneous miscarriage, stillbirth, stillborn child, termination of pregnancy, threatened miscarriage

Chapter overview

Loss experienced anywhere along the reproductive continuum inevitably leaves the woman and her family with a sense of loss and deprivation that needs to be addressed through the painful process of grief. Death, like birth, is part of human experience, and as midwives we have a unique opportunity to support women and their families in times of unexpected loss, in order to assist and enhance their ability to grieve.

This chapter focuses on grief, how it may present, and how it may be explained and understood. It offers strategies for midwives to develop their skills in recognising grief and working with women experiencing grief in order to offer support and help them to grieve.

Learning outcomes

Learning outcomes for this chapter are:

1. To recognise grief situations related to women before pregnancy, and through pregnancy and childbirth
2. To discuss aspects of grief and how they may present
3. To describe several theories of grief
4. To describe options for supporting women in their grief
5. To identify appropriate legal requirements related to death of a baby
6. To list some sources of support in the community
7. To develop awareness of your own grief issues
8. To establish a strategy for self-care.

Potential for loss and grief

When a woman enters her childbearing years, there are many times when she may experience grief because of a loss, either actual or potential. Infertility brings grief for the loss of anticipated fertility and the consequence of no children or a smaller family than planned or hoped for. For some women, the experience of pregnancy is different from their expectations, because of, for example, sickness, tiredness, altered appearance or discomfort, and they can grieve for the loss of those expectations. Some women experience violence in the home, which may begin or escalate during pregnancy, causing fear and perhaps grief for the loss of the hoped-for relationship with their partner (Espinosa & Osborne 2002; Ministry of Health 2001). Sexual abuse experienced by a woman during her own childhood may surface when she becomes pregnant, and as well as grieving for her own loss of innocence it may affect her pregnancy and raise fears for her baby's safety in the future (Stojadinovic 2003; Brewis et al 2004). Screening tests may raise the possibility of complications for the baby, such as a genetic abnormality, and alongside the worry and uncertainty a woman will then experience, she may also begin to grieve for the baby in anticipation that her fears will turn out to be real. A premature, abnormal or sick baby, or one that is the 'wrong' sex, can evoke grief. A decision to undergo a therapeutic abortion often leads to feelings of guilt and grief regardless of the reason for the decision. Miscarriage, ectopic pregnancy, blighted ovum, hydatidiform mole, stillbirth and neonatal death all mean the death of an anticipated baby and grief for the actual loss of the baby as well as loss of dreams of family life with that child in its midst.

The experience of labour is often different from women's expectations. When labour is assisted or altered through technological intervention, women may feel a loss of control and grieve for their unmet expectations. Separation from her baby for whatever reason, such as illness in the mother or baby, is usually distressing for a mother. Even when adoption is seen as a positive choice, there is still a sense of loss for the birth mother and her family, and possibly grief for the adoptive family in that they have not been able to bear their own child. Some women experience a sense of loss in no longer being pregnant even after birthing a healthy baby. They may miss their baby's movements or the positive feelings they had while carrying their babies. The experience of motherhood or breastfeeding is not always as one envisages, and women may grieve for the loss of the 'ideal' baby who feeds, sleeps and is 'easy' to care for.

There may be losses brought about by pregnancy that are not recognised as grief, such as loss of status, loss of employment and loss of income. Pregnancy and birth may rekindle or intensify distress and grief for the death of someone important to the woman, no matter how much time has elapsed since the death. The physical or emotional absence of her mother to share her childbearing time can be painful for a woman as she takes on her own mothering role. Similarly, being away from their own country or locality, or important people, may leave women feeling alone and isolated, grieving for the familiar and for the support of family and friends. Families may also experience grief when confronted by the loss of the woman they knew through postnatal depression or psychosis or post-traumatic distress disorder (PTSD), or through the rare but still possible occurrence of maternal death.

All these scenarios may leave a woman and her family grieving for what is lost or for what might have been.

Grief can be a response to many and varied losses. Often the experience of grief is not recognised as such and that which is mourned is unacknowledged. While this chapter deals primarily with pregnancy loss at various stages, much of it is equally relevant to grief experienced as a result of any kind of loss, as the same principles apply. Nor is there a timeframe for grief. It is a lifelong journey of adaptation, and many years later the feelings associated with a loss can resurface, especially if there is a new grief situation.

Grief

Like birth, 'grief is not a pathological state, it is a normal life event' (Golden 2000, p 30). Grief can be defined as 'mental pain, distress, or sorrow; deep or violent sorrow, caused by loss or trouble; a keen or bitter feeling of regret for something lost; remorse for something done; or sorrow for mishap to oneself or others' (*Oxford English Dictionary*). Bereaved means 'deprived or robbed; taken away by force; deprived by death of a near relative, or of one connected by some endearing tie' (*Oxford English Dictionary*).

Elisabeth Kübler-Ross (1969) brought grief issues to greater public awareness in her seminal text, *On Death and Dying*. She identified the stages of grief that people experience when they are facing their impending death. Figure 39.1 shows these stages, identified by Kübler-Ross as denial, anger, depression, bargaining and acceptance. The stages are not sequential and 'these stages do not replace each other but can exist next to each other and overlap at times' (Kübler-Ross 1969, p 264). The experience of grief is not a timely progression from one stage to another, but rather a roller coaster of feelings and thoughts occurring over a period of time, possibly many months, or years. The various stages of grief may occur intermittently and with no set pattern.

Other theorists also offer perspectives that can increase midwives' understandings of experiences of loss and grief. Worden (1997) identifies five 'tasks' of grieving as: accepting the reality of the loss, working through the pain of grief, adjusting to living without the deceased, 'relocating' the dead emotionally, and moving on with life.

After any major loss, such as a death, there is often a sense that it hasn't happened, and the first task is 'to come full face with the reality that the person is dead, that the person is gone and will not return' (Worden 1997, p 10). This generally begins with denial of the facts, then denial of the meaning of the loss, and finally denial of the irreversibility of the loss. Coming to terms with the reality of the loss involves searching

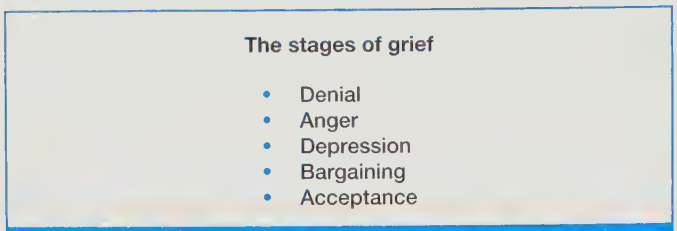

Figure 39.1 The stages of grief (based on Kübler-Ross 1969)

for the deceased or that which is lost, and it is common to swing between belief and disbelief. It is particularly difficult to accept the reality when the death is sudden, and especially if the griever does not see the body. The funeral helps, as does the common need to initially retain things (e.g. the baby's room) as they were before the death. Any formal recognition of that which is lost helps reinforce the reality, such as talking about the baby or acknowledging other, more hidden losses such as loss of fertility. Acceptance of the reality may take a long time and involves intellectual and emotional acceptance.

Working through the pain of grief requires effort. Freud used the term 'grief work' to describe this (cited in Worden 1997, p 10). Another theorist, Parkes (1972, p 173), said 'it is necessary for the bereaved person to go through the pain of grief to get the grief work done'. Not everyone experiences the same intensity of pain, or feels it in the same way, and it will vary for the individual depending on the significance of the loss to them. Worden (1997) identifies different expressions of pain as physical, emotional and behavioural pain. Some try to avoid the pain by idealising the dead (or their dream of what would have been), avoiding reminders, using alcohol or drugs (prescription or recreational), or physically moving away.

Worden's (1997) third task is adjusting to living without the deceased. In other words, adjusting to life without that person or without whatever it is they have lost. When a baby dies, the parents have to adjust not only to life without their child, but also to an alteration in their roles. No longer are they a new mother or new father, and the loss of these roles can be deeply tied to their sense of self or may challenge their femininity or masculinity. Sometimes people regress to more dependent behaviour such as withdrawing, being helpless, inadequate, incapable or childlike, as they learn new ways to deal with their world. There is often a challenge to fundamental life values and philosophical beliefs, bringing with it a loss of direction, and a search for meaning in order to make sense of the loss and regain some control of their life. Part of this task is to learn to live without an answer, to understand the fragility of life and the limits of human control. Sometimes this task needs to be addressed again at a later time. For example, parents who lose a baby may not be aware of all they have lost until a later time, such as when a subsequent baby is born and grows and develops new skills, and they realise the joy and work they have missed with the death of their previous baby.

Worden's fourth task involves a shift from thinking that the dead person is still here, to thinking about what the person would have done had they lived, to planning the future without them. It involves acknowledging one's ability to love others without loving the person who has died any less. Warden describes the feelings involved with this task as numbness, shock, sadness, fatigue, guilt, helplessness, loneliness, anger, anxiety, yearning, emancipation and relief. He also describes these emotions as physical sensations such as hollowness, depersonalisation (nothing seems real, including oneself), weakness, lack of energy, dry mouth, tightness of chest or throat, over-sensitivity to noise, shortness of breath, and headaches. Thoughts include disbelief, confusion, and preoccupation with the dead person, a sense of (their) presence, and hallucinations. Behaviours include crying, appetite and sleep disturbances, loss of interest in the outside world, sighing, social withdrawal, restless over-activity, absentmindedness, searching or calling out, nightmares or dreams of the deceased, avoiding reminders of the deceased or visiting places of significance, and carrying or treasuring objects that are reminders.

Worden's fifth task is related to moving on without the overwhelming sense of grief. As Mary, the mother of a stillborn baby said, 'I was really down for so long, you wonder if things are ever going to be normal again—but what is normal? I felt so empty' (Mary, in letter to author).

Rando's (1996) work identifies six patterns in the grief process:

- recognising the loss, which includes acknowledging and understanding the death
- reaction to separation by experiencing the pain and expressing reactions to the loss
- remembering the deceased and the relationship realistically, and re-experiencing the feelings
- relinquishing old attachments and one's old life
- readjusting and adapting to the new world (without forgetting the old), and developing a new relationship with the deceased as a new identity and new ways of being in the world are formed
- reinvesting in life again (Rando 1996).

Golden (2000, p 7) describes grief as a part of life that 'is the physical, emotional and mental responses we have to a loss of any kind'. He depicts joy and grief as inseparable emotions; however, joy is inevitably temporary and, once gone, one is left with a sense of loss. Golden (2000) describes our reactions to small losses being intensified and of longer duration with major grief. He likens grief to a beast, severe grief being like a dragon: 'their size is unreal to us, and they are so powerful', which draws us out of our normal functioning and into an inner world that feels fraught with danger and unknowns (Golden 2000, p 11). Golden identifies five common grief reactions as: getting in touch with the loss, holding on, letting go, making new attachments, and observing one's growth through the loss. He describes the experience of grief as being 'all consuming' and emotions such as anger, sadness, helplessness, fear, guilt and loneliness can be overwhelming, chaotic and unpredictable (Golden 2000). People in grief can feel confined by their loss and surrounded by grief, and so they can feel cut off from everyday life. In this unfamiliar and dark environment, people's coping skills can be less effective and

they have to find and draw on their strengths to find ways to get through their grief.

Greenspan (2003) concurs with Golden's belief that each person grieves uniquely; that each person needs to affirm their need to grieve; that grieving is a demanding physical and emotional process; that there is a need to find a safe place to grieve for periods of time to allow 'sorrow to be sorrow'(Greenspan 2003, p 113); and that there are both active and quiet ways to grieve.

As midwives we are mostly involved with loss that occurs during the childbearing cycle and we will not usually be part of the long-term grief experience of women and their families. So let us look at how we can assist women to begin to work through their grief and loss, and help them on the journey to understanding and living with their loss. Our role is to provide support, to share our knowledge, to open opportunities, to bring in other caregivers with specific expertise, and encourage the woman to have faith in herself to 'do' what she needs to do, to make good decisions for herself, to seek the support she needs, to recognise her strengths and to reinforce that she will survive the tragedy she is involved in.

What women need, ideally, is to be cared for by health professionals who are comfortable with death, who are in tune with women as people, who are empowering, and who can step back and work at the woman's pace (Tonkin 1998).

When midwives and women establish relationships of partnership, they are able to share power and control and make decisions together (Pairman 1998). Shared decision-making relies on midwives sharing knowledge and information and accessing resources, but consciously encouraging women to make the final decision on the basis of information and their personal feelings and circumstances. When women feel in control of decisions they feel empowered, and it is important for midwives to understand the link between a sense of control and later emotional wellbeing (Pairman 1998). This is particularly important for women inevitably debilitated by grief. They may need information offered at times when they are ready to hear it and may need to have it repeated a number of times. It is useful to provide information in written form (either in the midwifery notes, or as handouts, articles, books or leaflets) as well as talking it through. All decisions need time and women who are grieving particularly need time to assimilate options, relate them to their personal circumstances, make decisions, and be enabled to change their minds if necessary.

There is a sense of timelessness in grief. A woman may need longer than she would normally take to make good decisions for herself. It is very important that the time is taken to allow her to make the decisions herself. She may well have significant input from family and friends as well as midwifery, medical, religious and funeral professionals. Care must be taken to allow her the freedom (both in time, options and with lack of pressure) to make these decisions. It is then essential that we respect her choices regardless of our own beliefs (Hughes et al 2002; NZCOM 2005).

Midwives know the importance of telling the story of each birth and recording the context and feelings of the important events. Midwives know that the midwifery or hospital notes 'will become precious reminders of the pregnancy and birth once the immediate memories fade' (Pairman 1998, p 141). An important role for the midwife is to record the story of a baby's death, including the hours, days and weeks that follow. This can be demanding, and often we are more comfortable with recording physical aspects of midwifery care than in recording emotions. However, we need to write more—to record who was with the woman, the support she received, experiences shared, and her progression through coming to terms with her baby's birth, death and parting. The woman's story is very precious to her and will become a treasured part of her baby's being. Enabling women to carry their own notes ensures that they can refer back to written information and revisit their experiences as recorded. No information is hidden and as well as enhancing the relationship between a midwife and a woman, providing a woman with her clinical notes is 'a positive way of shifting power to the

WOMAN'S STORY

Bev's story of the death of her baby at term. This was Bev's second perinatal baby death.

On Monday about midnight, after I felt better and stronger in myself, it was time once again to focus on the baby. The paediatric registrar came down at 3 to 4 am to say things like liver dysfunction, profound hypotension, so I guess then I knew the writing was on the wall. We went to see Gemma again at six o'clock, when all I could say was, 'She is going to die' and refused to bond. Gordon, as you know, bonded beautifully and was then going into a real down. Finally, by midday, I realised that if I maintained this attitude I would suffer the long-term consequences so next visit I gave her a wee kiss and cuddle. By mid-afternoon the paediatrician talked about taking extra specimens and then turning the ventilator off, which was fine by me. A bit disappointed when I heard she would have to be cool overnight but obviously finding answers is especially important so if refrigeration gave better specimens then I was willing to compromise.

By Tuesday afternoon I had decided to let Gemma die at my breast and indicated so. Gordon had said he didn't want to see it but I gave him a ring and asked him if he wanted to reconsider, which he did of his own volition, which was great. At 8.30 pm or so I switched off the ventilator and she was removed and given to us.

We then had a magic moment which even got through my shell of numbness. Gemma actually opened her eyes and took a couple of small sucks from my breast. Whenever I want to think of this baby I shall think of that—the absolute sadness and joy as we had a wonderful moment of communication. She then died very peacefully over the next quarter hour and Gordon found it a very peaceful thing as it dispelled a lot of his fears (Bev Taylor, in letter to author, 1998).

woman and promoting self-responsibility' (Pairman 1998, p 143).

A woman's confidence in the decisions she has made is often strongly challenged when her baby dies. She has made the decisions to date and the outcome has been disastrous. She may well blame herself and lose confidence in her ability to make wise choices. Guilt is a normal aspect of grief and will probably see her searching for the 'what ifs?', looking to see what she could (or commonly 'should') have done differently. Our work as midwives is in listening to her explore these thoughts, often accompanied by distress, and helping her to be realistic about her control over what happened. Verbally, and in her notes, reinforcing the positive decisions she has made, and gently encouraging her to 'risk' making decisions again is one way of helping her to re-establish a sense of control and empowerment. As described elsewhere in this text, partnership with women is central to midwifery care and is particularly important in helping restore a sense of power and control for those women who have experienced a loss.

Early pregnancy loss

Although often almost dismissed as a common and relatively unimportant physical event because it is usually followed, sooner or later, by a successful pregnancy, a miscarriage still marks the death of a baby and can have a major emotional impact. It is estimated that 30% of pregnancies are lost to miscarriage (N Hung, personal communication, 2004). Grieving following the loss of a baby at this stage may be overwhelming, often with no or minimal acknowledgement from family or friends or sometimes even health professionals (Dent & Stewart 2004; Worden 1997).

It is important to always refer to the *baby*, not an embryo, fetus or product of conception (POC), for the mother has a *baby* from the moment she knows she is pregnant.

Women with bleeding or pain in early pregnancy need emotional support and acknowledgement of their feelings as well as physical care. A threatened miscarriage is often associated with feelings of uncertainty and fear. There is no known treatment for threatened miscarriage that ensures a term pregnancy, and while about 25% of threatened miscarriages may miscarry, there is also the probability that the rest can continue as pregnancies with no other adverse effects (Collier et al 2003).

It may be most appropriate for women with a threatened miscarriage, but who are not clinically compromised, to stay at home with close support from their midwives. Women should not be left unattended, and family and friends should be encouraged to provide emotional and physical support. Mild analgesia (e.g. paracetamol) or warmth (shower, hot water bottle or wheat pack) may help alleviate discomfort. Remember to administer Rh D immunoglobulin if the woman is Rhesus-negative.

Women need information about the possible course of events. A threatened miscarriage may settle and bleeding may cease. Or the bleeding may continue and clots may be passed followed by passage of the embryo and placenta. Sometimes, especially when the pregnancy is earlier than 12 weeks, it may be difficult to recognise that the embryo and placenta have been passed. The baby is not always recognised because of its small size and it is often accompanied by clot. Sometimes it is the marked decrease in cramping and blood loss that marks the completion of the miscarriage.

If women are at home waiting to see what happens, they should be informed to seek assistance if their condition changes. Hospital care may be more appropriate if they feel faint or unwell, as these changes may indicate heavy blood loss, an ectopic pregnancy, or an embryo that is lodged in the cervical os. Increasing or ongoing blood loss or signs of infection may indicate an incomplete miscarriage or retained products. This may need to be diagnosed by ultrasound scan. Women need to be informed that scans may be performed via the vagina (endovaginal scans) in early pregnancy. If the miscarriage is incomplete, a dilatation and curettage (D&C) may need to be performed in hospital.

Women should have the option of seeing and holding their baby if possible, including tissue from D&C, as it can give them a physical focus for their grief (Worden 1997). As with all options, it is an individual choice—for some women it may be undesirable, and for others very helpful.

Sometimes an embryo may be passed into a toilet unnoticed. Hospitals often dispose of remains through incineration. Women should be offered options and their desires respected regarding the disposal of their baby's remains. There is no legal requirement for burial or cremation at this stage of pregnancy; however, women may wish to do so and a ceremony of some kind may help acknowledge their baby and their loss. Giving their baby a name, perhaps a unisex name, helps provide a clear way to refer to their baby, and helps personalise their loss. Physical mementos may be impossible, although positive pregnancy test results, any scans, and measurements (weight, length) will all help. Planting a tree in memory of their baby, or having a special bush or vase or picture, are other ways of having a symbolic memorial.

WOMAN'S STORY

Kate

Kate miscarried at six weeks. For the children, her husband Jules, and Kate, a warm bond already existed for the unborn child she carried. They felt it was important for them to grieve and ritualise the death. They buried the remains at the end of the garden, preceded by a small procession, prayers and song. The immediate family attended (cited in Groufsky 1991, p 13).

Later pregnancy loss

When babies die later in pregnancy and are stillborn, women have to undergo labour and birth, often knowing that their baby is dead. To assist a woman to accept the reality of the

baby's death, midwives should encourage the woman to spend time with her baby in order to establish memories to reminisce over later. Women can experience a compounding sense of loss when they look back at the time of their baby's death and regret not having had the opportunity to see their baby, or be part of the baby's physical presence and care (Tonkin 1998).

There is considerable evidence to suggest that parents should be encouraged to spend as much time as possible with their baby, as this not only assists with dealing with grief but also acknowledges their role as parents (Trulsson & Radestad 2004). However, a study by Hughes et al (2002) suggests that women who saw and held their stillborn babies were more likely to be depressed, have greater anxiety, have higher symptoms of PTSD, and disorganisation of mother–infant attachment in the next-born child. While there are some concerns about aspects of the study (Lovett 2001; Sheehan 2001), it highlights the importance of women making decisions for themselves about what is the right thing for them to do, and their need for ongoing support and care, including through subsequent pregnancies.

It is common and normal for women to want to see their baby. Some will be afraid—they may never have seen a dead person before, or may have had an earlier unpleasant experience with death. Support a woman to share any fears, whether from the past or anticipatory, to think about the options, and to take time to do what she needs to do. Women need to be prepared for the silence of their stillborn babies (Trulsson & Radestad 2004). When women have time between the diagnosis of the baby's death and the baby's birth, whether spontaneous or induced, they have time to begin to come to terms with the death of their child, to rest, to learn about or reappraise their plans for their forthcoming labour, to know what to expect at birth, and to prepare themselves for the coming days.

Women need time to gather information and think through what they want for themselves, and their families, around the time of the birth of their babies. This may include delaying an induction of labour to enable time at home before the birth. Women need to be informed of options regarding how any induction of labour might be carried out, what to expect of the labour and birth, the baby's possible appearance (see Clinical box below), how time may be spent with baby after the birth, possible investigations that may need to be done, and funeral and legal requirements. They should be encouraged to think about who they want to share this time with and what mementos they wish to keep. Most of all they need plenty of time to try and think about what they want while coping with the impact of acknowledging their baby's death. It is a complex time, with overwhelming emotions of celebrating the birth while also grieving the death of their infant, and being mindful of how we work with women at this extremely vulnerable time can all improve the care (Trulsson & Radestad 2004).

WOMAN'S STORY

Lisa

I'm really pleased I continued with my plan and made it through without an epidural—it made me reach right into myself for a strength I didn't know I had and it made me reach out to my faith and trust in God for the mental and spiritual strength to see it through (comments made to author by Lisa, after her second son was stillborn).

Clinical point

Appearance of a stillborn baby

After death, changes can occur while the baby is still in utero. Known as maceration (to soften), this process of aseptic autolysis begins within 12 to 24 hours after death. Maceration causes the following changes in the baby:

- colour—pink, pale, livid
- blisters, eventually breaking and skin slippage, exposing red/livid subcutaneous tissue
- skull collapse
- papyraceous—flattened, paper-like fetus born long after its death.

After birth, further changes occur:

- increasing paleness
- darkening of lips, abdomen, dependent areas
- increasing skin fragility
- fluid leakage—may be bloodstained; from mouth, nose, umbilicus, skin.

WOMAN'S STORY

Margaret

As everything happened very quickly and he did not survive, we were not able to think clearly and we found your suggestions, such as taking photos and footprints, of great value. Some things were not easy at the time but we now appreciate that we did them, as it has since made it easier to accept that our son really existed (letter to author from Margaret after her baby's death).

Other support and advice

As midwives we are expected to consult and refer and work collaboratively with other health professionals when we reach the limit of our expertise (NZCOM 2005). It is appropriate to seek advice from midwifery colleagues and other professionals with more knowledge and experience, particularly if our experiences are limited. Because grief lasts well beyond the six-week postnatal period, it is important to ensure that the woman has networks in place that will continue to

Clinical point

Ways to create memories

Support the family to do as much as they can in their own time. Allow time for them to reach the stage where they are ready to move on to the next step. Offer options:

- take lots of photos, videos
- footprints and hand prints, plaster feet / hands, a snip of hair
- talk to baby, sing songs to baby, read stories to baby
- bathe baby (as many times as they like if baby's skin is sound)
- dress baby
- take baby home
- bath or shower with baby (especially for Dad)
- sleep with baby
- take baby for a walk in their garden, in pram, along the beach
- put baby in his or her own crib
- play baby their favourite or baby's own special music
- lots of cuddles
- share baby with siblings, grandparents, family and friends
- encourage the woman or family members to keep a diary of events, thoughts, feelings and activities
- keep mementos such as cot card with name, weight, measurements, time and date of birth; baby's name bracelet; copies of records, scans; clothing or wraps used with baby.

Clinical point

Tips on taking photos/videos

'The photos taken are so precious. We took piles of others at each stage but probably the Polaroid ones of Simon nearest to life are the most precious' (Bev Taylor, in letter to author).

- Use a camera that can focus well on close-up images.
- Be aware of backgrounds.
- Consider lighting.
- Try and have the baby held or with someone (e.g. a hand close by).
- Ensure that some photos show close-up of face, ears, hands and feet clearly.
- Take some photos as soon as possible after birth without impinging on the parents' needs.
- Take photos with each member of the family including children and grandparents.
- Take photos of the baby undressed, including abnormalities.
- Consider using a professional photographer.
- Polaroid photos may need to be copied as they tend to deteriorate with time.
- Provide prints of digital photos as well as electronic storage.

WOMAN'S STORY

Judy

Thank you for going into everything so thoroughly and clearly with us. It gave us a clear insight into what was going to happen, settled all our doubts, and enabled us to make the decision that was the right one for us. Those moments after delivery would have been very confusing and upsetting, whereas thanks to your efforts we found them very relaxed and loving. The memories we have of the time we spent with Kim are going to be a great comfort over the next few weeks and months, and the photo will always be there to look back at (Judy, letter to author).

support her through the months ahead. Midwives may suggest accessing a stillbirth support group, such as Stillbirth and Newborn Death Support (SANDS), a social worker, or grief or counsellor services; her GP and/or religious or lay spiritual support.

Midwives should be aware of local support agencies for women and the contact details for such organisations. There are many support groups available, such as:

- Bereaved Parents
- Compassionate Friends
- Trauma And Birth Stress (for those suffering from PTSD)
- Miscarriage Support
- Parent to Parent
- Action on Pre-eclampsia (NZApec)
- Heart Children
- Sudden Infant Death Syndrome (SIDS) Support
- Neonatal Unity for Mothers and Babies (NUMB)
- Citizens Advice Bureau
- National Association for Loss and Grief
- local counselling and church social services
- relationship services
- Barnadoes
- parents' centres
- women's refuges
- infertility support groups
- cultural support groups.

Establishing personal contact with these organisations means that midwives can be more aware of what they offer, and it is often easier for a woman to accept referral to someone who is known to the midwife.

Farewelling the baby

Trulsson and Radestad (2004, p 194) say that a woman needs to 'bond to her baby, recognise her pride in the baby, progress to the unavoidable fact that she and her baby must separate, and finally, say goodbye'. Different women will have different needs and different timeframes for what they need to do to achieve this. Remember, there is no hurry. The midwife can assist by providing information and options, helping to create memories and encouraging parents to trust and express their feelings. As Susan said in a letter to the author, 'We are forever grateful for the information so Jack could be buried the way we wanted'.

Instead of enjoying their newborn baby, couples whose baby has died must face death and the decisions that are required at such a time. It is important to encourage new parents to make decisions about funerals themselves and to advise those close to the couple not to 'take over' in an effort to spare them pain. Parents can make all funeral arrangements themselves, with the help of family and friends, or they can engage the services of a funeral director. The funeral or Tangi is one of the last physical parenting roles for the baby, and it is appropriate for them to plan and participate in this as they did for the baby's birth. Cultural mores and religious customs may provide significant guidance. Options to consider include:

- post mortem (see Clinical box)
- burial or cremation
- a service—where (e.g. home, hospital, park, beach, church, hall, graveside); time of day; religious or not; who will lead the service (e.g. themselves, family member, friend, hospital chaplain or own clergy, Justice of the Peace, funeral celebrant); what songs, hymns, music, poems, readings
- place they want baby buried or cremated (some cemeteries have special baby areas; baby may be able to be buried at the head of a relative's plot)
- wording of birth/death/funeral notice(s)
- coffin; what baby will wear; what will go in coffin (e.g. toys, mementos, letters, photos, flowers, siblings, drawings)
- digging the grave (needs to be with sexton's guidance)
- flowers from their own, family's or friends' gardens
- use their own car or funeral director's hearse for transport for baby
- carry baby's coffin themselves
- someone to photograph/video/record service
- lower the coffin themselves
- fill in the grave themselves
- pre- or post-service get-together
- make their own memorial headstone
- if using a funeral director, compare fees.

Clinical point

Post mortem examination

Making a decision may involve consideration of the following factors:

- the need to know what may have caused the death
- may identify or eliminate abnormalities and/or disease
- religious and cultural considerations
- may provide information that affects future pregnancies
- may not find cause of death
- generally performed within a few days of birth
- full or partial examination
- consent required, unless ordered by a Coroner if baby was born alive and cause of death is not certain.

Post mortem examination includes the following:

- consideration of maternal information and investigations (e.g. family, medical and obstetric history; pregnancy history; amniocentesis/CVS results; ultrasound scan results; microbiology, virology, cytogenesis, biochemistry, autoimmune, coagulopathy, haematology results)
- consideration of baby's investigations (e.g. microbiology, virology, cytogenesis)
- possible photographs and X-rays
- external measurements and examination
- surgical-type procedure requiring incisions to examine internal organs and repair by suturing
- incisions generally behind the head and Y on chest to abdomen
- internal examination of organs both macroscopically and microscopically
- histology of placenta even if baby not for post mortem.

After post mortem:

- Baby should be returned to the family or funeral director.
- Provisional results may be available shortly after the examination, but full results may be some weeks later.
- Results to be shared with the family, preferably by a health professional they know and who can help explain terminology and findings.

WOMAN'S STORY

Bev

We had Simon here the last night and it felt okay. He watched his sister have a bath and slept the last night in a coffin at the end of the bed where he was conceived, which felt good. We think he began to smell—both Gordon and I could feel ourselves dissociating from his physical body and were very ready to bury him. We couldn't give our son life but we tried to give him respect, dignity and an identity with love, the best we could do. I feel very, very good about that (Bev Taylor, letter to author,1998).

Subsequent pregnancy

Women approaching another pregnancy after the loss of a baby, or who have had to cope with a significant grief in a previous pregnancy, will inevitably bring anxieties to the new pregnancy. They may express ambivalence, fear of a recurrence, or uncertainty about their competence to make good decisions or to cope. They may have lost faith in their bodies, or in the normalcy of pregnancy and birthing, or in their caregivers. Subsequent pregnancies often bring the previous loss to mind and emotions may be raw again, often for protracted periods of time. Support, knowledge and reassurance are important to help women and their families through what may be a difficult time. Extra time may be needed to help women recognise their concerns and find ways to address them. Women may need acknowledgement that their apprehensions and fears are valid, and the reassurance of more frequent visits and baby checks, particularly around anniversary times. Support from family members (although they will have anxieties of their own) and support groups can play a major role in helping them through the months, and referral to other health professionals may be appropriate.

Men and grief

Men may grieve in ways that are different from women's. Golden (2000) describes feminine ways of grieving that often involve a community of support where the woman verbally shares and openly expresses her pain and relieves her pain through intimacy with others. Masculine ways of grieving are structured with the need for the man to know his own strength, know how he is going to use it and linking action to his pain (Golden 2000). Some men have difficulty expressing their sadness with tears, particularly when they may have been discouraged from crying when young. For some men their self-image involves being seen as the provider and protector who is independent, autonomous and strong, rather than vulnerable (Golden 2000). The sense of powerlessness involved in grief is another difficult aspect that conflicts with his sense of mastery and power and doesn't respond to his normal problem-solving methods (Golden 2000). Often 'the husband feels powerless and his need to act strong and to be supportive may be misinterpreted by the woman as not caring' (Worden 1997, p 104). Men are more likely to be action-orientated and may see grief as a 'problem' they should be able to manage themselves, rather than share with others. Some men may consciously acknowledge grief through activity such as making a coffin for their baby, preparing a funeral service, writing and giving an address at the funeral, gathering mementos for the baby's memory box, or fundraising for a cause related to their baby's death. Creative activities may help give meaning to his child's life and death (Golden 2000).

Although Western society has few rituals for grieving after the time of the death and funeral, personal or societal rituals can help people to put time and energy aside to be aware of and work with their grief. For example, unveilings of headstones, shared memorial services or annual candle lighting ceremonies can provide a focus for ongoing grief.

In Western societies, death, like birth, has also become a process of medicalisation that has moved the experience from the community to hospitals, funeral homes and crematoria. Media portrayals are often graphic and traumatic rather than gentle. Society has become insulated from death and our experiences of it are limited and mediated by these external processes. It is now rare for families lay out the dead where

Clinical point

Legal definitions and requirements in New Zealand

If a baby's death meets the legal definition of a miscarriage, the baby may be cremated or buried, or disposed of by the hospital (may be incinerated or cremated). If the baby is being buried at a cemetery or being cremated, the family will require a letter from the midwife (or nurse or doctor) confirming that the baby's death was defined as a miscarriage.

If a baby's death was defined as stillborn, a Notice of Birth (BDM9) must be completed by the occupier of the hospital (may be electronic) or midwife within five working days; a Medical Certificate of Cause of Fetal and Neonatal Death (BDM167) must be completed by a midwife or doctor, or a Coroner's Order be issued; the baby must be buried in a cemetery or cremated at a crematorium (complete an application form and a written statement confirming the baby was stillborn); and have a Notification of Birth for Registration (BDM27) which includes acknowledgement of the baby's death (stillbirth) completed by the parents.

If a baby is born alive (breathes or shows any sign of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of the voluntary muscles after issuing completely from the mother, whether or not the umbilical cord has been severed or placenta detached) at any gestation (including termination), a Notice of Birth (BDM9) must be completed by the occupier of the hospital (may be electronically) or midwife within five working days, and a Notification of Birth for Registration (BDM27) must be completed by the parents.

If the baby subsequently dies, a Medical Certificate of Cause of Fetal and Neonatal Death (BDM167) must be completed; the baby must be buried in a cemetery or cremated at a crematorium (if for cremation have an application form and medical referee's certificate) and have a Notification of Death for Registration (BDM28) completed by the parents (or their representative, may be a funeral director) within three working days after the disposal of the body.

(*Births, Deaths and Marriages Registration Act 1995*; *Burial and Cremation Act 1964*).

they died in their homes, or make their coffins, or dig their graves. These changes have deprived men, in particular, of active roles in addressing their grief (Golden 2000).

Self-care

> The loss of a loved person is one of the most intensely painful experiences any human being can suffer, and not only is it painful to experience, but it is also painful to witness, if only because we're so impotent to help (Bowlby 1980, p 7).

Facing loss and death in our work as midwives can bring up unresolved issues of our personal experiences of death and grief, and we may identify with the woman (or her relatives) and consequently expose ourselves to anxiety, anger, fear and other manifestations of loss. We may become more aware of our own health and mortality. We may project our own needs onto the women we work with, and we may feel guilty or disillusioned at not having coped as well as we expected of ourselves, or not having met the expectations of the women or their families, or our peers.

Blame is a common grief reaction, and both parents and midwives may express this. Blaming others allows individuals to shift responsibility from themselves and avoid painful introspection, and it may be a mechanism that is used to gain a sense of control. For midwives it is important to face what has occurred and to reflect on it, particularly in relation to the midwifery care we have provided and midwifery judgements we have made. Midwives need to explore the 'what ifs', to face any mistakes or poor judgement, to acknowledge the role of others, and learn from what has happened. There may well be the opportunity to also review the care given by the multidisciplinary team in a morbidity and mortality review that allows for a critical analysis of the systems and processes as a core component of any service quality plan (Ministry of Health 2002).

Loss experienced by someone we are caring for challenges our need to be helpful as well as making us aware of our own losses, whether actual or feared, and increases our awareness of our own health and mortality, or that of those close to us. Coping with our own responses to grief as well as assisting a woman to cope can be stressful and exhausting, and the care may feel difficult and be tiring because of the emotional work involved. Practice colleagues may help by sharing workloads. Just as we support a woman to establish supports for herself for birthing and parenting, and for grieving, so we need supports for ourselves when dealing with unexpected outcomes in our work. Sharing our experiences and seeking support is a normal need, not a personal or professional inadequacy. We need someone to return the gift of listening and caring that we have given the parents; someone who listens as we explore our thoughts and feelings associated with the experiences we have been involved with and the midwifery care we have given. McDrury and Alterio (2002, p 52) describe 'response dialogue', in which the listener(s) 'remain focused on the original story and dialogue centres on the elements of the experience being related, which helps the teller explore their experience in depth'. Response dialogue provides an opportunity for the teller to explore in more depth and detail, to be heard, and for both the teller and the listener to learn from the teller's experience. This type of interaction could be undertaken with other midwifery colleagues or with someone outside midwifery. Other strategies for coming to terms with grief in our work as midwives include writing, reflective journaling, relaxation activities, creative activities, physical activities, contemplation, and putting energy into relevant political activities or causes.

As midwives we owe it to ourselves as well as the women we care for to have a good support system established for ourselves, and to care for ourselves.

Critical thinking exercise

Immediately before Susan started to labour at 35 weeks, her husband was killed in a car crash.

1. As a midwife, what can you offer as you support Susan with her labour, birthing, early parenting and grief?
2. How would you recognise that she was grieving?

Reflective exercise

1. Reflecting on your own experiences of grief, what were your feelings, thoughts, actions, other responses? How did your family and friends react? What helped you most? How might this affect your support of women confronted with grief?
2. Think about a grief situation you have encountered as a midwife. How did you feel? What did you think? How did you help the woman? How did you help yourself to cope?
3. Identify six ways you can receive support for yourself when dealing with the grief of women you are caring for as a midwife.

Conclusion

In our practice as midwives we will inevitably work with grieving women. We may not be able to prevent their losses but we can support them with caring, knowledge, information and choices that can enhance their ability to cope with their grief and facilitate their chance of making the best of the experience. To do this, we need awareness of how our own experiences affect our care; we need to recognise grief situations and reactions, and understand the ways in which people work through their grief over time. Midwives need to know what options are available for women and families, and to support them to make choices that will meet their needs. Grief is a lifelong process but one that midwives can support women and their families to begin positively.

Review questions

1. List the kinds of grief situations experienced by women you have cared for.
2. Identify two theories of grief, and explain these.
3. Discuss how one theory of grief could relate to a non-death loss being experienced by a woman you have cared for.
4. How might men express their grief differently to women?
5. What are the legal requirements for registration and disposal of a dead baby at each stage of pregnancy?
6. How can you help women establish memories of their stillborn babies?
7. What local organisations could you recommend to women who have grief issues?
8. Name three strategies you can implement in your care to help women deal with grief.
9. Identify six ways in which you can assist women and their families to grieve for their stillborn child.
10. Identify three strategies for self-care when working with women and families experiencing loss and grief.

APPENDIX: Definitions

- *miscarriage*—the issue from its mother, before the 21st week of pregnancy, of a dead fetus* weighing less than 400 g (*Births, Deaths and Marriages Act 1951* NZ and 1953 Australia):
  - *spontaneous*—the natural complete expulsion of a dead embryo or fetus from the uterus
  - *threatened*—abdominal pain and bleeding with the embryo/fetus still alive, cervical os is closed
  - *incomplete*—most but not all the products of conception (POC) have been passed
  - *complete*—complete expulsion of a dead embryo or fetus from the uterus
  - *inevitable*—cervical os open, usually bleeding and pain
  - *missed*—the fetus has died but is retained
  - *induced, termination of pregnancy* (TOP)—legal medical or surgical procedure to terminate a pregnancy and empty the uterus
  - *recurrent*—loss of three or more consecutive pregnancies
- *blighted ovum, anembryonic pregnancy*—the fertilised egg develops the placental tissue but the embryo doesn't develop or dies very early (Collier et al 2003)
- *ectopic pregnancy*—the fertilised ovum implants outside the uterine cavity (Collier et al 2003)
- *stillbirth*—NZ: the issue from its mother of a stillborn child (*Births, Deaths and Marriages Act 1951* NZ); Australia: death prior to the complete expulsion or extraction from its mother (ABS 2005; NHDC 2003)

  of the products of conception of 20 or more completed weeks of gestation or of 400 grams or more birthweight: the death is indicated by the fact that after such separation the fetus does not breathe or show any other signs of life, such as heartbeat, pulsation of the umbilical cord, or definite movement of voluntary muscles
- *stillborn child*—a dead fetus born after the 20th completed week of pregnancy or weighing 400 grams or more (*Births, Deaths and Marriages Registration Act 1951* NZ)
- *perinatal death*—NZ: stillbirth or death of the baby in the first week of life; Australia: fetal or neonatal death (ABS 2005; NHDC 2003)**
- *neonatal death*—NZ: death in the first 28 days of life (*Births, Deaths and Marriages Act 1995*); Australia: death of a live-born infant within 28 days (ABS 2005; NHDC 2003)
  - *early neonatal death*—death of a live-born infant within seven completed days after birth
  - *late neonatal death*—death of a live-born infant after seven completed days and before 28 completed days after birth
  - *post-neonatal death*—death of a live-born infant after the first completed 28 days after birth and before the end of the first year after birth
- *infant death*—death in the first year of life
- *hydatidiform mole*—multivesicular mass as result of degeneration of chorionic villi at early stage of pregnancy.

* Legislation uses terms such as 'fetus' and 'embryo', but most women refer to the loss of their baby, and midwives should acknowledge this by referring to 'the baby'.

** There are different definitions in Australia for reporting and registering *perinatal deaths*. The *National Health Data Dictionary* specifies a definition of perinatal deaths to include all fetal and neonatal deaths of at least 400 grams birthweight or at least 20 weeks gestation (NHDC 2003). The Australian Bureau of Statistics (ABS) definition of perinatal deaths includes birthweight of at least 400 grams or, where birthweight is unknown, a gestational age of at least 20 weeks (ABS 2005). The data on perinatal deaths published by the ABS are based on the year of registration rather than on the year of birth.
In Australia, the states all have different regulations concerning registration and burial. For example, under the NSW *Births, Deaths and Marriages Registration* Act 1995, all deaths that occur in New South Wales must be registered within seven days after the burial or cremation.

midwifery

preparation for practice

pairman pincombe thorogood tracy

Midwifery: Preparation for Practice focuses on placing the woman and the midwife at the centre of midwifery care. This is in line with the philosophy, education and practice standards set by the Australian College of Midwives and the New Zealand College of Midwives, and reflects the socio-political contexts in which students in these two countries practise. While acknowledging that current work contexts may either support or limit the individual midwife's ability to practise autonomously, this book promotes a midwife-led and woman-centred approach to midwifery practice.

The book is the first of its kind in Australia and New Zealand and provides a sound foundation on which students and practitioners can base their practice.

Features:

- **Develops and supports competent and confident midwives who are able to make professional judgements — in partnership with women — on their own authority.**
- **Chapter features include chapter overviews, learning outcomes, key terms, clinical interest boxes, reflective and critical thinking questions, context-specific boxes, research and critical appraisal activities, many diagrams and illustrations, summary boxes and questions for review, references, further reading lists and online resources.**
- **Uniquely, this text emphasises a woman-centred approach which promotes and supports childbirth as a physiological life event and a normal process: that is, childbirth without unnecessary intervention.**
- **Equips midwives to work autonomously within the full scope of midwifery practice, and collaboratively with other health professionals.**

Editors:

Dr Sally Pairman DMid, MA, BA, RM, RGON; Head of School, School of Midwifery and Group Manager Health, Otago Polytechnic, Dunedin; Chair of Midwifery Council of New Zealand

Dr Jan Pincombe PhD, MAppSc, PGradDipEd, BA(Psych), RM, RN, RIN, FACMI; Professor of Midwifery, Program Director, School of Nursing and Midwifery, University of South Australia, Adelaide

Dr Carol Thorogood PhD, MPhil, BAppSc Psych, PGradDipArts, DipEdRN, RM, FACMI; School of Nursing, Midwifery and Postgraduate Medicine; Co-ordinator Midwifery Studies, Edith Cowan University, Perth

Dr Sally K Tracy DMid, MA, BNurs, ADN, RM, RGON; Research Fellow (NH&MRC), HERON Project, AIHW National Perinatal Statistics Unit Associate Professor (conjoint), School of Women's and Children's Health, Faculty of Medicine, University of New South Wales, Sydney
